**Abstract:** Understanding aerosol particle activation is essential for evaluating aerosol indirect effects (AIEs) on climate. Long-term measurements ~~on~~ of aerosol particle activation help to understand the AIEs and narrow down the uncertainties of AIEs simulation; ~~. However~~, they are still scarce. In this study, more than 4-year aerosol comprehensive measurements were utilized at the central European research station Melpitz, Germany, to gain insight into the aerosol particle activation and provide recommendations on improving the prediction of number concentration of cloud condensation nuclei (CCN,  $N_{CCN}$ ). As supersaturation ( $SS$ ) increases from 0.1% to 0.7%, the median  $N_{CCN}$  increases from 399 to 2144  $\text{cm}^{-3}$ , which represents 10% to 48% of the total particle number concentration with a diameter range of 10 – 800 nm, while the median hygroscopicity factor ( $\kappa$ ) and critical diameter ( $D_c$ ) decrease from 0.27 to 0.19 and from 176 to 54 nm, respectively. Aerosol particle activation is highly variable across seasons, especially at low  $SS$  conditions. At  $SS = 0.1\%$ , the median  $N_{CCN}$  and

27 activation ratio (AR) in winter are 1.6 and 2.3 times higher than the summer values,  
28 respectively. Both  $\kappa$  and the mixing state are size dependent. As the particle diameter  
29 ( $D_p$ ) increases,  $\kappa$  increases at  $D_p$  of  $\sim 40$  to 100 nm and almost stays constant at  $D_p$  of  
30 100 to 200 nm, whereas the degree of the external mixture keeps decreasing at  $D_p$  of  
31  $\sim 40$  to 200 nm. The relationships of  $\kappa$  vs.  $D_p$  and degree of mixing vs.  $D_p$  were both  
32 fitted well by a power-law function. Size-resolved  $\kappa$  improves the  $N_{CCN}$  prediction. We  
33 recommend applying the  $\kappa - D_p$  power-law fit for  $N_{CCN}$  prediction at Melpitz, which  
34 performs better than using the constant  $\kappa$  of 0.3 and the  $\kappa$  derived from particle chemical  
35 compositions and much better than using the  $N_{CCN}$  (AR) vs.  $SS$  relationships. The  $\kappa -$   
36  $D_p$  power-law fit measured at Melpitz could be applied to predict  $N_{CCN}$  for other rural  
37 regions. For the purpose of improving the prediction of  $N_{CCN}$ , long-term monodisperse  
38 CCN measurements are still needed to obtain the  $\kappa - D_p$  relationships for different  
39 regions and their seasonal variations.~~The overall characteristics of aerosol particle~~  
40 ~~activation at Melpitz are first summarized. For supersaturation ( $SS$ ) levels of 0.1%,~~  
41 ~~0.2%, 0.3%, 0.5%, and 0.7%, the mean cloud condensation nuclei (CCN) number~~  
42 ~~concentration ( $N_{CCN}$ ) increases with the increase of  $SS$  from 513 to 2477  $\text{cm}^{-3}$ , which~~  
43 ~~represents 11% to 52% of the total particle number concentration with diameter ranging~~  
44 ~~from 10 to 800 nm, while the hygroscopicity factor ( $\kappa$ ) and the critical diameter ( $D_e$ )~~  
45 ~~decrease from  $0.28 \pm 0.08$  (mean value  $\pm$  one standard deviation) to  $0.20 \pm 0.09$  and~~  
46 ~~from  $177 \pm 19$  to  $54 \pm 8$  nm, respectively. Aerosol particle activation is highly variable~~  
47 ~~across seasons, especially at low  $SS$  conditions. At  $SS = 0.1\%$ , the seasonal mean  $N_{CCN}$~~   
48 ~~is  $681 \text{ cm}^{-3}$  in winter, which is almost twice higher than the summer value ( $347 \text{ cm}^{-3}$ );~~  
49 ~~the seasonal mean activation ratio (AR) in winter (0.18) is three times higher than the~~  
50 ~~summer one. Subsequently, size dependency of both  $\kappa$  and the state of mixing were~~

51 ~~investigated. As the particle diameter ( $D_p$ ) increases,  $\kappa$  increases at  $D_p$  of ~40 to 100 nm~~  
52 ~~and almost stays constant at  $D_p$  of 100 to 200 nm, whereas the degree of the external~~  
53 ~~mixture keeps decreasing at  $D_p$  of ~40 to 200 nm. The relationships of  $\kappa$  vs.  $D_p$  and~~  
54 ~~mixture degree vs.  $D_p$  were both fitted well by the power-law function for each season.~~  
55 ~~Finally, we recommend applying the  $\kappa$ - $D_p$  power-law fit for  $N_{CCN}$  prediction, which~~  
56 ~~can narrow down the median uncertainty within 10% for different  $SS$  conditions and~~  
57 ~~seasons at Melpitz; it also could be applied to predict  $N_{CCN}$  at other rural and continental~~  
58 ~~regions with a similar aerosol background. Additionally, the mean  $\kappa$  value over  $D_p$  of~~  
59 ~~100 to 200 nm also works well on the  $N_{CCN}$  prediction when  $SS$  is less than 0.2%.~~

## 60 **1. Introduction**

61 The specific subset of aerosol particles that serves as nuclei for the condensation  
62 of water vapor, forming cloud droplets at a given supersaturation ( $SS$ ) condition, is  
63 known as cloud condensation nuclei (CCN). Aerosol particle activation affects the  
64 aerosol and cloud interactions (ACI), thereby changing the cloud microstructure (Zhao  
65 et al., 2012; Jia et al., 2019; Wang et al., 2019), precipitation (Khain, 2009; Wang et al.,  
66 2011; Fan et al., 2012, 2018), radiation (Twomey, 1974, 1977; Albrecht, 1989; Zhao  
67 and Garrett, 2015), and by these effects the global climate (Ramanathan et al., 2001;  
68 Rosenfeld et al., 2019). The latest sixth assessment report from IPCC (2021) pointed  
69 out that aerosol indirect effects (AIEs) remain the most considerable uncertainty in  
70 assessing the anthropogenic contribution to present and future climate change.

71 The ambient  $SS$  and aerosol activation ability are both important for predicting the  
72 number concentration of activated-cloud droplets. The classical Köhler theory (Köhler,  
73 1936), combining the Raoult law with the Kelvin effect, illustrates that the aerosol  
74 particle activation depends on particle size, chemical composition and the given  $SS$ .

