17 **Abstract**

18 Airborne dust is one of the most important natural aerosols, it has various
19 environmental impacts on air quality, ocean fertilization, and the global climate change.

20 Asian dust, representing one of the major dust sources in the world, has been widely
21 studied due to its long-range transport capability. However, its transport to the Arctic

22 has been less investigated. In this study, two typical transport routes were identified
23 based on the recorded dust events in China during 2011-2015. Accordingly, two specific

24 Asian dust long-range transport events were selected and compared, i.e., one observed

25 at Barrow, Alaska (travelled mostly over lands within 6-7 days) and the other one
26 observed at Alert, Canada (travelled mostly over oceans within 7-8 days). The transport
27 routes of the two dust events had been cross-validated by using air mass trajectory
28 modeling, meteorology reanalysis data, ground-based aerosol columnar and profiling
29 observations, and spaceborne remote sensing. It was found that different transport
30 routes to the Arctic had divergent effects on the evolution of aerosol properties,
31 revealing different mixing extents between dust, anthropogenic particles, smoke, and
32 sea salts. Based on the SNow ICe Aerosol Radiative model, the albedo simulation
33 indicated that dust and elemental carbon together reduced the surface albedo by 0.35%
34 to 2.63% compared to the pure snow condition. This study implied that the dust long-
35 transport from China to the Arctic was ubiquitous and may be a potential contributor to
36 the Arctic regional climate and ecosystem.

37

38 **1. Introduction**

39 In the context of global warming, the Arctic temperature has been increasing at a rate
40 higher than the global average in recent decades, which is the so-called “Arctic
41 Amplification” effect (Serreze et al., 2009; Serreze and Francis, 2006). Although the
42 increase of greenhouse gases concentrations was an important driver of the Arctic and
43 global warming, the underlying cause of Arctic amplification remained uncertain as
44 Arctic warming and ice cap melting were also associated with changes in surface albedo,
45 aerosol radiative forcing, cloud cover, atmospheric water vapor content, seawater
46 temperature, and etc. (Screen and Simmonds, 2010; Gillett et al., 2008). The

47 magnitudes of direct radiative forcing of Arctic aerosols were closely related to the
48 origin of aerosol, transport, and deposition (Quinn et al., 2008). During the long
49 transport of aerosols to the Arctic, the solar radiation could be absorbed or scattered by
50 some components in the aerosols (black carbon, sulfate, etc.), which led to a decrease
51 of the amount of solar radiation reaching the surface. However, this cooling effect may
52 be diminished by the decrease of Arctic aerosol concentrations in recent decades
53 (Gagne et al., 2017; Breider et al., 2017). On the other hand, aerosol-radiation
54 interactions also contributed to Arctic warming in the following ways. Firstly,
55 absorbing aerosols at low latitudes could enhance the latitudinal gradient of temperature,
56 thus enhancing heat transport from other regions to the Arctic (Sand et al., 2013b; Sand
57 et al., 2013a); Secondly, absorbing aerosols absorbed solar radiation and warmed the
58 Arctic atmosphere while the surface was cooled, which enhanced atmospheric stability
59 and constrained the diffusion of air pollutants (Blanchet and List, 2010; Koch and Del
60 Genio, 2010; Brock et al., 2011); Thirdly, deposition of absorbing aerosols onto snow
61 and ice could reduce the surface albedo of the Arctic and thus led to local warming.
62 Besides, the formation of mixed-phase clouds in the Arctic were found related to low
63 concentrations and acid coating of dust particles based on both global and parcel model
64 simulations (Fan, 2013). Overall, direct and indirect radiative forcings caused by
65 aerosols had significant impacts on the Arctic climate as demonstrated by the model
66 simulation results (Shindell and Faluvegi, 2009; Flanner, 2013). In addition to the
67 impact of absorbing aerosols on the Arctic climate, the snow-albedo feedback and
68 cloud-albedo feedback in Central Siberia significantly regulated the variation of dust

69 emissions in spring over the Gobi Desert (Liu et al., 2018).

70 Due to the sparse human activities in the Arctic, most of the air pollutants
71 originated from the middle and lower latitudes, e.g., Eurasia, Siberia, North America,
72 and Southeast Asia. Eurasia was the main source area for the lower Arctic altitudes and
73 the higher Arctic altitudes was mainly influenced by South and Central Asia (Qi et al.,
74 2017; Fisher et al., 2011; Sharma et al., 2013; Stohl, 2006). Di Pierro et al. (2011) and
75 Huang et al. (2015a) both used ground-based lidar data and satellite remote sensing
76 images to demonstrate that aerosols from China can be transported to the Arctic within
77 4-6 days. Similarly, Di Biagio et al. (2018) found that aerosols in the high Arctic north
78 of Svalbard from October, 2014 to June, 2015 were mainly from Russia. Warneke et al.
79 (2010) found that forest fires in Russia strongly affected air pollutant concentrations in
80 the Arctic atmosphere and surface snowpack based on aircraft observations and
81 numerical simulation. Marelle et al. (2015) investigated a long-transport event from
82 Europe to the Arctic in April, 2008 and estimated a maximum shortwave radiation of
83 3.3 W m^{-2} at the top of the atmosphere, yielding a significant local warming effect.
84 Sobhani et al. (2018) applied the WRF-STEM (Weather Research and Forecasting -
85 sulfur transport and deposition model) model to study the long-range transport of
86 aerosols to the Arctic and calculated the contribution of various anthropogenic and
87 biomass burning emissions. Europe and China were found as the main source regions
88 of Arctic black carbon, contributing about 46% and 25% in the middle and upper
89 troposphere, respectively.

90 Different from black carbon, dust had a much larger geographic influencing

91 coverage due to that dust particles were usually accompanied with strong winds.
92 Although a number of studies focused on local or regional dust in the Arctic (Ferrero et
93 al., 2019; Ranjbar et al., 2021; Dagsson-Waldhauserova et al., 2019), the long-range
94 transport of dust to the Arctic has been frequently observed. Asian dust can be
95 transported across the Pacific Ocean to reach North America and even the Arctic (Wang
96 et al., 2018b; Guo et al., 2017). Zwaafink et al. (2016) combined a Lagrangian particle
97 dispersion model FLEXPART (FLEXible PARTicle dispersion model) and surface
98 particle concentration observations to simulate the global dust emissions. It was
99 estimated that the dust loading in the Arctic was dominated by Asia (38%) and Africa
100 (32%) sources while the local contribution was around 27%. The instantaneous
101 radiative forcing in the Arctic caused by dust was also dominated by Asia and Africa.
102 In addition, the deposition of dust on snow was responsible for almost all of the bottom
103 of the atmosphere instantaneous radiative forcing (Kylling et al., 2018).

104 Although both observational and modeling studies showed a persistent source of
105 the Arctic dust from Asia (Fan, 2013; Ginoux et al., 2012), the transport pathways were
106 seldom explored. Huang et al. (2015b) revealed an unreported transport path of Asian
107 dust to the Arctic and estimated its transport duration. In this study, the frequency of
108 dust from China that had the capability to be transported to the Arctic was estimated.
109 Two typical dust transport pathways to the Arctic were investigated based on a synergy
110 of remote sensing data and Arctic monitoring data. The evolutions of aerosol optical
111 properties during the long-range transport were analyzed. Finally, the potential impact
112 of absorbing aerosol on the decrease of surface albedo was quantified.

113

114 **2. Data and Methodology**

115 **2.1. Receptor sites in the Arctic**

116 Two Arctic monitoring sites were chosen as the investigated receptors (Figure 1). One
117 site is Barrow (71.32°N, 156.61°W) located in the northernmost part of the Alaska
118 region of USA. It is surrounded by the Arctic Ocean on three sides and has a large ice
119 cap. Barrow is characterized of a cold and dry climate and covered by snow and ice
120 all year round with an average annual temperature of about -11°C (Dong et al., 2010).
121 In winter, the frequency of northerly air currents was high. The average surface
122 temperature reached as low as -25°C in January and February and most of the
123 snowfall occurred at the end of February. Since April, the invasion of warm and moist
124 air masses from the North Pacific Ocean began to prompt the snowpack in Alaska to
125 melt (Stone et al., 2002). This site is managed by Earth System Research Laboratory
126 of National Oceanic and Atmospheric Administration.

