Abstract. The global atmospheric methane growth rates reported by NOAA for 2020 and 2021 are the largest since systematic measurements began in 1983. To explore the underlying reasons for these anomalous growth rates we use newly available methane data from the Japanese Greenhouse gases Observing SATellite (GOSAT) to estimate methane surface emissions. Relative to baseline values in 2019 we see the largest annual increases in methane emissions during 2020 over Eastern Africa (13 Tg), tropical Asia (4 Tg), tropical South America (3 Tg), and temperate Eurasia (3 Tg), and the largest reductions over China (-6 Tg) and India (-2 Tg). We find comparable emission changes in 2021, relative to 2019, except for tropical and temperate South America where emissions increased to 9 Tg and 5 Tg, respectively, and tropical Asian emissions increased to 8 Tg. The elevated contributions we saw in 2020 over the western half of Africa (-5 Tg) and Europe (-3 Tg) are substantially reduced in 2021, compared to our 2019 baseline. We find statistically significant positive correlations between anomalies of tropical methane emissions and groundwater, consistent with recent studies that have highlighted a growing role for microbial sources over the tropics. Emission reductions over India and China are expected in 2020 due to the Covid-19 shutdown but continued in 2021, which we do not currently understand. Based on a sensitivity study for which we assume a conservative 5% decrease in hydroxyl concentrations in 2020, due to reduced pollutant emissions during the Covid-19 shutdown, we find that the global increase in our a posteriori emissions in 2020 is ~22% lower than our control calculation. We conclude therefore that most of the observed increase in atmospheric methane during 2020 and 2021 is due to increased emissions.

1 Introduction

The atmospheric growth rate of methane in the 21st century has defied a definitive explanation: following a period of near-zero growth during 2000-2007 (Rigby et al. 2008) growth rates have accelerated, with values reported by NOAA for 2020 (15.29±0.38 ppb) and 2021 (16.94±0.38 ppb) exceeding all prior values since their records began in 1983. The underlying reasons for these anomalous growth rates in 2020 and 2021 are currently subject to intense debate with some studies attributing
most of the growth in 2020 to a reduction in the hydroxyl radical (OH) sink of methane due to global-scale reductions in nitrogen oxides due to pandemic-related industry shutdowns (Laughner et al. 2021). On the face of it, this appears to be a reasonable explanation, but recent studies have used satellite observations of atmospheric methane to reveal regional hotspots over the tropics that are responding to changes in climate and have global significance (Pandey et al. 2021; Lunt et al. 2019; 2021; Pandey et al. 2017; Feng et al. 2022; Palmer et al. 2021; Wilson et al. 2020). Here, we use satellite observation of methane from the Japanese Greenhouse gases Observing SATellite (GOSAT) to document global and regional changes in emissions, extending a recent study (Feng et al. 2022). In the next section we describe the data and methods used to infer methane emissions. In section 3 we describe our results and conclude the study in section 4.

2 Data and Methods

We follow closely the methodology from a recent study (Feng et al. 2022) so that for the sake of brevity we include only details relevant to the calculations shown here.

2.1 GOSAT methane proxy data

We use version 9.0 of the proxy GOSAT XCH₄:XCO₂ retrievals (X denotes atmospheric column-averaged dry-air mole fraction) from the University of Leicester (R. J. Parker et al. 2020; R. Parker and Boesch 2020), including both nadir observations over land and glint observations over the ocean. Analyses have shown that these retrievals have a bias of 0.2%, with a single-sounding precision of ~0.72%. We globally remove a slightly larger 0.3% bias from the GOSAT proxy data to improve the comparison with independent in situ observations. We assume that each single GOSAT proxy XCH₄:XCO₂ ratio retrieval has an uncertainty of 1.2% to account for possible model errors, including the errors in atmospheric chemistry and transport.