75 Petters and Kreidenweis (2007) parameterized the Raoult term with a single

76 hygroscopicity factor  $\kappa$  to capture the water activity without needing to know anything  
77 about the dissolved compounds. ~~Petters and Kreidenweis (2007) utilized a single~~  
78 ~~hygroscopicity factor  $\kappa$  to describe the CCN activity at each particle diameter ( $D_p$ ),~~  
79 ~~which facilitates studying the activation process without considering the complex~~  
80 ~~chemical compositions of aerosol particles (McFiggans et al., 2006).~~ — Different  
81 perspectives have been presented on the influence of particle size and composition on  
82 the CCN activation. In terms of a single aerosol particle, the actual particle size plays a  
83 more important role than the chemical composition for activation because of the  
84 different range in which  $\kappa$  and particle diameter ( $D_p$ ) vary and the reciprocal relationship  
85 between  $\kappa$  and the third power of the critical  $D_p$  ( $D_c^3$ ) $D_p^3$  at a given  $SS$ . As for a  
86 population of aerosol particles, Dusek et al. (2006) concluded that particle number size  
87 distribution (PNSD) matters more than the chemical composition distribution, which  
88 has been supported by many experiments. Even sometimes, assuming a constant  $\kappa$  still  
89 predicted CCN number concentration ( $N_{CCN}$ ) well (e.g., Sihto et al., 2011; Wang et al.,  
90 2018a). Andreae and Rosenfeld (2008) reviewed the previous studies on aerosol particle  
91 activation and recommended that for modeling purposes, the global  $\kappa$  values of  $0.3 \pm 0.1$   
92 and  $0.7 \pm 0.2$  can be representative for continental and marine aerosol, respectively,  
93 which has been widely used to predict  $N_{CCN}$ . The regional variability should be  
94 underlined-emphasized because the mean  $\kappa$  measured in urban, rural, and forest exhibits  
95 significant differences. For instance, Sihto et al. (2011) suggested an average  $\kappa$  of 0.18  
96 to predict the CCN activation well in boreal forest conditions in Hyytiälä, Finland; a  
97 A fixed  $\kappa$  of 0.31 suffices to calculate the  $N_{CCN}$  in a suburban site located in the center  
98 of the North China Plain (Wang et al., 2018a); the The mean  $\kappa$  is 0.5 in a near-coast  
99 background station (CESAR Tower) in Netherlands (Schmale et al., 2018); the The  
100 median  $\kappa$  ranges from 0.02 to 0.16 at  $SS = 0.1$ – $1.0\%$  in an urban background site in

101 Budapest, Hungary (Salma et al., 2021). Therefore, the assumption of a constant  $\kappa =$   
102 0.3 may not be appropriate when trying to predict  $N_{CCN}$  for different continental regions.

103 Additionally, some experiments, especially conducted on more diverse particulate  
104 sources, have indicated chemistry does play an important role in  $N_{CCN}$  variability (e.g.,  
105 Nenes et al., 2002; Petters and Kreidenweis, 2007; Rose et al., 2010). Not only the bulk  
106 chemical composition with a constant  $\kappa$  should be considered for  $N_{CCN}$  prediction, but  
107 the size-resolved chemical composition (Deng et al., 2011; Wu et al., 2016) and the  
108 mixing state should be applied (Su et al., 2010; Zhang et al., 2014). Information on the  
109 organic aerosol fraction improves  $N_{CCN}$  prediction considerably (Poulain et al., 2010;  
110 Zhang et al., 2016; Kuang et al., 2020). Freshly formed particles are about 1 nm in  
111 diameter (Kulmala et al., 2012); ~~they, which~~ must grow to tens of nanometers in  
112 diameter to serve as the effective CCN at a relatively high  $SS$  of  $\sim 1\%$  (Dusek et al.,  
113 2006) and even larger than 200 nm to be efficient at  $SS$  less than 0.1% (Deng et al.,  
114 2013). Aerosol chemical composition changes during the growing and aging processes.  
115 For instance,  $\kappa$  increases with particle size caused by photochemical processes which  
116 enhancing secondary inorganic species formation and going along with an increase in  
117 particle size (Massling et al., 2009; Zhang et al., 2017; Wang et al., 2018b). On the other  
118 hand, in sulfate dominated new particle formation (NPF) events with subsequent  
119 particle growth by condensation of organic vapors, the  $\kappa$  of small particles may exceed  
120 the  $\kappa$  of the larger ones (Wang et al., 2018a). If the  $\kappa$  of organic aerosol increases from  
121 0.05 to 0.15, the global average aerosol radiative forcing would decrease by  $\sim 1 \text{ W m}^{-2}$ ,  
122 which is in the same order of magnitude as the overall climate forcing of anthropogenic  
123 aerosol during the industrialization period (Rastak et al., 2017).

124 To obtain the regional parameters of aerosol particle activation, extensive field  
125 campaigns have been conducted worldwide. Besides the significant difference in spatial,

126 also the temporal variations of aerosol activation characteristics are essential for  $N_{CCN}$   
127 prediction (Andreae and Rosenfeld, 2008). Most of the observations lasted 1–2 months  
128 or even less; ~~–, they~~ mainly ~~foeused~~ focusing on the effects of short-term weather  
129 processes or pollution events on aerosol particle activation, such as the effects of the  
130 summer monsoon (Jayachandran et al., 2020), wet removal (Croft et al., 2009), NPF  
131 events (Dusek et al., 2010; Wu et al., 2015), biomass burning (Rose et al., 2010), and  
132 aerosol particle aging as well as oxidation processes (Zhang et al., 2016, 2017). The  
133 long-term CCN measurements (of at least one full year) are still rarely reported,  
134 resulting in insufficient knowledge concerning the seasonal and annual cycles of  
135 aerosol particle activation, which are also critical for model predictions and evaluations.  
136 Burkart et al. (2011) reported the particle activation in the urban background aerosol of  
137 Vienna, Austria, based on 11-month aerosol and CCN concentration measurements.  
138 Paramonov et al. (2015) reported a synthesis of CCN measurements within the  
139 EUCAARI network using the long-term data collected at 14 locations. Pöhlker et al.  
140 (2016) presented the climatology of CCN properties of a remote central Amazonian rain  
141 forest site using 1-year measurements. Che et al. (2017) provided the aerosol-activation  
142 properties in the Yangtze River Delta, China, based on ~1-year measurements. Using  
143 the long-term (of most > 1 year) aerosol and CCN concentration measurements from  
144 12 sites, Schmale et al. (2018) presented the spatial differences in aerosol particle  
145 activation for various regional backgrounds. However, systematic studies focusing on  
146 the seasonal cycle of size-resolved particle activation and respective CCN predictions  
147 are still scarce in the central European continent. Such a study would be of great help  
148 for understanding ACI and narrowing down the regional uncertainties in climate  
149 predictions.