127 The other site is Alert (82.50°N, 62.34°W) in the Nunavut region of Canada, the
128 northernmost permanent human settlement in the world. This site is located about 500
129 km north of Greenland, near the North Pole and far from any industrial emissions. It
130 is very cold due to the long-lasting polar night with four months in a year. The
131 average temperature was below -30°C from December to March and the average
132 annual temperature was -17.9°C (Weijers et al., 2017). This site is managed by
133 Environment Canada.

137

138 2.2. Aerosol measurements

139 Particles at Barrow and Alert were measured by the three-wavelength (450, 550, and
140 700nm) Integrating Nephelometer (Model 3563). The nephelometer measured the
141 angular integral of light scattering and Beer-Lambert Law was applied to calculate the
142 light extinction. In this study, the measurement results at 550nm were used. Aerosol
143 Robotic Network (AERONET) established a global observational network of
144 columnar aerosol optical properties based on Cimel-31 Sun Photometers (Holben et
145 al., 1998). Key parameters of aerosol optical properties were retrieved at 440 nm, 670
146 nm, 870 nm, and 1020 nm, respectively. The quality-assured level 2.0 data were used.
147 The AD-Net (Asian dust and aerosol lidar observation network) operated by National
148 Institute for Environmental Studies (NIES) established a lidar network of dual-
149 wavelength depolarization lidars (Model: L2S-SM II), aiming to obtain the four

150 dimensional distributions (sites/time/height/aerosol properties) of aerosol particles in
151 East Asia (Shimizu et al., 2017). The lidar could measure backscattering coefficients
152 and the depolarization ratio at the wavelength of 532 nm. The lidar continuously
153 operated with 15 min intervals and 30m height resolution.

154 In addition to the ground-based sites, remote sensing from space was used to
155 provide widespread spatial information of aerosols. The MODIS (Moderate-resolution
156 Imaging Spectroradiometer) Level-3 aerosol products ($1^\circ \times 1^\circ$) were obtained from
157 NASA's Giovanni (<https://giovanni.gsfc.nasa.gov/giovanni/>). Aerosol optical depth
158 (550nm) data was based on the Dark Target and Deep Blue algorithm and Angström
159 exponent (0.412-0.47nm) data was based on the Deep Blue algorithm. The CALIOP
160 (Cloud-Aerosol Lidar with Orthogonal Polarization) Lidar onboard the CALIPSO
161 (Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation) satellite provided
162 global data on aerosol and cloud layers with a horizontal and vertical resolution of
163 around 5km and 60m. Track scale vertical aerosol profiles were derived. In addition,
164 major aerosol subtypes can be identified, including dust, smoke, clean continental,
165 polluted continental, clean marine, and polluted dust.

166

167 **2.3. Air mass trajectories modeling**

168 To track the possible source regions of airborne particles, HYSPLIT4 (HYbrid Single-
169 Particle Lagrangian Integrated Trajectory) was run online at the NOAA (National
170 Oceanic and Atmospheric Administration) ARL (Air Resource
171 Laboratory) READY (Real-time Environmental Applications and Display sYstem)

172 Website (<http://www.arl.noaa.gov/ready/hysplit4.html>). The HYSPLIT model is a
173 complete system for calculating simple air mass backward trajectories, in addition to
174 dispersion and complex deposition simulations (Draxier and Hess, 1998). The
175 meteorological input data used in the model were obtained from the National Center
176 for Environmental Prediction's (NCEP) global data assimilation system (GDAS) with
177 a horizontal resolution of $0.5^\circ \times 0.5^\circ$.

178

179 **2.4. Snow albedo modeling**

180 The Snow–Ice–Aerosol–Radiative (SNICAR) model was used to simulate the impact
181 of impurity (e.g. dust, black carbon, and volcanic ash) on the surface albedo of snow
182 and ice (Flanner et al., 2007). The application of the SNICAR model required inputs
183 such as snow grain effective radius, snowpack thickness/density, surface albedo, the
184 concentrations of impurities in snow. The effective grain sizes of snow ranged from
185 $100 \mu\text{m}$ for fresh clean snow to $1500 \mu\text{m}$ for aged snow and granular ice. Table 1 lists
186 the parameters considered for SNICAR in this study. The parameters of snow were
187 derived from field measurements at Barrow in April, 2015 (Dou et al., 2017) and near
188 Alert in February and April, 2000 (Domine et al., 2002). The estimation of impurities
189 concentrations in snow will be presented in Section 3.7.1.

190

191 **Table 1. The input parameters in the SNICAR model**

Parameters	Barrow	Alert
Incident radiation	Direct	
Surface spectral distribution	Summit Greenland, clear-sky	

Snow grain effective radius (μm)	180(Dou et al., 2017)	500 (0.1-1.5mm)(Domine et al., 2002)
Snowpack thickness (m)	0.35(Dou et al., 2017)	0.4(Domine et al., 2002)
Snowpack density (kg/m^3)	350(Dou et al., 2017)	300(Domine et al., 2002)
Albedo of underlying ground	0.73 (300-700nm)	0.33 (700-5000nm) (Dou et al., 2017)

192

193 3. Results and Discussion

194 3.1. Overview of dust events in China from 2011-2015

195 Table 2 summarizes the occurrence frequency and duration of dust events in the dust
 196 source regions of China during 2011-2015 recorded by China's Sand-dust Weather
 197 Almanac (Cma, 2013, 2014, 2015, 2016, 2017). A total of 50 dust events occurred,
 198 which were categorized into three types, i.e., floating dust, dust storm, and severe dust
 199 storm. Among them, the occurrence frequency of floating dust reached 36, accounting
 200 for 72% of the total dust events. On average, floating dust occurred about 7 times a year
 201 with a total duration of 61 days. The occurrence frequencies of dust storm and severe
 202 dust storm events were both 7 times with the total duration of 18 days. Compared with
 203 2000-2010, the frequency of dust storm and severe dust storm events during the last
 204 five years decreased significantly, while that of floating dust increased.

205

206 **Table 2. Summary of dust weather conditions in China during 2011 – 2015**

Year	floating dust		dust storm		severe dust storm		Total frequency
	frequency	days	frequency	days	frequency	days	
2011	5	10	1	3	2	6	8
2012	5	10	3	8	2	4	10
2013	9	15	1	2			10

2014	4	8	1	2	2	6	7
2015	13	18	1	3	1	2	15
Total	36	61	7	18	7	18	50

207

208

209 On a seasonal basis (Table 3), the springtime (March-May) was the peak period of
210 dust outbreak in China. 41 dust events occurred, accounting for 82% of the total dust
211 events. Of which, relatively high frequencies of dust storm and severe dust storm events
212 were observed, accounting for 37.5% of the total events in April. This high frequency
213 of dust occurrence in the spring of China was mainly related to the climatic
214 characteristics, geographic conditions, and geological structure of northern China.
215 Strong winds caused by the Inner Mongolia cyclone and cold fronts in spring resulted
216 in the frequent outbreak of dusty weather in northern China. In terms of the
217 geographical dust source areas in China, the source regions of dust included the South
218 Xinjiang basin, central and western Inner Mongolia, central and western Gansu, and
219 northern Shaanxi.

220

221 **Table 3. Monthly summary of dust days in China during 2011 – 2015**

Month	floating dust	dust storm	severe dust storm	total
February	3			3
March	12	1	2	15
April	10	3	3	16
May	7	1	2	10
June	1			1
August	1			1
November	2	2		4

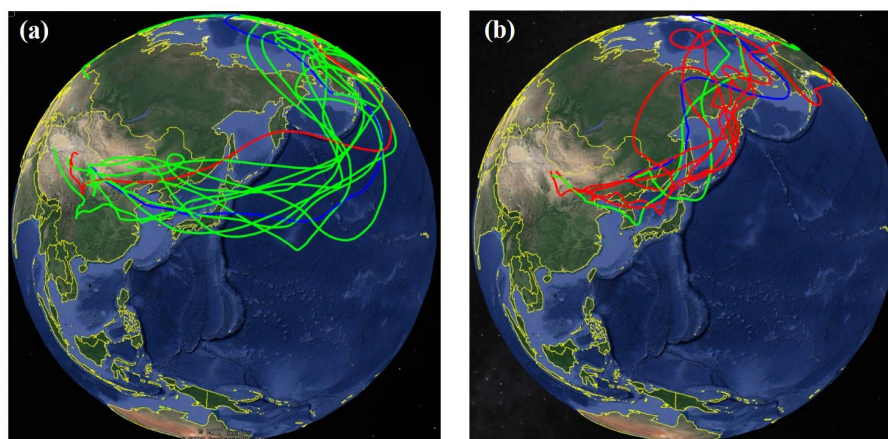

222

223 3.2 Transport pathways of Asian dust to the Arctic

224 In order to investigate the frequency and transport pathways of dust from China to the
225 Arctic, the HYSPLIT trajectory model was applied in this study. Based on the outbreak
226 time and source areas of dust recorded by China's Sand-dust Weather Almanac, 10-15
227 days forward trajectories starting at altitudes of 500m, 1000m, and 1500m were
228 computed for each dust event in China during 2011-2015. If the trajectories entered the
229 Arctic Circle (latitudes higher than $66^{\circ}34'N$), the specific dust event was recorded as
230 one dust long-range transport event from China to the Arctic.