2.2 In situ data

To anchor the GOSAT proxy ratio observations (Fraser et al. 2014b), we also ingest simultaneously the CO₂ and methane mole fraction data at surface-based sites, chosen from the NOAA compilation of the multi-laboratory in-situ measurements (Di Sarra et al. 2021; 2022; Cox et al. 2021; 2022). We include the same subset of the surface sites used by a recent study that documented year to year variations of methane emissions during 2010-2019 (Feng et al. 2022). We assume uncertainties of 0.5 ppm and 8 ppb for these in situ observations of CO₂ and methane respectively (Feng et al. 2022).

2.3 GEOS-Chem atmospheric chemistry transport model

We use the GEOS-Chem model of atmospheric chemistry and transport at a horizontal resolution of 2° (latitude) × 2.5° (longitude), driven by the MERRA2 meteorological reanalyses from the Global Modeling and Assimilation Office Global Circulation Model based at NASA Goddard Space Flight Center. Our CO₂ and methane model calculations are described in recent study (Feng et al. 2022). Our a priori CO₂ flux inventory includes monthly biomass burning emission (van der Werf et
al. 2017); monthly fossil fuel emissions for 2019 in the absence of more recent data (Oda and Maksyutov 2021); monthly climatological ocean fluxes (Takahashi et al. 2009); and hourly terrestrial biosphere fluxes (Olsen and Randerson 2004). Our a priori methane fluxes from nature include monthly wetland emissions, including rice paddies (Bloom et al. 2017); monthly fire methane emissions (van der Werf et al. 2017); and termite emissions (Fung et al. 1991). We include emissions from geological macroseeps (Kvenvolden and Rogers 2005; Etiope 2015). For a priori anthropogenic emissions we use the EDGAR v4.32 global emission inventory for 2012 (Janssens-Maenhout et al. 2019) that includes various sources related to human activities (e.g., oil and gas industry, coal mining, livestock, and waste). We use monthly 3-D fields of OH, consistent with observed values for the lifetime of methyl chloroform, from the GEOS-Chem full chemistry simulation (Mao et al. 2013; Turner et al. 2015) to describe the main oxidation sink of methane. Using pre-computed fields of OH greatly simplifies our calculations. To explore the sensitivity of our methane emission estimates for 2020 due to inferred reductions in OH due to large-scale industrial shutdown due to Covid-19 (Cooper et al. 2022), we scale down our baseline monthly 3-D OH fields by 5% where combustion emissions of CO₂ (Oda and Maksyutov 2021) were larger than the mean emissions over Africa, resulting in reductions mainly between 15°N and 65°N. Our choice of 5% represents a conservative reduction based on a recent study (Laughner et al. 2021). We also include the net microbial consumption of methane in soils (Fung et al. 1991), and reaction with chlorine atoms (Thanwerdas et al. 2019).

2.4 Ensemble Kalman filter inverse method

We use an ensemble Kalman Filter (EnKF) framework to estimate simultaneously CO₂ and methane fluxes from satellite measurements of the atmospheric CO₂ and methane (Feng et al. 2022). Our state vector includes monthly scaling factors for 487 regional pulse-like basis functions (Figure A1) that describe CO₂ and methane fluxes, including 476 land regions and 11 oceanic regions. We define these land sub-regions by dividing the 11 TransCom–3 land regions into 42 nearly equal sub-regions, with the exception for temperate Eurasia that has been divided into 56 sub-regions due to its large landmass. We use the 11 oceanic regions defined by the TransCom–3 experiment. We use a 4-month moving lag window to reduce the computational costs for projecting the flux perturbation ensemble into observation space long after (>4 months) their emissions, beyond which time it is difficult to distinguish between the emitted signal from variations in the ambient background atmosphere (Fraser et al. 2014a; Feng et al. 2017). Our a priori fluxes are described above. For simplicity we assume a fixed uncertainty of 40% for coefficients corresponding to the a priori CO₂ fluxes over each sub-region, and a larger uncertainty (60%) for the corresponding methane emissions. We also assume that a priori errors for the same gas are correlated with a spatial correlation length of 300 km and with a temporal correlation of one month.