150 In this investigation, more than 4-year comprehensive measurements of aerosol  
151 physical, chemical, and activation properties collected at the ACTRIS (Aerosol, Clouds  
152 and Trace Gases Research Infrastructure, <http://www.actris.eu/>) site Melpitz, Germany,  
153 are utilized. The major objective is to gain insight into the aerosol particle activation  
154 and provide recommendations on methods for  $N_{CCN}$  predictions. We present therefore  
155 the long-term observations and seasonal cycles of various particle activation variables  
156 such as ~~CCN number size distribution~~,  $N_{CCN}$ , activation ratio, critical diameter, size-  
157 resolved  $\kappa$  and mixing state ~~degree~~. Furthermore, we evaluated the accuracy of  $N_{CCN}$   
158 calculated from five different activation schemes and finally provide recommendations  
159 ~~to use a power-law based parameterization for the dependence of  $\kappa$  on particles diameter~~  
160 ~~for long-term~~  $N_{CCN}$  prediction at Melpitz and for other rural regions ~~with a similar~~  
161 ~~aerosol background condition~~.

## 162 **2. Methodology**

### 163 **2.1 Experiment details**

164 Atmospheric aerosol measurements were conducted at the Melpitz observatory  
165 (51.54°N, 12.93°E, 86 m above sea level), 50 km to the northeast of Leipzig, Germany.  
166 The aerosol particles observed at Melpitz can be regarded as representative for the  
167 central European rural background conditions (Birmili et al., 2009). The surroundings  
168 of the site are mostly pastures and forests without significant sources of anthropogenic  
169 emissions. More detailed descriptions of the Melpitz site can be found ~~in~~, for example,  
170 in Poulain et al. (2020).

171 This study focuses on the physicochemical properties and the activation ability of  
172 aerosol particles using the data collected at Melpitz from August 2012 to October 2016.  
173 Figure 1 ~~demonstrates shows~~ the experimental setup. All instruments were in the same  
174 container laboratory and utilized the same air inlet. Ambient aerosol particles were first

175 pretreated through a PM<sub>10</sub> Anderson inlet and an automatic aerosol diffusion dryer kept  
176 the relative humidity in sampling lines at a relative humidity less than 40% (~~Tueh et al.,~~  
177 ~~2009~~) following the ACTRIS recommendations. Subsequently, the aerosol flow was  
178 divided into the different instruments using an isokinetic splitter. Particle number size  
179 distributions (PNSD) were measured using a Dual-mobility particle size spectrometer  
180 (D-MPSS, TROPOS-type; Birmili et al., 1999; Wiedensohler et al., 2012) ~~with in the a~~  
181 diameter ~~ranging range from of~~ 5 ~~to~~ 800 nm. An aerosol chemical ~~speciationspecies~~  
182 monitor (ACSM, Aerodyne Inc; Ng et al., 2011) was used to measure the chemical  
183 compositions of ~~the near-PM<sub>1</sub>~~ non-refractory submicron aerosol ~~particulate~~  
184 ~~matterparticles~~ (nitrate, sulfate, chloride, ammonium, and organics). A multi-angle  
185 absorption photometer (MAAP, model 5012, Thermo Scientific; Petzold and  
186 Schönlinner, 2004) was used to measure the particle light absorption coefficients and  
187 to estimate the equivalent black carbon (eBC) mass concentration. For simultaneous  
188 measurement of particle and CCN number size distributions, dried aerosol particles  
189 were passed through the bipolar charger to establish charge equilibrium (Wiedensohler,  
190 1988) and then through a differential mobility analyzer (DMA) for selecting a  
191 monodisperse particle fraction; ~~after~~ After the DMA, the flow was ~~divided into two~~  
192 ~~parts, respectively~~ split to passed through a condensation particle counter (CPC, model  
193 3010, TSI) to measure the total number concentration of the selected monodisperse  
194 condensation nuclei ( $N_{CN}$ ) and through a cloud condensation nuclei counter (CCNC,  
195 model 100, Droplet Measurement Technologies; Roberts and Nenes, 2005) to measure  
196 the  $N_{CCN}$ . Thus, the size dependent activated fraction (AF,  $N_{CCN}/N_{CN}$ ) curve, i.e., the AF  
197 at a certain diameter ( $D_p$ ) of dry particles, could be obtained. The losses in both  
198 instruments were checked and it was corrected for in the inversion routine. The coupling  
199 between size selection and CCNC was programmed in a way that the size resolved

200 measurements started only after the temperature and thereby the SS of the CCNC was  
201 stabilized. As the diameter scan started after SS stabilization, the measurement itself  
202 was the same length at all SS conditions. At fully stabilized CCNC conditions we did  
203 one  $D_p$  scan at per SS setting. A total of five different SS conditions was set in the CCNC  
204 instrument (0.1%, 0.2%, 0.3%, 0.5%, and 0.7%). A complete SS cycle lasted ~2.5 hours-  
205 and the slight variations in the 2.5h total SS cycle was only due to the waiting time until  
206 the temperature of the CCNC was stabilized.