231

232

233 **Figure 2. Two common transport pathways of dust originating from China**
234 **to the Arctic, i.e., (a) the northern China - Korean Peninsula/Japan - North**
235 **Pacific Ocean – Arctic pathway and (b) the northern China - Korean**
236 **Peninsula/Japan - Kamchatka Peninsula - East Siberia – Arctic pathway. Red,**
237 **blue, and green curves represent forward trajectories starting at altitudes of**
238 **500m, 1000m, and 1500, respectively. The map is © Google Earth 2019.**

239

240 Based on this criterion, 38 out of the 50 dust events that originated from China

241 during 2011-2015 had the potential migrating to the Arctic Circle. Among these
242 identified dust events, most occurred in spring with 32 events and the transport duration
243 varied between 4 and 13 days. Two main types of dust transport from China to the
244 Arctic were distinguished in Figure 2. As for Type I (Figure 2a), dust mainly originated
245 from the central parts of Inner Mongolia and central Gansu. It passed through northern
246 China, Korean Peninsula, Japan and the North Pacific Ocean, and finally reached
247 Siberia and the northern part of Alaska. This transport type was characterized of wide
248 geographic coverage, relatively long transport duration (about 7-10 days), and mainly
249 over the open ocean. This was due to the high lifting altitude (mostly over 1500m) over
250 the dust source regions, so particles can be transported to even further areas.

251 As for Type II (Figure 2b), dust mainly originated from northeast China and
252 western Inner Mongolia, then passing over the Korean Peninsula, northern Japan,
253 Kamchatka Peninsula, and finally reaching East Siberia and its northern areas.
254 Compared to Type I, the Type II transport pathways travelled more over land and had
255 relatively shorter duration of about 4-8 days. This was due to the presence of a low-
256 pressure system over northern Japan in spring, which induced the air masses deflecting
257 northward.

258

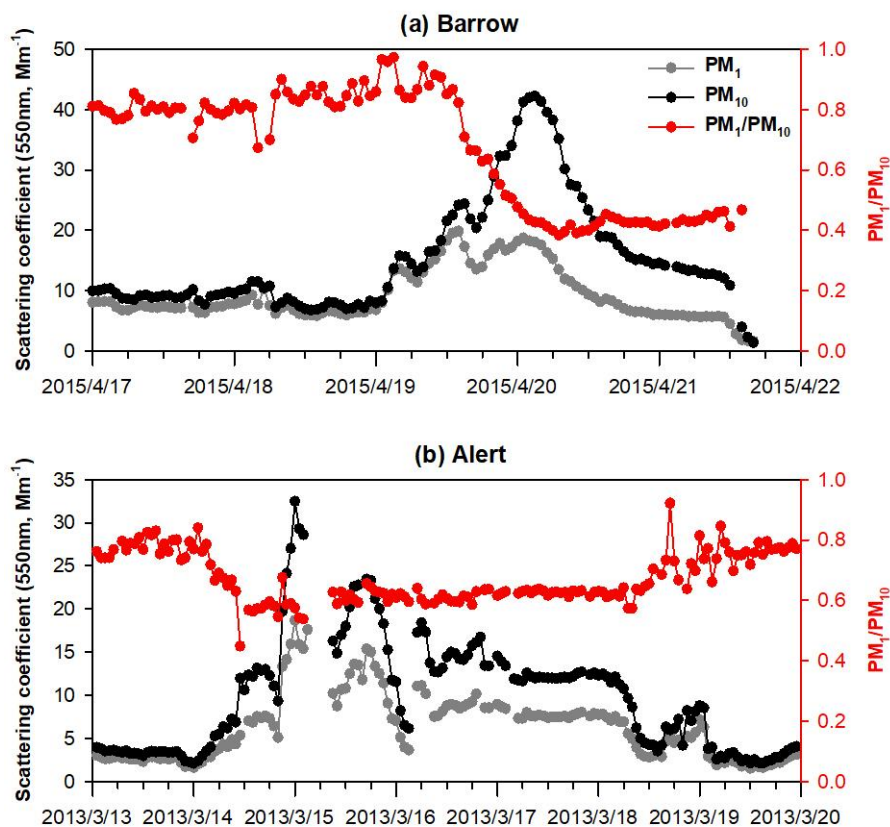

259 **3.3 Two cases of long-range transported dust to the Arctic**

260 Figure 3a shows the time series of scattering coefficients (σ_{sp}) of PM_1 and PM_{10} at 550
261 nm at Barrow during April 17-21, 2015. The scattering coefficients stayed at low levels
262 from the early morning of April 17 to the evening of April 18, which were similar to

263 the annual average values at Barrow in 2015 (4.8 Mm^{-1} and 8.1 Mm^{-1} for PM_1 and PM_{10} ,
264 respectively). Since the early morning of April 19, both $\sigma_{\text{sp}}(\text{PM}_1)$ and $\sigma_{\text{sp}}(\text{PM}_{10})$
265 climbed simultaneously, indicating the invasion of air pollutants. At 15:00 on April 19,
266 $\sigma_{\text{sp}}(\text{PM}_1)$ reached relatively high value of 19.8 Mm^{-1} and was still close to that of PM_{10}
267 with the $\sigma_{\text{sp}}(\text{PM}_1)/\sigma_{\text{sp}}(\text{PM}_{10})$ ratio of 0.82, indicating fine particles dominated during
268 this period. Afterwards, $\sigma_{\text{sp}}(\text{PM}_{10})$ continued to increase until it reached the maximum
269 value of 42.2 Mm^{-1} at 4:00 on April 20, more than 5 times of its annual average. The
270 mean $\sigma_{\text{sp}}(\text{PM}_1)/\sigma_{\text{sp}}(\text{PM}_{10})$ ratio during 14:00, April 19 - 12:00, April 21 decreased to
271 0.47 ± 0.10 , obviously indicating the enrichment of coarse particles. This episode is
272 defined as CASE I.

273 Figure 3b shows the time series of scattering coefficients of PM_1 and PM_{10} at 550
274 nm at Alert from March 13 to 19, 2013. The annual average $\sigma_{\text{sp}}(\text{PM}_1)$ and $\sigma_{\text{sp}}(\text{PM}_{10})$
275 at Alert was 4.2 Mm^{-1} and 6.0 Mm^{-1} , respectively, slightly lower than those observed at
276 Barrow. From 0:00 on March 14, $\sigma_{\text{sp}}(\text{PM}_1)$ and $\sigma_{\text{sp}}(\text{PM}_{10})$ started to increase and
277 reached the maximum values of 18.6 Mm^{-1} and 32.3 Mm^{-1} at 0:00 on March 15, which
278 were more than 4 and 5 times of their annual average, respectively. The mean $\sigma_{\text{sp}}(\text{PM}_1)/$
279 $\sigma_{\text{sp}}(\text{PM}_{10})$ ratio during 11:00, March 14 to 7:00 on March 18 was 0.61 ± 0.03 , also
280 indicating the enrichment of coarse particles. This episode is defined as CASE II.