As a sensitivity test, we also report methane fluxes inferred using the same EnKF approach but using the proxy GOSAT XCH₄ data. These GOSAT XCH₄ retrievals are calculated from the XCH₄/XCO₂ ratio by applying an ensemble mean of model XCO₂, and then bias-corrected according to comparison with TCCON XCH₄ retrievals (R. J. Parker et al. 2020).
2.5 Correlative data

To help interpret the changes in methane emission estimates we use additional datasets that are relevant to microbial or pyrogenic production of methane. We use monthly surface temperature fields at a spatial resolution of 2°x2.5° from the Modern-Era Retrospective Analysis for Research and Applications, version 2 (MERRA2) developed by the Global Modeling and Assimilation Office, NASA Goddard Space Flight Center (Bosilovich et al., 2015). Precipitation data are taken from the NOAA CMAP (CPC Merged Analysis of Precipitation) long-term global rainfall dataset (Xie and Arkin 1997) that provides near-global monthly coverage at a spatial resolution of 2.5° × 2.5°, from 1979 to near-present. In addition, we use monthly total water storage (liquid water equivalent depth, LWE) on a 1° × 1° global grid from the NASA/DLR Gravity Recovery and Climate Experiment Follow-on (GRACE-FO) (Landerer et al. 2020). Finally, we explore monthly biomass burning emissions from the Global Fire Emissions Database (GFED v4) (van der Werf et al. 2017).

2 Results

Table 1 summarizes our global emission estimates inferred from GOSAT for 2020 and 2021; and for 2019, which we use as our baseline year throughout this study (Figure A2). The largest change in our global \textit{a posteriori} emissions occurs during 2019—2020 (27 Tg) from 583.7 to 610.7 Tg/yr. Our \textit{a posteriori} emission estimates for 2019 and 2020 are within 2% of values reported by an independent study (Qu et al, \textit{Attribution of the 2020 surge in atmospheric methane by inverse analysis of GOSAT observations}, submitted to ERL, 2022, available from their group website https://acmg.seas.harvard.edu/publications-acmg; hereinafter denoted as Qu et al, 2022), consistent with our reported uncertainties. These elevated emissions are sustained, but not further increased, during 2021 (609.5 Tg/yr).

The 27 Tg emission increase in 2020 and the lack of further emissions growth in 2021 may appear inconsistent with the NOAA global annual mean growth rates of 15.3 and 16.9 ppb in 2020 and 2021, respectively (Table 1). Based on these reported atmospheric growth rates, and after considering the effects of methane sinks, we find that a one-box model calculation predicts an increase in emissions of 12.6 Tg between 2019 and 2020 and a further 15.1 Tg increase in 2021 (see Appendix B and Figure B1). These calculations use annual mean values that effectively represent the emissions increase between the middle of each successive year rather than the beginning and end. After considering the increases in monthly mean NOAA data, we find that the simple box model predicts a similar increase in emissions between December 2019 (583 Tg yr\(^{-1}\)) and December 2020 (610 Tg yr\(^{-1}\)) of 27 Tg yr\(^{-1}\), with emissions thereafter stabilizing, with mean emissions of 610 Tg yr\(^{-1}\) in 2021. As such, we conclude that the global mean emission results inferred from GOSAT are consistent with those inferred from NOAA surface data, assuming a fixed methane atmospheric lifetime.

Figure 1 shows the broad geographical breakdown for our reported global changes in methane emissions. Relative to 2019, we find widespread increased emissions during 2020 except for China and India. Relative to baseline values in 2019 we see the
largest annual increases in methane emissions during 2020 over Eastern Africa (13 Tg), tropical Asia (4 Tg), tropical South America (3 Tg), and temperate Eurasia (3 Tg), and the largest reductions over China (-6 Tg) and India (-2 Tg). Emission changes relative to 2019 are comparable in 2021, except for tropical and temperate South America increases to 9 Tg and 5 Tg, respectively, and tropical Asia increases to 8 Tg. The elevated contributions we saw in 2020 over the western half of Africa (-5 Tg) and Europe (-3 Tg) are substantially reduced in 2021, compared to our 2019 baseline.