207 All the instrumentation was frequently calibrated within the framework of the  
208 European Center for Aerosol Calibration (ECAC, <https://www.actris-ecac.eu/>). The  
209 ACSM was regularly calibrated according to the manufacturer's recommendations with  
210 350 nm monodispersed ammonium nitrate and ammonium sulfate particles (Freney et  
211 al., 2019). The D-MPSS was calibrated following the recommendations in  
212 Wiedensohler et al. (2018). Throughout the campaign, the CCNC was ~~regularly~~  
213 calibrated once a year following the procedures outlined in Rose et al. (2008) with using  
214 the E-AIM model (Clegg et al. 1998). The measurement uncertainties of these  
215 instruments should be noted. The uncertainty in the MAAP is within 10% (Müller et al.,  
216 2011), and those in the D-MPSS and CCNC are both on the order of 10% (Wiedensohler  
217 et al., 2018; Rose et al., 2008). For the SS setting in CCNC, Gysel and Stratmann (2013)  
218 pointed out that an achievable accuracy in SS is 10 % (relative) at  $SS > 0.2\%$ , and less  
219 than 0.02 % (absolute) at the lower SS. For the ACSM data, the uncertainty in  
220 determining the total non-refractory mass is 9% ~~W~~ while for the individual chemical  
221 components, the uncertainty is 15% for nitrate, 28% for sulfate, 36% for ammonium,  
222 and 19% for organic matter (Crenn et al., 2015).

223 Due to instrument failures and maintenance operations, missing measurements  
224 occurred during the campaign. Effective data coverage is shown in Figure S1 in

225 ~~Supporting Information (SI) in Figure 2.~~ Overall, the CCNC, D-MPSS, and ACSM-  
226 MAAP captured 45578 AF curves, 103052 PNSDs, and 26876-hour aerosol chemical  
227 measurements, which covered 63%, 92%, and 77% of the campaign time, respectively.  
228 For 42% of the time all these instruments were measuring together.

## 229 2.2 Methods

230 Each AF curve ( $N_{CCN}/N_{CN}$  vs.  $D_p$ ) was first~~ly~~ corrected for multiply charged  
231 particles. Multiply (mostly doubly) charged particles appear in the AF curve as a plateau  
232 or shoulder at small diameters because they have the same electrical mobility diameter  
233 as singly charged smaller particles ~~;~~ ~~thus, they are falsely selected in the DMA~~ (Rose et  
234 al., 2008; Henning et al., 2014). To correct for this, the fraction of multiple charged  
235 particles as determined from the D-MPSS measurements was subtracted from each  
236 value of  $N_{CCN}/N_{CN}$  in AF. ~~For this was corrected by subtracting the multiply charged~~  
237 ~~particle fraction as determined from the D-MPSS measurements from each value of~~  
238  ~~$N_{CCN}/N_{CN}$  in AF.~~ The PNSD from the D-MPSS measurements (5 to 800 nm) are needed  
239 as the DMA-CCNC size range does not cover the large particle fraction, which is  
240 essential for the correction. Subsequently, we obtained the corrected AF curves.

241 Each corrected AF curve was fitted with a sigmoid function,

$$AF = a + b / \left( 1 + \exp \left( - \frac{D_p - D_c}{\sigma_s} \right) \right) \quad (1)$$

242 where  $a$  is the offset from 0 in the y direction and  $b$  is the height of the upper plateau of  
243 the sigmoidal function,  $D_c$  is the critical diameter, and  $\sigma_s$  is a measure for the width of  
244 the sigmoid function. ~~where  $a$  and  $b$  are the lower and upper limits for calculating critical~~  
245 ~~diameters ( $D_c$ ) at the set nominal SS, and  $\sigma_s$  is a measure for the width of the sigmoid~~  
246 ~~function.~~ This AF fit was multiplied with the PNSD to gain the CCN number size  
247 distribution and by integrating the total number of CCN, i.e.,  $N_{CCN}$ .

248 The critical diameter ( $D_c$ ) of dry particles,  $\kappa$ , and mixing state at each *SS* condition  
249 can be derived from the AF fit results. Affected by aerosol mixing, the AF rises  
250 gradually from 0 to the max ( $\sim 1$ ) rather than displaying an intermittent mutation.  $D_c$  is  
251 defined as the diameter of the dry particles from which 50% of the particles are activated  
252 at the given *SS*.

253 The shape of the AF curve, i.e., the relative width of the AF, represents the degree  
254 of external mixture, which can be quantified by the ratio of  $(D_{75} - D_{25})/D_c$  (Jurányi et  
255 al., 2013).  $D_{75}$  and  $D_{25}$  are the diameters at which 75% and 25% of the particles are  
256 activated at the given *SS*. Internal mixture implies that all particles with any given  
257 equal dry size have equal  $\kappa$  with  $(D_{75} - D_{25})/D_c = 0$ , whereas a distribution of different  
258  $\kappa$  at a given particle size can be observed for externally mixed aerosol with higher  $(D_{75}$   
259  $- D_{25})/D_c$  values. Note that the particle composition varying at different sizes is not  
260 defined as external mixing in this study. Jurányi et al. (2013) confirmed the reliability  
261 of this approach by comparing the  $\kappa$  distributions derived from parallel monodisperse  
262 CCN measurements and HTDMA measurements.

263 According to the derivation of  $\kappa$ -Köhler theory (Petters and Kreidenweis, 2007),  
264 the  $\kappa$  can be calculated from  $D_c$  at a given *SS*:

$$\kappa = \frac{4A^3}{27D_c^3 \ln^2(1 + SS/100)} \quad (2a)$$

265 with

$$A = \frac{4\sigma_{s/a}M_w}{RT\rho_w} \quad (2b)$$

266 where  $\sigma_{s/a}$  is the droplet surface tension (assumed to be that of pure water,  $0.0728 \text{ Nm}^{-2}$ ),  
267  $M_w$  the molecular weight of water,  $R$  the universal gas constant,  $T$  the absolute  
268 temperature,  $\rho_w$  the density of water, and  $A$  can be considered a function of  $T$ . Thus, the

269 size-resolved  $\kappa$  (pair of  $\kappa$  and  $D_c$ ) can be obtained at each SS cycle. Our monodisperse  
270 CCN measurements provide the size-resolved  $\kappa$  within  $D_p$  ( $D_c$ ) of  $\sim 40$ – $200$  nm, which  
271 depends largely on the SS setting of 0.1% to 0.7%. Note that equation 2a is an  
272 approximation of  $\kappa$ -Köhler equation and when  $\kappa$  is less than 0.2, it causes a slight bias  
273 in calculating  $\kappa$  (Petters and Kreidenweis, 2007). Additionally, the debate about the  
274 importance of  $\sigma_{s/a}$  changes and the connected bulk/surface partitioning on activation of  
275 aerosols is on ongoing (e.g., Ovadnevaite et al., 2017; Vepsäläinen et al., 2022), which  
276 is not focused on in this study.