281
282 **Figure 3. (a) Time series of hourly scattering coefficients of PM₁ and PM₁₀ at 550**
283 **nm and the ratio of PM₁/PM₁₀ at Barrow during April 17-21, 2015. (b) The same**
284 **but for Alert during March 13 to 19, 2013.**

285

286 In comparison, the pollution during CASE I lasted for a relatively short period of
287 about 2.5 days while had higher peak values of $\sigma_{sp}(\text{PM}_{10})$ than CASE II, indicating that
288 CASE I was subject to stronger long-range transport and more significant variations of
289 synoptic conditions. The pollution during CASE II lasted for nearly four days,
290 suggesting relatively weak cleanup processes of the air pollutants. As for the $\sigma_{sp}(\text{PM}_1)/$
291 $\sigma_{sp}(\text{PM}_{10})$ ratio, it was much lower in CASE I than that in CASE II. This indicated the
292 intrusion of coarse particles was more intense during CASE I, which could be related

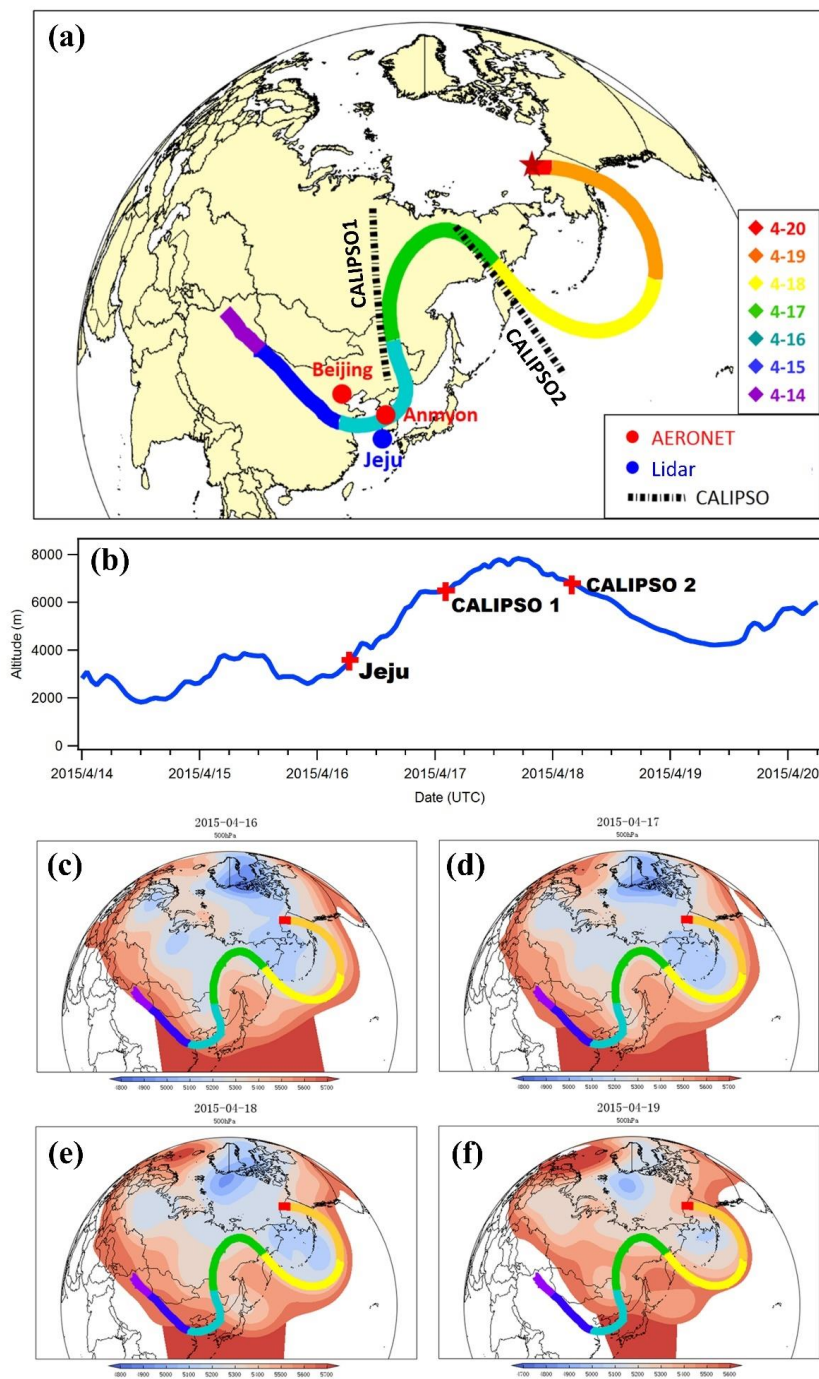

293 to various factors such as the emission source regions, transport pathways, and
294 evolution of particles. In the next section, the transport pathways of the two cases above
295 were validated by using backward trajectory analysis and remote sensing from both
296 space and ground-based observations.

297

298 **3.4 Identification of dust long-range transport pathways**

299 To determine the sources and transport pathways of the two Arctic pollution events, the
300 HYSPLIT model was applied to compute the air masses transport trajectories. Figure
301 4a shows the 7-days backward trajectory simulated at an altitude of 6 km above Barrow
302 starting from 04:00 on April 20, 2015 (CASE I). The different segments of the trajectory
303 were colored to represent the continuous dates. On 14-15 April, air masses originated
304 from the Taklamakan and Gobi deserts in China, then passed over East Asia, Siberia of
305 Russia, and the Pacific Ocean, and finally reached Barrow about 6 days later. The
306 geopotential height fields based on the NCEP reanalysis data are plotted in Figure 4c-
307 4f to verify the dust transport path. On April 16, a low-pressure trough over Northeast
308 China caused the eastward air masses to turn northward. On April 17, the air masses
309 followed the high-pressure ridge over eastern Russia and entered the North Pacific.
310 Then its direction was again deflected by a low-pressure system near the Bering Strait
311 on April 18 and 19, finally reaching Barrow on April 20.