Figure 2 shows the distribution of methane emissions from 2020 and 2021 and the relative changes from 2019 (Figure A1). During 2020, there are significant decreases (20-30%) over the manufacturing regions such as eastern China, India, central America, and eastern Europe. There are also significant increases across eastern Africa (30-40%), eastern North America (30%), and maritime Southeast Asia (30%). During 2021, we see similar changes in emissions, but they are typically exaggerated. There is more of a pronounced increase over East Africa (>50%), southern Brazil (50%), and eastern North America (up to 40%), and large decreases over eastern China (-50%) and western Russia (-50%). During 2021 there is also a large decrease over equatorial West Africa and eastern Europe (Figure 1). There are substantial seasonal changes in methane emissions (Figure A3) that are broadly consistent with seasonal changes in temperature and rainfall (not shown).

Figure 3 shows different annual surface temperature warming patterns in 2020 and 2021. During 2020 the high northern latitudes are dominated by summer warming over Siberia (2-3 K on an annual scale) that has been linked to greenhouse gas emissions (Ciavarella et al. 2021) and surface temperatures over Alaska were 2-3 K cooler than baseline values in 2019, where there were comparatively small changes in groundwater (< 5 cm). North America, western Europe and Scandinavia also experienced anomalously warm annual mean temperatures (typically within ±2 K of 2019 values). There were smaller changes in temperatures at low latitudes (typically ±1 K of 2019 values), but larger increases in groundwater (±10-20 cm) associated with higher changes in rainfall (Figure A4), particularly over East Africa and eastern Brazil. During 2021, high northern latitudes were cooler than 2019 (<2-3 K) except for the contiguous US and Canada (higher than 2019 values by 2-3 K). Midlatitudes and low latitudes generally did not experience the warm temperatures of 2020. Elevated groundwater was sustained in 2021 over East and Southern Africa, eastern tropical South America (principally Brazil but stretching up to Venezuela), central America, India, maritime Southeast Asia, and north and southeast Australia. Groundwater decreased over the contiguous US, part of tropical South America and parts of Eurasia. We find generally stronger annual and seasonal relationships between methane emission anomalies and hydrological anomalies (rainfall and groundwater) for 2020 and 2021 than for temperature anomalies. Particularly, we find statistically significant large-scale positive correlations (typically 0.5-0.6; p<0.001) for all seasons between methane and groundwater anomalies over Eastern Africa, tropical South America, and tropical Asia, but no significant correlation between methane and surface temperature anomalies. This is consistent with recent studies that have highlighted an increasing role for microbial sources in the tropical methane budget (Lunt et al. 2019; Feng et al. 2022; Wilson et al. 2020). Over North America, we find a significant negative correlation (from -0.3 to -0.5; p<0.001) with rainfall during MAM and JJA and a significant positive correlation with temperature during JJA (0.3; p < 0.001), which we do
not currently understand. Fire emissions did not increase much where we report the largest increases in methane emissions in 2020 or 2021, except over central Canadian provinces. (Figure A4).

To explore the robustness of our results, we explore two sensitivity runs. First, we ran our inversion for 2020 with OH concentrations decreased by 5% over regions with large anthropogenic emissions (as described in section 2.3), a conservative estimate for the value we expect based on widespread reductions in nitrogen oxide emissions due to shutting manufacturing and other industries during Covid-19 lockdowns (Laughner et al. 2021). A reduction in OH, assuming constant emissions, would lead to an increase in atmospheric methane. Ignoring that possibility would result in a positive bias for reported methane emissions estimates. We find that our imposed 5% decrease in OH concentrations results in an emission reduction of 6.0 Tg/yr, representing 22% of the emission increase, relative to 2019, in the control run. Figure 4 show that the largest impacts of reducing OH on a posteriori methane emissions are of the order of ±10% over regions where there are the largest decreases in nitrogen oxide emissions (Cooper et al. 2022), including China, India, Europe, North America. The regions where values are higher than the control are a consequence of mass balance. Our conservative 5% OH decrease cannot fully explain the increase in atmospheric methane, and consequently regions where OH were not decreased have had to compensate. The results for a smaller 1% decrease in OH have similar distributions but smaller changes (not shown). Second, we ran an experiment in which we used the methane columns determined by the proxy data, assuming model values for CO2 (R. J. Parker et al. 2020). Using these data, we find our results for 2020 and 2021 are within a few percent of the values we report using the proxy data directly (Figure A5). Both sensitivity experiments provide confidence in our emission estimates and that most of the atmospheric methane growth in 2020 was due to an increase in emissions.