277 Besides deriving it from the monodisperse CCN measurements,  $\kappa$  can be  
278 ~~determined-derived~~ from the ACSM and MAAP chemical composition measurements  
279 ( $\kappa_{chem}$ ) using the Zdanovskii–Stokes–Robinson (ZSR) mixing rule (Zdanovskii, 1948;  
280 Stokes and Robinson, 1966) combined with  $\kappa$ -Köhler theory:

$$\kappa_{chem} = \sum_i \varepsilon_i \kappa_i \quad (3)$$

281 where  $\kappa_i$  and  $\varepsilon_i$  mean the  $\kappa$  and volume fraction for each component, respectively, and  
282  $i$  is the number of the component in the mixture. The  $\varepsilon_i$  was derived from its measured  
283 component  $i$  mass concentration and density ( $\rho_i$ ). A simple ion-pairing scheme (Gysel  
284 et al., 2007) was used in this study with the  $\kappa_i$  and  $\rho_i$  values listed in Table 1 (Wu et al.,  
285 2015). ~~Note that a~~  $\kappa$  of 0.1 is used for particulate organics (Dusek et al., 2010; Gunthe  
286 et al., 2009, 2011); ~~F~~ for black carbon, we use a  $\kappa$  of 0 (Rose et al., 2011; Schmale et  
287 al., 2018).

288 The CCN number size distribution is a part of the particle number size distribution  
289 (PNSD), which approximately corresponds to the part of PNSD with  $D_p > D_c$  when  
290 assuming particles to be internally mixed (Figure S2 in SI). The assumption of the  
291 internal mixing could be reasonable because the median values of the parameter  $b$  and

292  $(D_{75} - D_{25})/D_c$  are 1.0 and 0.18. Thus,  $D_c$  plays a critical role on diagnosing  $N_{CCN}$  in  
293 models, which can be derived from  $\kappa$  parameterization at a given  $SS$ . When  $\kappa$  is obtained,  
294  $D_c(\kappa, SS)$  is calculated from equation 2a. When  $\kappa$  is given, we can predict the  $N_{CCN}$  at  
295 each  $SS$ . Thereto,  $D_c(\kappa, SS)$  is calculated from equation 2a. And, assuming an internal  
296 mixture, the predicted  $N_{CCN}$  is the integration of the PNSD from  $D_c$ , that is,

$$\text{Predicted } N_{CCN} = \int_{D_c}^{800} \text{PNSD}(D_p) dD_p \quad (4)$$

## 297 **3. Results**

### 298 **3.1 Aerosol activation characteristics**

299 As  $SS$  increases, the CCN number size distribution broadens towards smaller  
300 particle sizes (Figure S3 in SI), causing an increase in  $N_{CCN}$  and activation ratio (AR,  
301 i.e., ratio of  $N_{CCN}$  to total aerosol number concentration with a diameter range of 10 to  
302 800 nm,  $N_{aero}$ ). At Melpitz, the median  $N_{CCN}$  and AR increases from 399 to 2144  $\text{cm}^{-3}$   
303 and 0.10 to 0.48 when  $SS$  increases from 0.1% to 0.7%. As shown in Figure 2, the  $N_{CCN}$   
304 measured at Melpitz is slightly higher than that measured in more remote rural  
305 background stations, e.g., in Vavihill, Sweden (Fors et al., 2011), Hyytiälä, Finland  
306 (Paramonov et al., 2015), Southern Great Plains, USA (Liu and Li, 2014),  
307 Mahabaleshwar, India (Singla et al., 2017). However, compared to the  $N_{CCN}$  measured  
308 in polluted regions (e.g., Rose et al., 2010; Deng et al., 2011; Kim et al., 2014; Varghese  
309 et al., 2016), the Melpitz  $N_{CCN}$  is much lower.

310 Figure 3a presents the  $N_{CCN}$  vs.  $SS$  and AR vs.  $SS$  relationships at each season and  
311 all datasets at Melpitz. The two relationships are similar, and both can be fitted well  
312 with using a power-law function (Twomey, 1959). The fit was also performed with an  
313 error function (Pöhlker et al., 2018) and the fitted parameters are in the SI (Table S2).  
314 Over the whole period, the median values of the slope parameter and the coefficient in

315 the  $N_{CCN}$ - $SS$  power-law fit are  $2851 \text{ cm}^{-3}$  and 0.75, respectively, which are within the  
316 range of values for continental aerosol (slope parameter of  $600\text{--}3500 \text{ cm}^{-3}$  and  
317 coefficient of 0.4–0.9) reported in Seinfeld and Pandis (2016). The slope parameters in  
318 the power-law fitting represent the sensitivity of the  $N_{CCN}$  and AR to the variation in  $SS$ ,  
319 which are highest in summer and lowest in winter. The seasonal variations of  $N_{CCN}$  and  
320 AR at  $SS = 0.1\%$  and  $0.7\%$  are shown in Figure 3b. In summer, the median  $N_{CCN}$  and  
321 AR are both lowest at  $SS = 0.1\%$ , which contributed to the largest sensitivity of  $N_{CCN}$   
322 and AR to  $SS$ , i.e., the largest slope parameter in the power-law fitting among the four  
323 seasons. Additionally, the shape of the PNSD contributed to explain the sensitivity of  
324  $N_{CCN}$  and AR to  $SS$ . The PNSD in summer was steepest in the 40-200 nm size range  
325 among the four seasons (Figure S4 in SI). Thus, in summer, a small shift in  $D_c$  will  
326 change the  $N_{CCN}$  and AR much more than those in winter where the PNSD looks broader,  
327 causing the strong sensitivity of  $N_{CCN}$  and AR to  $SS$ .