312
313
314

Figure 4. (a) The 7-days backward trajectory simulated at an altitude of 6 km

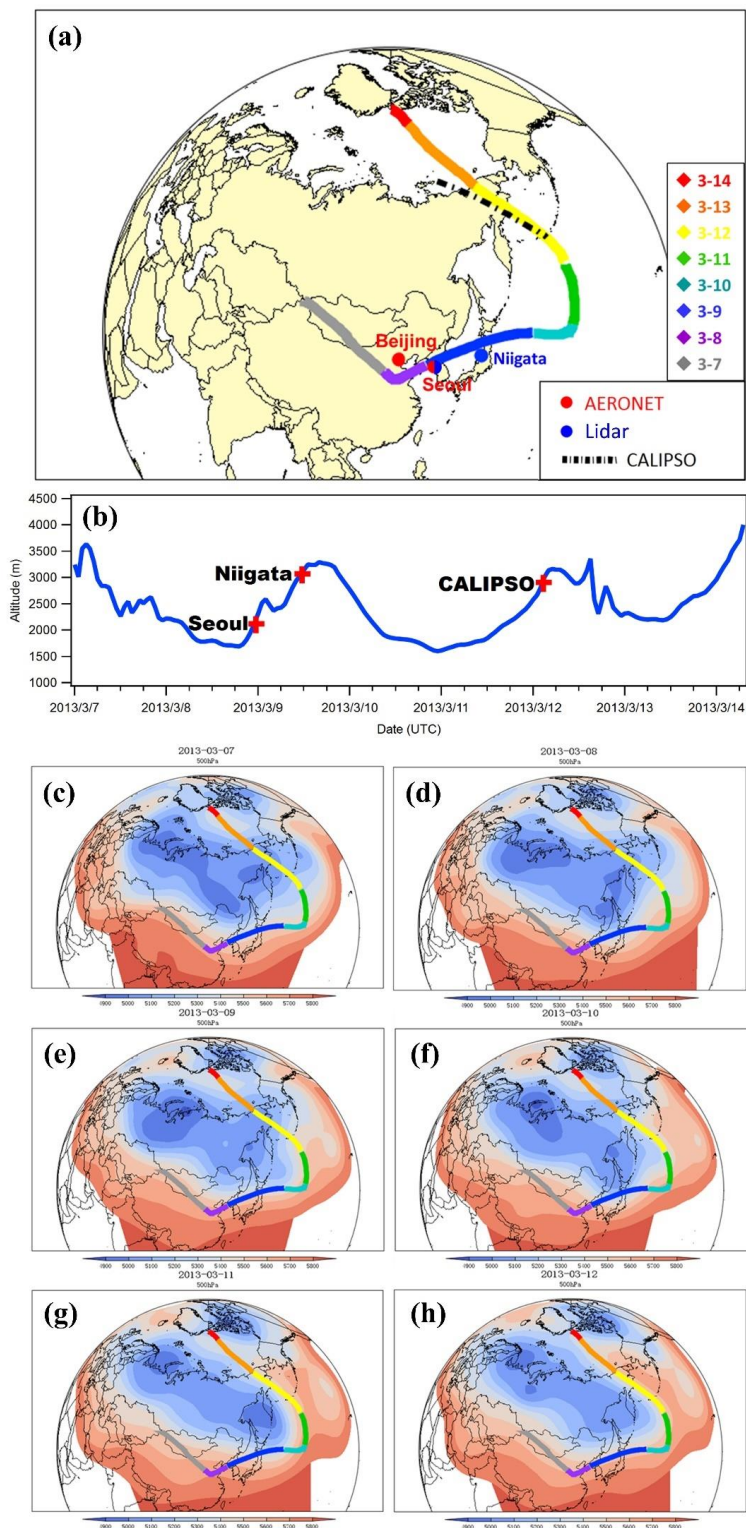

315 **above Barrow starting from 04:00 on April 20, 2015. The locations of AERONET,**
316 **Lidar sites, and CALIPSO tracks nearby the trajectory are plotted. (b) The height**
317 **of the trajectory along the transport path. The height and time of dust layers**
318 **observed by lidars and CALIPSO in Figure 4a are indicated by the red plus**
319 **symbols. (c-f) Daily geopotential height fields from the NCEP reanalysis data**

320

321 Figure 5a shows a typical backward trajectory simulated at an altitude of 4 km
322 above Alert on March 14, 2013 (CASE II). On March 7, air masses travelled over the
323 Gobi Desert on the border between Mongolia and the north of China, then passed over
324 Korea and Japan, and directly entered the Pacific Ocean. Afterwards, it kept moving
325 northward across the Arctic Ocean and reached Alert on March 14. Based on the
326 geopotential heights (Figure 5c-5h), a low-pressure system was observed over the
327 eastern coast of Russia and kept moving to the southeast from March 7 to 11. On March
328 11, the low-pressure system moved over the Sea of Okhotsk in Russia and turned to be
329 stronger, causing the air masses deflect and follow the geopotential height contours all
330 the way north to Alert.

331

333 **Figure 5. Same as Figure 4 but for CASE II.**

334

335 **3.5 Verification of dust transport pathways based on satellite and ground-based**
336 **observations**

337 Although the air mass transport pathways of the two Arctic coarse particle pollution
338 cases were visualized based on trajectory modeling, whether dust particles were indeed
339 present in the air masses has not been confirmed. In this section, the aerosol optical
340 properties along the transport pathway were explored using both ground-based
341 observations (AERONET and AD-Net) and satellite inversion data (CALIPSO). In
342 Figure 4a and 5a, the red dots denoted the AERONET sites, which observed columnar
343 aerosol optical properties. The blue dots denoted the AD-Net sites, which observed
344 vertical profiles of aerosol extinctions and particle spheric information. The black
345 dashed lines represented the orbits of CALIPSO profiles, which were used to
346 supplement the aerosol information in the blank areas without available ground-based
347 observations. The validation results of the two cases are described separately as below.

348

349 **(i) CASE I**

350 Figures 6 shows the aerosol optical properties of two AERONET sites, i.e., Beijing
351 (China) and Anmyon (Korea), which were located nearby the air mass transport
352 pathway in CASE I (Figure 4a). AE (Angström exponent) is a parameter of
353 characterizing the particle size. The smaller AE represents the larger particle size, and
354 vice versa. In general, $AE < 1$ suggested the dominance of coarse particles, which were

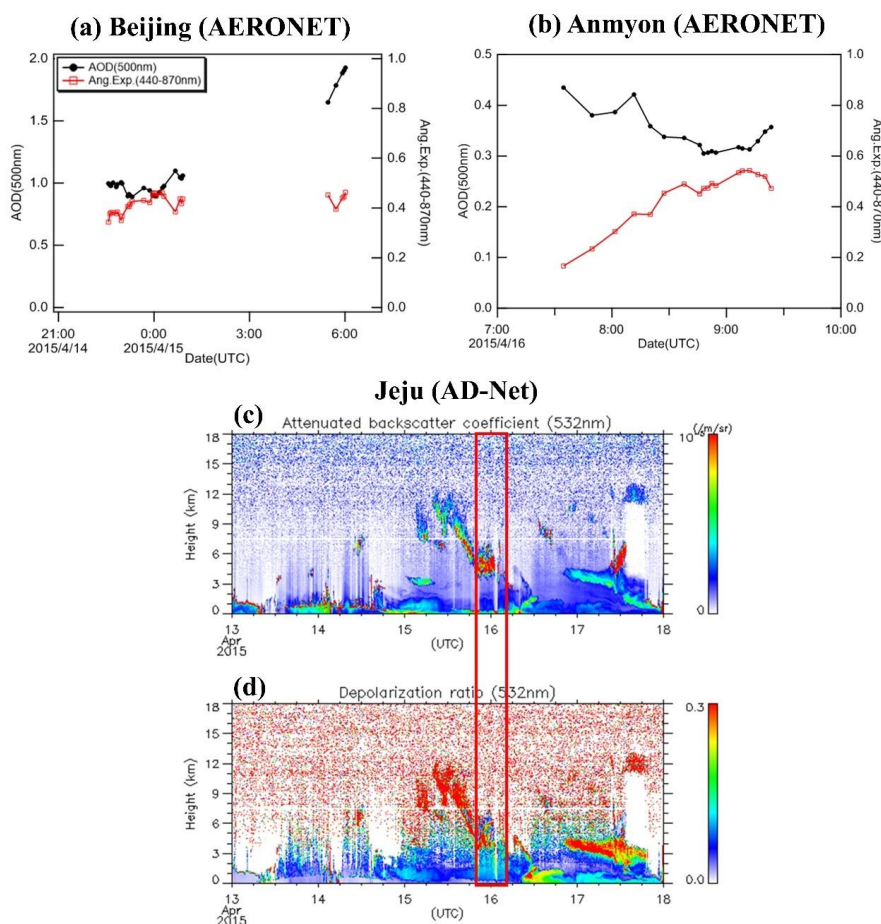

355 usually associated with dust or sea salts. While $AE > 1$ suggested the dominance of fine
356 particles, which derived from anthropogenic emissions and biomass burning.

357 As shown in Figure 6a, AOD over Beijing doubled from about 1.0 at around 0:00
358 on April 15 to nearly 2.0 at around 6:00, while AE remained below 0.5. When the air
359 masses passed over Anmyon, Korea, AOD was about 0.4 at 8:00 on April 16 (Figure
360 6b). AOD at Anmyon was much lower compared to Beijing, which should be due to the
361 removal process during the transport and lower local emissions at Anmyon. Similarly,
362 AE at this site was low below 0.4 and it slightly increased to above 0.5 after 8:00. As a
363 whole, the observation of high AOD and low AE at both sites indicated that the air
364 masses contained abundant coarse dust aerosols.

365 Figure 6c shows the vertical profiles of aerosol optical properties over Jeju Island,
366 Korea. The depolarization ratio represents the degree of particle approximation to a
367 sphere in the range of 0 - 1. The depolarization ratio of a spherical object is equal to 0,
368 and vice versa (Mishra et al., 2010). Since dust aerosols were irregularly shaped
369 particles, the depolarization ratio of dust aerosols usually ranged between 0.2 and 0.3.
370 As for the intense dust storm events, the depolarization ratio of particles could reach
371 over 0.4 (Liu et al., 2003). High extinction coefficients and depolarization ratios
372 between 0.1 and 0.3 at around 4 km over Jeju in the early morning of April 16, 2015
373 were observed. By comparing the simulated height of the air mass backward trajectory
374 and the observed plume height over Jeju, good agreement was found (Figure 4b),
375 corroborating the same origin of the Arctic pollution and the Asian downstream dust
376 plumes.