3 Concluding Remarks

We reported regional emission estimates of methane during 2020 and 2021, two years with record-breaking atmospheric growth rates, inferred from satellite observations of methane from the Japanese Greenhouse gases Observing SATellite.

We find in both years that emissions from Eastern Africa, tropical Asia, and tropical South America dominate the global atmospheric growth rate, increasing by 11-13 Tg/yr, 4-8 Tg/yr, and 3-9 Tg relative to the 2019 baseline year, respectively. During 2020, we also find substantial increased emissions, relative to the 2019 baseline values, from Australia (3 Tg) and temperate Eurasia (3 Tg). Emission changes relative to 2019 are comparable in 2021, except for temperate South America that increases to 5 Tg and temperate North America that increases to 3 Tg. The elevated contributions we saw in 2020 over the western half of Africa (5 Tg) and Europe (3 Tg) are substantially reduced in 2021, compared to our 2019 baseline. We find statistically significant positive correlations between tropical methane emission and hydrological anomalies, consistent with recent studies that have highlighted a growing role for microbial sources over the tropics (Lunt et al. 2019; Feng et al. 2022;
Wilson et al. 2020). Our results are broadly consistent with a recent study of the 2020 period (Qu et al, 2022), including the magnitude of change associated with a change in OH, albeit concluded using an independent method.

Substantial, widespread reductions in nitrogen oxides during 2020 associated with the shutdown of manufacturing and other industries will have perturbed atmospheric concentrations of the OH loss of methane. A reduction in OH could also help explain, in principle, the record-breaking atmospheric increase in methane. Here we explore that issue by scaling back our prescribed OH fields by 5% over fossil fuel combustion regions to assess the impact of our reported increases in methane emissions. We find a 5% decrease in OH results in an a posteriori emission reduction of 6.0 Tg compared to our control run that does not consider a decrease in OH, equivalent to 22% of the emission increase in our control run for 2020. These changes are mainly focused over fossil fuel emitting regions, as expected. This result suggests that an increase in emissions was predominately responsible for the observed growth in atmospheric methane during 2020.

This study highlights the tremendous value of using satellite observations to understand rapid changes in atmospheric methane. They provide crucial information not only to identify regional column hotspots associated with emissions but also provide correlative information to help attribute those hotspots to specific anthropogenic or natural emissions.

Data availability. The University of Leicester GOSAT Proxy v9.0 XCH₄ data are available from the Centre for Environmental Data Analysis data repository at https://doi.org/10.5285/18ef8247f52a4eb64a140138235cc1eb. Precipitation, temperature, and the GRACE datasets are available at http://grace.jpl.nasa.gov. The community-led GEOS-Chem model of atmospheric chemistry and model is maintained centrally by Harvard University (http://geos-chem.seas.harvard.edu), and is available on request. The ensemble Kalman filter code is publicly available as PyOSSE (https://www.nceo.ac.uk/data-tools/atmospheric-tools/).

Author contributions. LF and PIP designed the research; LF and MFL prepared the calculations; RJP and HB provided the GOSAT data and expert advice on its usage; PIP wrote the paper, with comments from LF, RJP, MFL, and HB.

Competing interests. The contact author has declared that neither they nor their co-authors have any competing interests.