328 To explain the seasonal variations in aerosol activation characteristics, we  
329 investigated the PNSD and chemical compositions as shown in Figure 4. In summer,  
330 affected by the frequent NPF events (Ma et al., 2015; Wang et al., 2017), the Aitken-  
331 mode particles with  $D_p < 100 \text{ nm}$  accounted for the largest portion of the PNSD (Figure  
332 S4 in SI), resulting in the highest  $N_{aero}$  and the smallest geometric mean diameter  
333 ( $GMD = \exp\left(\frac{\sum_i n_i \times \ln D_i}{N_{aero}}\right)$ ) among the four seasons. Additionally, in summer, there was  
334 the lowest bulk  $\kappa_{chem}$  with median value of 0.24 corresponding to the highest organic  
335 mass fraction (56% of total mass), which could be related to the strong formation of the  
336 secondary organic aerosol (SOA). Therefore, the  $N_{CCN}$  and AR both kept relatively low  
337 values in summer, especially at low  $SS$  conditions (e.g., at  $SS = 0.1\%$ ). On the contrary  
338 in winter, the relatively low number concentration of Aitken-mode particles caused the  
339 lowest  $N_{aero}$  and the largest  $GMD$  among the four seasons, which could be owing to the

340 rare NPF events. Meanwhile, in winter, low temperatures favored the particulate phase  
341 of nitrate (Poulain et al., 2011), causing the highest nitrate mass fraction (31% of total  
342 mass) among the four seasons, which might explain the highest  $\kappa_{chem}$  (median value of  
343 0.34). Taking all three together, the lowest  $N_{aero}$ , the largest  $GMD$ , as well as the highest  
344  $\kappa_{chem}$ , contribute to the highest AR value in winter at each  $SS$  condition. The  
345 relationships between  $\kappa_{chem}$  and each particle component, and the correlations among  
346 seasonal median values of  $N_{aero}$ ,  $GMD$ , and  $\kappa_{chem}$  are in SI (Text S1, Figures S5 and S6).

347 ~~Figure 3a presents the time series of the mean CCN number size distribution at~~  
348 ~~each  $SS$  condition. As  $SS$  increases, CCN number size distribution broadens towards~~  
349 ~~smaller particle sizes, causing an increase in  $N_{CCN}$  and activation ratio (AR, i.e., ratio~~  
350 ~~of  $N_{CCN}$  to total aerosol number concentration with diameter ranging from 10 to 800 nm,~~  
351  ~~$N_{aero}$ ). At Melpitz, the mean  $N_{CCN}$  is 513, 1102, 1466, 2020, and 2477  $cm^{-3}$  at  $SS$  of 0.1%,~~  
352 ~~0.2%, 0.3%, 0.5%, and 0.7%, respectively. The mean AR ranged from 0.11 to 0.52 at~~  
353  ~~$SS = 0.1\%$  to 0.7%. As shown in Table 2, the mean  $N_{CCN}$  measured at Melpitz is~~  
354 ~~generally higher than that measured in more remote rural background stations. For~~  
355 ~~instance, as  $SS$  increased from 0.1% to 1.0%, the mean  $N_{CCN}$  increased from 362 to 1795~~  
356  ~~$cm^{-3}$  in Vavihill, Sweden (Fors et al., 2011) and 274 to 1128  $cm^{-3}$  in Hyytiälä, Finland~~  
357 ~~(Paramonov et al., 2015); in Southern Great Plains, USA, the mean  $N_{CCN}$  at  $SS = 0.4\%$~~   
358 ~~was 1248  $cm^{-3}$  (Liu and Li, 2014); the mean  $N_{CCN}$  increased from 118 to 1826  $cm^{-3}$  as~~  
359  ~~$SS$  increased from 0.1% to 0.94% in Mahabaleshwar, India (Singla et al., 2017).~~  
360 ~~However, the mean  $N_{CCN}$  measured at Melpitz is far lower than that measured in~~  
361 ~~polluted regions. For example, in a rural site of Guangzhou, China, the mean  $N_{CCN}$~~   
362 ~~increased from 995 to 10731  $cm^{-3}$  as  $SS$  increased from 0.068% to 0.67% (Rose et al.,~~  
363 ~~2010); higher  $N_{CCN}$  was observed in Wuqing, China, with the mean  $N_{CCN}$  of 2192–12963~~  
364  ~~$cm^{-3}$  at  $SS = 0.056$ –0.7% (Deng et al., 2011); in an urban site of Seoul, Korea, the mean~~

365  $N_{CCN}$  increased from 4145 to 6067  $\text{cm}^{-3}$  as  $SS$  increased from 0.4% to 0.8% (Kim et al.,  
366 2014); in a polluted continental site of Mahabubnagar, India, the mean  $N_{CCN}$  at  $SS = 1.0\%$   
367 was  $\sim 5400 \text{ cm}^{-3}$  (Varghese et al., 2016).

368 At Melpitz, aerosol activation characteristics are highly variable across seasons.  
369 At  $SS = 0.1\%$ , CCN number size distribution is wider in spring and winter than in  
370 summer and autumn; the mean  $N_{CCN}$  at  $SS = 0.1\%$  is 585, 347, 440, and 681  $\text{cm}^{-3}$  in  
371 spring, summer, autumn, and winter, respectively. The mean  $N_{CCN}$  at  $SS = 0.1\%$  in  
372 winter is almost twice as high as that found in summer. The highest mean AR at  $SS =$   
373  $0.1\%$  was 0.18 observed in winter, whereas the lowest mean AR (0.06) was observed  
374 in summer. In spring and autumn, the mean AR at  $SS = 0.1\%$  is 0.1. As  $SS$  increases,  
375 CCN number size distribution gradually peaks in summer, especially at  $SS = 0.5\%$  and  
376  $0.7\%$ . At  $SS = 0.7\%$ , the mean  $N_{CCN}$  is 2622, 2530, 2222, and 2495  $\text{cm}^{-3}$ , and the mean  
377 AR is 0.49, 0.41, 0.51, and 0.68 in spring, summer, autumn, and winter, respectively.

378 The AR- $SS$  and  $N_{CCN}$ - $SS$  relationships in each season and all datasets are shown in  
379 Figures 3b and 3c. The two relationships are similar, and both can be fitted well with  
380 using the power law function (Twomey, 1959) and the error function (Pöhlker et al.,  
381 2018). The fit results are shown in Table 3. The error function fits the relationships  
382 better than the power law function because of more parameters. The power parameter  
383 in the power law function means the change rate of the controlled variable with the  
384 independent variable, that is the slope in a log-log coordinate system, so it is also called  
385 the slope parameter. In the power law fits of the two relationships, the slope parameters  
386 are highest in summer and lowest in winter. Therefore, AR and  $N_{CCN}$  are most sensitive  
387 to  $SS$  in summer, whereas the opposite is true in winter. The coefficients in the power-  
388 law fits represent the AR and  $N_{CCN}$  at  $SS = 1\%$ . The coefficient in AR- $SS$  fit is highest  
389 in winter (0.89) and lowest in summer (0.61). However, the coefficient in  $N_{CCN}$ - $SS$  fit

390 is highest in summer ( $3951 \text{ cm}^{-3}$ ) and lowest in autumn ( $3136 \text{ cm}^{-3}$ ). Over the whole  
391 period, the mean values of the slope parameter and the coefficient in the  $N_{CCN}$ - $SS$  power-  
392 law fit are  $3497 \text{ cm}^{-3}$  and 0.81, respectively, which are within the range of values for  
393 continental aerosol (slope parameter of  $600$ – $3500 \text{ cm}^{-3}$  and coefficient of 0.4–0.9)  
394 reported in Seinfeld and Pandis (2016).