383 **red rectangle denotes the time when dust passed over the site.**

384

385 After April 16, the dust plume moved towards Russia and the North Pacific. Due
386 to the lacking of ground-based observations in this region, CALIPSO inversion
387 products were used to fill in these blank regions. At about 5:00 UTC on April 17, 2015,
388 over the northeastern part of Russia (54.19°N, 122.17°E), CALIPSO observed an

389 aerosol layer, about 5 km above the ground. This height was generally consistent with
390 that of the simulated backward trajectory (Figure 4b) and the plume was identified as a
391 mixture of dust, polluted dust, and other types of aerosols (Figure 7). At 2:00 UTC on
392 April 18, CALIPSO observed a similar mixed layer of dust, polluting dust, and lifted
393 smoke at 4–6 km over the Kamchatka Peninsula in Russia (Figure 7). Compared to the
394 previous day, the lifted smoke was more abundant, suggesting that smoke aerosols from
395 forest fires may have been mixed with the air masses passed over Russia.

396

399 **aerosol types on April 17 (a-b) and 18 (c-d), 2015. The red rectangles denote the**
400 **regions as indicated by the CALIPSO tracks in Figure 4a.**

402 **(ii) CASE II**

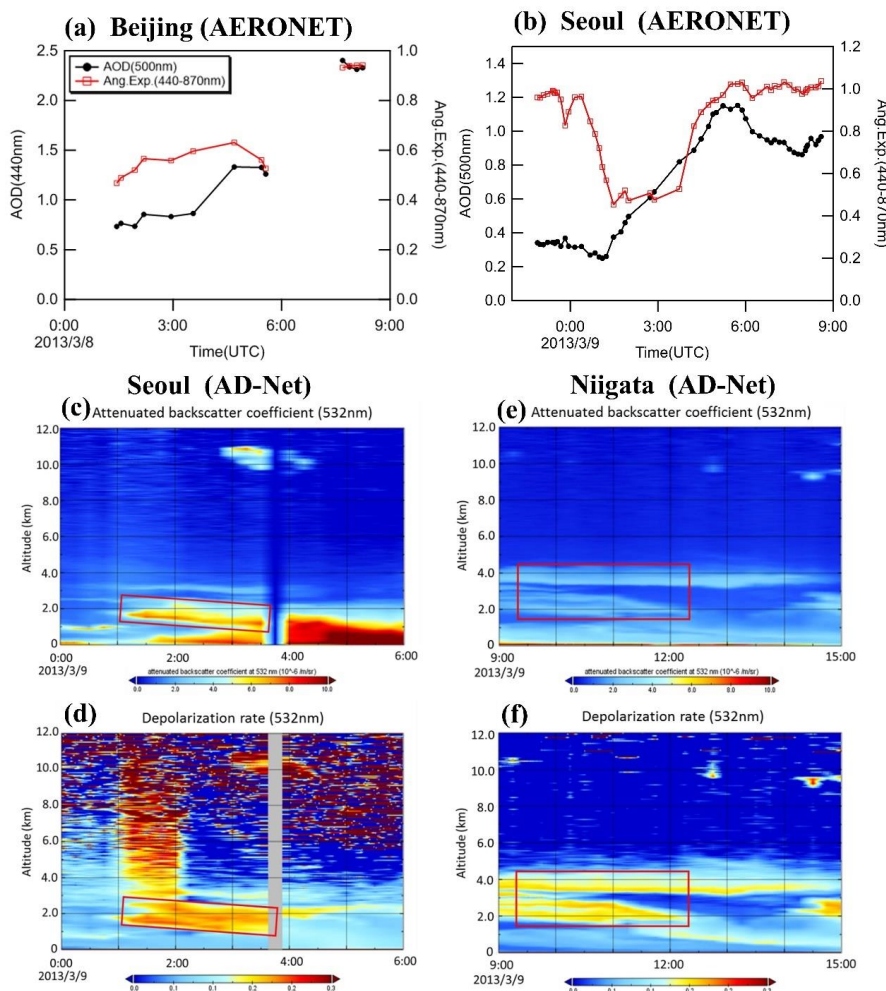

403 Figure 8 shows the available ground-based observations close to the transport pathway
404 during CASE II. At the Beijing AERONET site, at 3:00 UTC on March 8, 2013, AOD
405 was 0.73 while AE was 0.47. This was indicative of the dominance of dust particles.
406 Afterwards at 8:00, AOD increased more than twice and approached 2.5, while AE also

407 increased to more than 0.9, indicating that the dust in CASE II was more mixed with
408 fine particles than CASE I.

409 From 0:00 to 6:00 UTC on March 9, 2013, observed AE at the Seoul AERONET
410 site decreased to a low level of about 0.6 and increased to around 1.0 for several hours.
411 This process was accompanied by a continuous increase of AOD, reaching a maximum
412 of 1.15. In addition, the vertical profiles of the aerosol optical properties in the early
413 morning of March 9 indicated a 1-2 km thick dust layer at altitudes of 1-3 km height
414 over Seoul (Figure 8c), which was in good agreement with the height of the backward
415 trajectory (Figure 5b). Figure 8d shows the lidar vertical observations in Niigata, Japan.
416 A 1-2km thick dust layer at altitudes of 2 – 4km was also observed at 9:00-12:00 UTC
417 on March 9. The heights of the dust layers observed from lidars were also in good
418 agreement with the time and height of the simulated backward trajectory as shown in
419 Figure 5b.

420

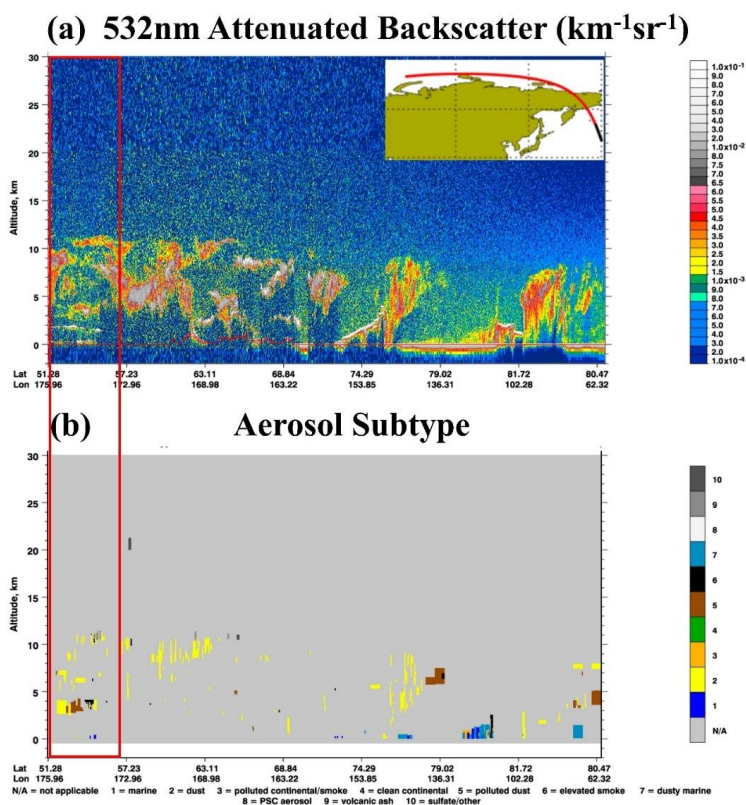

421
 422 **Figure 8.** Aerosol optical properties observed at ground-based sites during CASE
 423 **II.** (a) AOD and Angström exponent at the Beijing AERONET site (b) AOD and
 424 Angström exponent at the Seoul AERONET site (c-d) Vertical profiles of
 425 backscattering coefficient and depolarization ratio at the Seoul AD-Net site (e-f)
 426 Vertical profiles of backscattering coefficient and depolarization ratio at the
 427 Niigata AD-Net site. The red rectangle denotes the time when dust passed over the
 428 site.

429

430 Figure 9 shows the aerosol vertical structure observed from CALIPSO over the
 431 Bering Sea (51.28°N, 175.96°E - 57.23°N, 172.96°E) on March 12, 2013. At around
 432 2.5 - 4 km, an aerosol layer was evident, consisting of dust and polluted dust,

433 confirming that the aerosols transported to the remote ocean still contained a large
434 amount of dust particles.