Appendix B: Description of box model calculation

To calculate global emissions of methane from the NOAA global mean data we use a simple one-box model. In this model, the change in global mean methane concentration over time is given by:

$$\frac{dB}{dt} = Q - kB$$

where B is the atmospheric mass of methane in Tg, k is the loss rate given as 1/lifetime and Q is the emissions rate. From this, after integration, the annual emissions rate can be calculated as:

$$Q_t = \frac{k(B_t - B_{t-1} e^{-k})}{k(1 - e^{-k})}$$

The loss rate was tuned to match a steady state concentration of 1775 ppb during 2000-2006 based on constant emissions of 530 Tg yr\(^{-1}\) during this period. We calculated the rolling 12-month annual emissions to track the progression of global emissions between 2019 and 2021. We used the difference between the atmospheric concentration in January 2019 and January 2020, February 2019 to February 2020, etc. to calculate the change in emissions in the intervening 12 months. Figure B1 shows the increase in emissions throughout 2020 followed by more variable month-to-month changes in 2021. The large increase in emissions primarily occurs in 2020, with emissions at the 12-month period ending in Dec 2020 being 27 Tg yr\(^{-1}\) larger than the emissions one year earlier. In contrast if emissions are calculated using annual mean concentrations, it appears as if there is a larger emission increase in 2021. The box model results show that the highly simplified calculation based on global average data is consistent with the more complex inverse modelling approach applied to the GOSAT data.
Figure B1 Global box model methane emission estimates between 2011 and 2021, respectively. Emission estimates are based on NOAA global mean surface data. The blue line denotes the rolling 12-month annual emissions, and the orange line denotes the emissions based on annual mean concentrations.

By how much?

3-1 Aug 5, 2022 at 3:00 PM, Reviewer
For both CO2 and CH4, or just CH4?

3-2 Jul 1, 2022 at 4:53 PM, Reviewer
Olsen and Randerson is a downscaling technique. What biospheric model did you use?

3-3 Aug 5, 2022 at 3:00 PM, Reviewer
A 5% reduction is not that conservative. The spatial pattern of OH reduction is quite important. Miyazaki et al, 2021 (Science Advances) shows that the global mean reduction in OH is about 4%. However, the reductions can be substantially higher, (>30%) locally. These will directly affect the methane inferences, especially over Europe and parts of Asia.

Please review the paper and perform a sensitivity analysis closer to reported spatial changes in OH.

3-4 Aug 5, 2022 at 3:00 PM, Reviewer
We could expect, however, that the CO2 emission in 2020 and 2021 to be different than 2019. Not sure how this really addresses the OH issue.

As noted next, the Miyazaki et al, 2021 provides a more observationally constrained pattern of OH.

3-5 Jul 1, 2022 at 4:53 PM, Reviewer
Is this a correlation in flux or concentration space? If it is the former, where did 300km come from?

4-1 Jul 1, 2022 at 4:53 PM, Reviewer
You should be able to calculate the simulated atmospheric CH4 growth rate for 2020 and 2021 from your inversion. You should add that to the table (1).

The box-model approach carries its own assumptions, and can't be really used to validate the CH4 top-down estimates.

4-2 Jul 1, 2022 at 4:53 PM, Reviewer
Based upon NOx emission changes during 2020-2021, we would not expect CH4 lifetime to be fixed.

5-1 Aug 5, 2022 at 3:00 PM, Reviewer
There are no uncertainty estimates in this calculation. I can not assess whether these changes are statistically significant or not.

Uncertainty estimates need to be added to these flux estimates. These could be done through comparison with other inversions or independent observations.

It looks like the increases in SA in 2021 are an acceleration of the 2020 increases. What is going on there?

How is anomalous defined here? The temperature variations need to be calculated relative to the long term temperature variability to assess whether they are not within climatology.

Please put plots of those regressions in the supplemental.
Cooper didn’t discuss NOx emissions, only concentrations. The impact on OH would need to be calculated separately and would be affected by other reactive species, e.g., ozone.

It’s hard to see the differences in a spatial plot. Please make a difference plot using the regions used in Fig. For 2020 and 2021 between the proxy retrieval and the simultaneous estimate.

The implication of East Africa as the single largest driver of the methane growth rate is puzzling. Yes, there is a correlation with water anomalies, but it’s not the largest driver of methane in driver. A more plausible set of physical mechanisms needs to be proposed for why we could expect this region as a dominant driver.

This is not clear to me at all that this is a valid assumption. The OH responses will depend on the regional NOx emission reductions and the timing of those reductions, in part because it will also affect ozone production. There are better sources for OH than this crude assumption.