395 CCN number size distribution is a part of the particle number size distribution  
396 (PNSD), which approximately corresponds to the part of PNSD with  $D_p > D_e$  when  
397 assuming particles to be internally mixed. The schematic diagram in Appendix A shows  
398 the relationship between the PNSD and the CCN number size distribution. Aerosol  
399 chemical composition determines the  $\kappa$  through equation 3, thereby changing  $D_e$  at a  
400 given  $SS$  condition through equation 2a. Thus, we present the time series of the PNSD  
401 and chemical compositions in Figure 4 to explain the variations in aerosol activation  
402 characteristics.

403 In summer, affected by the frequent NPF events (Ma et al., 2015; Wang et al.,  
404 2017), the Aitken-mode particles with  $D_p < 100 \text{ nm}$  account for the largest portion of  
405 the PNSD, resulting in the highest  $N_{aero}$  with a mean value of  $6224 \text{ cm}^{-3}$  and the smallest  
406 geometric mean diameter ( $GMD = \exp\left(\frac{\sum_i n_i \times \ln D_i}{N_{aero}}\right)$ ) with a mean value of 50 nm among  
407 the four seasons. On the contrary, in winter, the mean  $GMD$  increases to 58 nm, which  
408 is the largest among the four seasons, and the  $N_{aero}$  decreases to the lowest with a mean  
409 value of  $3686 \text{ cm}^{-3}$  because of the rare NPF events. During the NPF events, only a part  
410 of newly formed particles grows to sizes larger than  $D_e$  (e.g.,  $\sim 55 \text{ nm}$  at  $SS = 0.7\%$ ),  
411 whereas most of the new particles are still unactivated at  $SS \leq 0.5\%$ . Therefore, CCN  
412 number size distribution gradually peaks as  $SS$  increases in summer, whereas AR keeps  
413 a minimum even at relatively high  $SS$  conditions as shown in Figure 3a. In winter, the  
414 lowest  $N_{aero}$  and the largest  $GMD$  contribute to the highest AR at each  $SS$  condition.

415 Figure 4b shows the average changes of the aerosol particle chemical compositions  
416 over a year and the estimated bulk  $\kappa_{\text{chem}}$  of submicron aerosol particles. At Melpitz, the  
417 mean value of bulk  $\kappa_{\text{chem}}$  is 0.36 with one standard deviation of 0.09 over the whole  
418 period; the seasonal mean  $\kappa_{\text{chem}}$  plus/minus one standard deviation are  $0.38 \pm 0.09$ ,  
419  $0.29 \pm 0.08$ ,  $0.36 \pm 0.08$ , and  $0.40 \pm 0.08$  in spring, summer, autumn, and winter,  
420 respectively. Because the  $\kappa_{\text{chem}}$  depends on aerosol particle chemical composition  
421 through equation 3, we examined the correlation between  $\kappa_{\text{chem}}$  and the mass fraction  
422 of each component to explain the variations of  $\kappa_{\text{chem}}$ . As shown in Figures 5a and 5b, a  
423 negative correlation between the  $\kappa_{\text{chem}}$  and the organic mass fraction ( $f_{\text{org}}$ ) was observed,  
424 while an opposite trend was found for the nitrate ( $f_{\text{nitrate}}$ ). Additionally, the  $\kappa_{\text{chem}}$  is not  
425 correlated with the sulfate mass fraction ( $f_{\text{sulfate}}$ ) and the BC mass fraction ( $f_{\text{BC}}$ ), as  
426 shown in Figures 5c and 5d.

427 In summer, there is the lowest bulk  $\kappa_{\text{chem}}$  with  $0.29 \pm 0.08$  corresponding to the  
428 highest  $f_{\text{org}}$  (56% of total mass on average), which could be related to the strong  
429 formation of the secondary organic aerosol. In winter, low temperatures favor the  
430 particulate phase of nitrate (Poulain et al., 2011) with a mean  $f_{\text{nitrate}}$  of 31%, which might  
431 explain the highest  $\kappa_{\text{chem}}$  ( $0.40 \pm 0.08$ ). According to equation 2a,  $D_e$  increases as  
432  $\kappa$  decreases at a given  $SS$  condition. Thus, the lowest  $\kappa_{\text{chem}}$  results in the narrowest CCN  
433 number size distribution and a decrease in  $N_{\text{CCN}}$  in summer, especially at relatively low  
434  $SS$  conditions (e.g., 0.1% and 0.2%) as shown in Figure 3a.

### 435 3.2 Size-resolved particle hygroscopicity factor and mixing state

436 The hygroscopicity factor and the mixing state directly influence the  $D_e$  and the  
437 shape of the AF curve, thereby changing the  $N_{\text{CCN}}$  at a given  $SS$  condition. Affected by  
438 the variations of particle composition, These two parameters are not constant and both

439 vary with particle size and season.