435
436
437 **Figure 9. CALIPSO profiles of (a) aerosol backscattering coefficients and (b)**
438 **identified aerosol types on March 12, 2013. The red rectangles denote the regions**
439 **as indicated by the CALIPSO tracks in Figure 5a.**

440
441 By comparing the transport pathways of CASE I and CASE II, CASE I passed
442 over more terrestrial areas, increasing the probability of mixing between dust and air
443 pollutants from anthropogenic emissions. While CASE II travelled more over the open
444 ocean, which was more likely to mix with sea salts. In terms of transport time, the air
445 masses in CASE I took about four days to reach the receptor after getting out of the

446 Asian dust source regions, while the air masses in CASE II took about six days. The
447 longer transport time in CASE II may lead to more deposition of coarse dust particles
448 due to the gravitational effect and other removing processes such as wet scavenging.

449

450 **3.6 Evolution of aerosol optical properties during long-range transport to the** 451 **Arctic**

452 In the previous section, it has been well demonstrated that the Arctic air pollution events
453 in both CASE I and CASE II were caused by the long-range transport of Asian dust.
454 However, only a limited observation from ground-based sites and CALIPSO was
455 available for the analysis of aerosol properties. In order to analyze the evolution of
456 aerosols during the transport, MODIS data with a wide spatial coverage was used to
457 quantify the changes of aerosol optical properties.

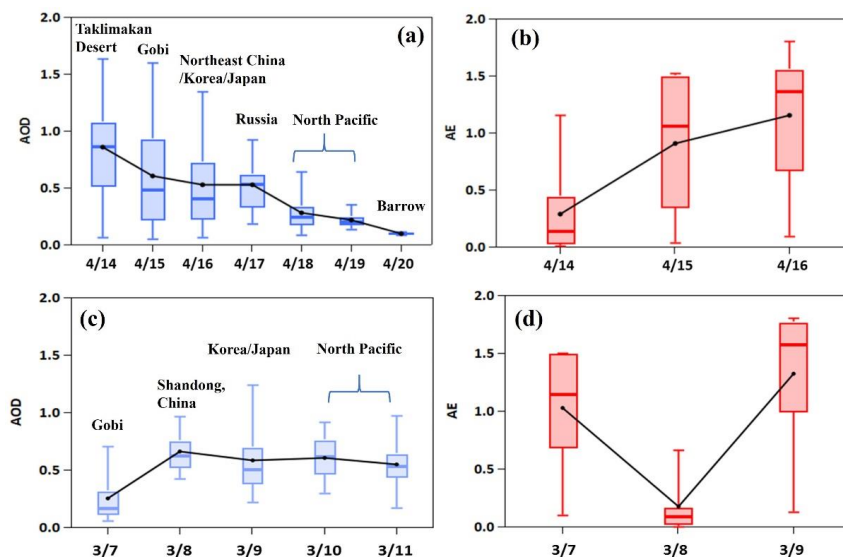

458 As shown in Figure S1, MODIS data were analyzed on a daily basis. Since
459 simulated backward trajectories were subject to certain uncertainties (Draxler and Hess,
460 1998), the rectangular subsection that covered the daily trajectory was extracted to
461 represent the aerosol properties along the transport pathway. Figure 10 compares the
462 mean values of AOD and AE over the daily transport coverage area between the two
463 cases. As shown in Figure 10a, AOD in CASE I exhibited an evidently decreasing trend
464 with time. It averaged 0.86 on April 14, 2015 over the dust source regions, while it was
465 0.10 at Barrow on April 20, indicating a tremendous AOD decrease of nearly 8 times.
466 In the meanwhile, AE showed an increasing trend (Figure 10b). This indicated that, on
467 the one hand, the high aerosol concentrations from the dust source regions had been

468 significantly eliminated by various physical scavenging processes. On the other hand,
469 dust mixed with fine particles such as black carbon, nitrate, and sulfate and gradually
470 modified the irregular dust particles to be more spheric.

471 In contrast, less variation of AOD during the transport was observed in CASE II
472 (Figure 10c). The level of AOD stayed in the range of 0.56 - 0.68 from March 8 to 11.
473 Meanwhile, except for the low value of AE on March 8 (possibly due to the small
474 number of data points as shown in Figure S1b), the mean AE values were above 1.0 on
475 March 7 and 9. This suggested that dust mixed with more fine particles and coarse
476 particles were more removed. Overall, by comparing these two cases, it was evident
477 that different transport routes to the Arctic had divergent effects on the evolution of
478 aerosol optical properties.

479

480

481

482 **Figure 10. Regional (a) AOD and (b) Angström exponent in CASE I. Regional (c)**

485 **represent the 25 and 75% limits, respectively; and bottom and top short lines**
486 **represent the minimum and maximum values, respectively. The geographic region**
487 **in each day is defined in Figure S1.**

488

489 **3.7 Impact assessment of transported aerosols on the Arctic surface albedo**

490 Surface albedo is an important parameter for energy exchange between the surface and
491 the atmosphere in polar regions. The changes in snow and ice albedos could have
492 important climatic impacts on the polar regions as well as the whole world. Due to the
493 large difference between the multiple scattering effect of snow and ice and absorption
494 effects of absorbing impurities (e.g. black carbon and dust), very small amounts of
495 deposited impurities can lead to a decrease of snow and ice albedo (Zhang et al., 2017).
496 Hansen and Nazarenko (2004) showed that the effect of soot on reducing snow and ice
497 albedo was around 1.5% in the Arctic and 3% in the snow and ice covered areas of the
498 Northern Hemisphere. Kaspari et al. (2014) showed that black carbon reduced snow
499 and ice albedo by 6-10% relative to pure snow in the Himalayas in winter and spring,
500 and other impurities such as dust even reduced snow and ice albedo by 40 - 42%. In
501 this regard, decreases of snow and ice albedo would cause surface warming, thinning
502 of sea ice, melting permafrost, and consequently sea level rise that may have serious
503 impacts on the global water resources and ecosystems.

504 In this section, the impacts of the two Arctic pollution events on changing the surface
505 albedo were assessed. The SNICAR snow and ice albedo model was applied to estimate
506 the contributions of dust and black carbon to the reduction of snow and ice albedo.

507

508 **3.7.1 Estimation of mass concentrations of impurities in snow and evaluation of**
509 **model performance**

510 In this study, we only considered airborne dust and elemental carbon (EC) as the
511 dominant contributors to the impurities in the Arctic snow and ice. Firstly, the
512 atmospheric concentrations of absorbing aerosols were estimated by using the revised
513 IMPROVE (The Interagency Monitoring of Protected Visual Environments) Equation
514 (Pitchford et al., 2007). It was assumed that airborne dust and EC dominated the
515 scattering of coarse particles and absorption of fine particles, respectively (Eq. 1-2).

$$516 \quad C_{\text{dust}} = b_{\text{sca},(\text{PM}_{10} - \text{PM}_1)} / 0.6, \quad (1)$$

$$517 \quad C_{\text{EC}} = b_{\text{abs},\text{PM}_1} / 10, \quad (2)$$

518 Of which, the constant 0.6 and 10 (m^2/g) is the mass scattering efficiency and mass
519 absorption efficiency of dust and EC, respectively (Pitchford et al., 2007). Since the
520 concentrations of impurities in snow were required as inputs for the SNICAR model,
521 we estimated them based on the following assumption. Dou et al. (2017) conducted
522 field sampling at Barrow during April and May in 2015 and measured elemental carbon
523 concentration of 3.30 ng/g in the snow sample on April 30, 2015. The airborne
524 elemental carbon concentration was estimated to be 6.25 ng/m^3 on the same day by
525 using the equations above. Thus, the ratio of the particulate matter in the snow versus
526 that in the atmosphere was calculated to be 0.528 m^3/g . This ratio was then applied to
527 estimate the concentrations of dust and elemental carbon in snow during the two cases.

528 To evaluate the model performance, Figure S2 compares the simulated values of
529 surface albedo and the observations at an ARM (Atmospheric Radiation Measurement)

530 site located at Barrow during 14 – 19, April, 2015. A correlation coefficient of 0.74 was
531 derived, indicating the relatively good model performance on simulating the Arctic
532 surface albedo. However, deviations of simulated values from observations were still
533 found. The bias may derive from the following aspects. First, the concentrations of dust
534 and elemental carbon in snow as inputs for the model were not in-situ measured, as well
535 as for the other input parameters such as snow radius, thickness, and density. Secondly,
536 the simulation only considered the absorbing substances deposited from the atmosphere
537 while the pre-existing impurities in snow and ice were ignored. Last but not the least,
538 impurities such as brown carbon were not included for the simulation.

539

540 **3.7.2 Comparison of the changes of Arctic surface albedo between two cases**

541 In this section, the impacts of transported particles on the change of surface albedo in
542 both cases were evaluated. Figure S3 shows the time-series of estimated dust and
543 elemental carbon in snow during the two pollution cases. As for CASE I (Figure S3a),
544 the peak time of elemental carbon was about half a day ahead of that of dust. This
545 phenomenon was as similar as some other dust events that anthropogenic air pollutants
546 were ahead of dust pushed by the cold front (Guo et al., 2004; Wang et al., 2018a). In
547 regard of the variations of pollutants, four representative moments were selected, i.e.,
548 0:00 on April 18 (the beginning of pollution), 13:00 on April 19 (the peak time of
549 elemental carbon), 3:00 on April 20 (the peak time of dust), and 15:00 on April 21 (the
550 end of pollution). As for CASE II (Figure S3b), the estimated concentrations of
551 impurities in snow stayed at relatively low levels and varied less strongly compared to

552 CASE I. We chose 12:00 on March 14 (the beginning of pollution), 17:00 on March 15
553 (the peak time of dust), and 13:00 on March 18 (the end of pollution) for the analysis.

554 By using the SNICAR model, the effects of dust, elemental carbon, and
555 combination of dust and elemental carbon on the surface albedo were separately
556 assessed. As shown in Table 4, the reduction of surface albedo caused by long-range
557 transported Asian light-absorbing pollutants ranged from 0.35% to 2.63%, which were
558 consistent with previous studies. For instance, Dou et al. (2017) calculated a 1.6-5.1%
559 reduction in snow and ice albedo caused by dust and black carbon at Barrow from late
560 April to May 2015, with a 5-10 fold increase in pollutant concentrations compared to
561 the pre-April period due to the snowmelt period during that time. Zhang et al. (2017)
562 calculated that dust and black carbon reduced snow and ice albedo by 0.72-1.00% on
563 glaciers in the southeastern Tibetan Plateau in June 2015. In CASE I, the highest
564 concentration of elemental carbon in snow reached more than 72 ng/g, which could
565 reduce the albedo by 1.47%. And the highest concentration of dust reached more than
566 37 $\mu\text{g/g}$, which could reduce the albedo by 2.26%. During this pollution event, the
567 combined effect of dust and elemental carbon significantly reduced the snow and ice
568 albedo by 2.28%. In CASE II, elemental carbon concentrations were much lower than
569 CASE I and its effect on albedo was below 0.40%, while dust can reduce albedo up to
570 1.87%. The combined effect of dust and elemental carbon reached more than 2%
571 compared to the pure snow condition.

572

573 **Table 4. Simulated changes of albedo due to dust, elemental carbon, and**
574 **combination of dust and elemental carbon (SA represents the simulated surface**

575 **albedo of pure snow)**

Time (UTC)	BC snow (ng/g)	Dust snow (µg/g)	SA Pure	SA+EC	SA+Dust	SA+EC & Dust	EC (%)	Dust (%)	EC&Dust (%)
Barrow									
2015/4/18 0:00	24.31	8.31	0.7990	0.7901	0.7915	0.7852	1.12%	0.94%	1.73%
2015/4/15 15:00	72.14	21.39	0.8392	0.8270	0.8300	0.8218	1.47%	1.10%	2.07%
2015/4/20 3:00	21.16	37.11	0.8143	0.8077	0.7959	0.7929	0.83%	2.26%	2.63%
2015/4/21 15:00	6.08	1.93	0.8379	0.8361	0.8365	0.8350	0.22%	0.17%	0.35%
Alert									
2013/3/14 13:00	7.75	10.77	0.7995	0.7964	0.7912	0.7891	0.39%	1.04%	1.30%
2013/3/15 17:00	7.37	20.74	0.7923	0.7892	0.7775	0.7758	0.40%	1.87%	2.08%
2013/3/18 13:00	6.52	3.68	0.7956	0.7929	0.7921	0.7899	0.34%	0.44%	0.72%

576

577 As discussed above, the concentrations of dust and elemental carbon were
 578 relatively higher in CASE I, hence the resulting effects on snow and ice albedo were
 579 more obvious. On the one hand, the transport time in CASE I was shorter and the
 580 particulate matters were scavenged less along the transport. On the other hand, the air
 581 masses in CASE I passed over a large number of terrestrial areas, including northeast
 582 China and Siberia. Fine particles from anthropogenic emissions and biomass burning
 583 in Siberia mixed with dust and transported to Barrow together, making the elemental
 584 carbon at the receptor significantly higher. As for CASE II, the receptor site at Alert is
 585 a higher latitudinal area, which was much less affected by local anthropogenic activities.

586 In addition, the transport pathway of CASE II was mostly over the open ocean with
587 longer duration. This finally induced much lower air pollutant concentrations and
588 weaker impact on the reduction of surface albedo.

589

590 **4. Conclusions**

591 In this study, the long-range transport of Asian dust to the Arctic was investigated.
592 During 2011-2015, 50 dust events in China were recorded, of which 38 dust events had
593 the capability to reach the Arctic based on the air mass trajectory simulation. Two main
594 transport routes were identified. One typical transport type was characterized of wide
595 geographic coverage, long transport duration (generally 7-10 days), and mainly marine
596 transport due to the high lifting altitude of dust particles (mostly over 1500m) over the
597 dust source regions. The other typical transport type was characterized of dust transport
598 mostly over land with relatively short duration of about 4-8 days. This was due to the
599 presence of a low-pressure system over northern Japan in spring, which induced the air
600 masses deflecting northward.

601 Two typical coarse particle dominated cases observed in the Arctic were
602 specifically investigated, i.e., one at Barrow in April 2015 (CASE I) and the other one
603 at Alert in March 2013 (CASE II), respectively. Based on the air mass trajectory
604 simulation, in CASE I, dust originated from the Taklamakan and Gobi deserts in China,
605 then passed over East Asia, Siberia of Russia, and the Pacific Ocean, and finally reached
606 Barrow. In CASE II, dust originated from the Gobi Desert, then passed over Korea and
607 Japan and directly entered the Pacific Ocean, and finally moved northward across the

608 Arctic Ocean and reached Alert.

609 The dust transport pathways during both cases were verified based on a synergy
610 of NCEP reanalysis data (geopotential height fields), ground-based observations
611 (AERONET aerosol columnar properties and lidar aerosol profiles), and satellite
612 products (CALIPSO profiles). The passing time and height of the dust plume based on
613 trajectory simulation coincided very consistently with various observations. The
614 evolution of aerosol optical properties during the transport was assessed by using the
615 large-scale MODIS data. In CASE I, AOD showed a significant decreasing trend while
616 Angström exponent showed an increasing trend from the dust source region to the
617 receptor. In contrast, AOD varied much less significantly in CASE II. It was evident
618 that different transport routes to the Arctic had divergent effects on the evolution of
619 aerosol properties.

620 The SNICAR snow and ice model was applied to simulate the impact of impurities
621 on the reduction of surface albedo in the Arctic during the two cases. The concentrations
622 of dust and elemental carbon in snow were estimated and the effects of dust, elemental
623 carbon, and combination of dust and elemental carbon on snow and ice albedo were
624 separately quantified. The reduction of snow and ice albedo caused by long-range
625 transported Asian light-absorbing pollutants ranged from 0.35% to 2.63%. This study
626 highlighted that the long-range transport of Asian dust to the Arctic was ubiquitous and
627 its impact on changing the radiative forcing and regional climate in the Arctic should
628 be considered by the atmosphere-ocean-cryosphere interaction.

629

630 **Data availability**

631 The measurement data at Barrow and Alert are from the EBAS database
632 (<https://ebas.nilu.no/>). Aerosol columnar data are from AERONET
633 (<https://aeronet.gsfc.nasa.gov/>). Aerosol vertical profiles are from AD-Net
634 (<https://www-lidar.nies.go.jp/AD-Net/>). The MODIS Level-3 aerosol products are
635 from NASA's Giovanni (<https://giovanni.gsfc.nasa.gov/giovanni/>). The NCEP/NCAR
636 reanalysis data are from <https://www.esrl.noaa.gov/psd/data/gridded/reanalysis/>