440 Figure ~~6a-5a~~ presents monthly median values of  $\kappa_{\text{chem}}$  ~~monthly averages of and~~  
441  $\kappa$  calculated from monodisperse CCN measurements ( $\kappa_{\text{CCN}}$ ) at SS of 0.1% and 0.7%.  
442 ~~Their each SS condition, and their~~ seasonal mean-median values are summarized in  
443 Table 42. At Melpitz, the median  $\kappa_{\text{CCN}}$  decreased from 0.27 to 0.19 as SS increased from  
444 0.1% to 0.7%, which was less than the median bulk  $\kappa_{\text{chem}}$  of 0.3. The seasonal variation  
445 of  $\kappa_{\text{CCN}}$  at SS of 0.1% is similar to that of  $\kappa_{\text{chem}}$ , whereas the seasonal trend in  $\kappa_{\text{CCN}}$  is  
446 much weaker at SS = 0.7%. Essentially, the relationship between  $\kappa_{\text{CCN}}$  and SS is  
447 determined by the  $\kappa_{\text{CCN}}$  vs.  $D_p$  relationship. The  $\kappa_{\text{CCN}}$  at SS of 0.1% and 0.7%  
448 correspond to the median  $D_c$  (i.e.,  $D_p$ ) of 176 and 54 nm, respectively. As the ACSM is  
449 sensitive to particle mass rather than number concentration, the bulk composition is  
450 dominated by the contribution of the larger particles. In the median volume size  
451 distribution of particle, the peak diameter was at ~300 nm (Poulain et al., 2020). Thus,  
452  $\kappa_{\text{chem}}$  may be representative for the larger particles rather than for the smaller particles.  
453 Owing to the positive correlation between  $\kappa$  and  $D_p$  (Figure 6a), the  $\kappa_{\text{chem}}$  representing  
454 for the larger particles could be greater than the  $\kappa_{\text{CCN}}$  for the smaller particles. Figure  
455 5b depicts the monthly variation of  $D_c$  at SS of 0.1% and 0.7%, which shows the  
456 opposite trend to  $\kappa_{\text{CCN}}(\text{SS})$  because of the negative correlation of  $D_c^3(\text{SS})$  vs.  $\kappa(\text{SS})$   
457 shown in equation 2a. Compared to the  $D_c$  at lower SS conditions (e.g., 0.1%),  $D_c$  has a  
458 more significant seasonal trend at higher SS conditions (e.g., 0.7%). At SS = 0.7%, the  
459 low  $\kappa_{\text{CCN}}$  caused the large  $D_c$  in summer, whereas the high  $\kappa_{\text{CCN}}$  caused the small  $D_c$  in  
460 spring and winter.

461 ~~At Melpitz, the mean  $\kappa_{\text{CCN}}$  plus/minus one standard deviation over all datasets are~~  
462  ~~$0.28 \pm 0.08$ ,  $0.28 \pm 0.10$ ,  $0.24 \pm 0.10$ ,  $0.21 \pm 0.09$ , and  $0.20 \pm 0.09$  at SS = 0.1%, 0.2%,~~

463 0.3%, 0.5%, and 0.7%, respectively, where the mean  $\kappa_{CCN}$  were all less than the mean  
464 bulk  $\kappa_{chem}$  of 0.36. The seasonal variation of  $\kappa_{CCN}$  at each SS condition is similar to that  
465 of  $\kappa_{chem}$ . In summer,  $\kappa_{CCN}$  is lowest among the four seasons, with mean values of 0.23,  
466 0.25, 0.21, 0.19, and 0.19 at SS = 0.1%, 0.2%, 0.3%, 0.5%, and 0.7%, respectively. The  
467 highest  $\kappa_{CCN}$  at each SS condition was observed in winter, with mean values of 0.32,  
468 0.32, 0.28, 0.23, and 0.21 at SS = 0.1%, 0.2%, 0.3%, 0.5%, and 0.7%, respectively.  $\kappa_{CCN}$   
469 in spring are slightly lower than that in winter, with mean values of 0.31, 0.32, 0.27,  
470 0.22, and 0.21 at SS = 0.1%, 0.2%, 0.3%, 0.5%, and 0.7%, respectively. In autumn, the  
471 mean  $\kappa_{CCN}$  are 0.27, 0.26, 0.22, 0.19, and 0.19 at SS = 0.1%, 0.2%, 0.3%, 0.5%, and  
472 0.7%, respectively, which is slightly higher than that observed in summer.

473 Figure 6b presents the monthly variation of  $D_e$  at each SS condition, which shows  
474 the opposite trend to  $\kappa_{CCN}$  - SS because of the negative correlation of  $D_e^3$  vs.  $\kappa$  shown  
475 in equation 2a. The seasonal mean  $D_e$  are shown in Table 4. The mean  $D_e$  plus/minus  
476 one standard deviation over the whole period are  $177 \pm 19$ ,  $112 \pm 14$ ,  $91 \pm 15$ ,  $67 \pm 9$ , and  
477  $54 \pm 8$  nm at SS = 0.1%, 0.2%, 0.3%, 0.5%, and 0.7%, respectively. The largest  $D_e$  at  
478 each SS condition were observed in summer, with mean values of 187, 116, 94, 69, and  
479 55 nm at SS = 0.1%, 0.2%, 0.3%, 0.5%, and 0.7%, respectively. Followed by autumn  
480 and spring, the smallest  $D_e$  at each SS condition was observed in winter, with mean  
481 values of 168, 107, 86, 64, and 53 nm at SS = 0.1%, 0.2%, 0.3%, 0.5%, and 0.7%,  
482 respectively.

483 The monthly average trend of the external-mixing degree ( $(D_{75} - D_{25})/D_c$ ) is shown  
484 in Figure 6e5c. The degree of external mixture is quantified by the ratio of  $(D_{75} -$   
485  $D_{25})/D_c$ . The seasonal mean  $(D_{75} - D_{25})/D_c$  are presented in Table 4. Jurányi et al. (2013)  
486 pointed out that the  $(D_{75} - D_{25})/D_c$  ranged from 0.08 to 0.12 for ammonium sulfate  
487 calibration measurements at SS = 0.1–1.0%, which indicated an internal mixture within

488 measurement accuracy. For our measurements, the ~~median~~<sup>mean</sup>  $(D_{75} - D_{25})/D_c$  over all  
489 datasets range from ~~0.17-15~~ to ~~0.25-20~~ at  $SS = 0.1-0.7\%$ . ~~The median  $(D_{75} - D_{25})/D_c$~~   
490 ~~was low in summer and spring and high in winter and autumn. The results tend to~~  
491 ~~indicate that the aerosol particles at Melpitz were more internally mixed in summer and~~  
492 ~~spring whereas less internally mixed in winter and autumn.~~~~In summer,  $(D_{75} - D_{25})/D_c$~~   
493 ~~is lowest ranging from 0.14 to 0.18 at  $SS = 0.1-0.7\%$ , implying that aerosol particles~~  
494 ~~were extremely close to being internally mixed. Followed by spring and autumn, the~~  
495 ~~highest  $(D_{75} - D_{25})/D_c$  was observed in winter with values ranging from 0.24 to 0.36 at~~  
496  ~~$SS = 0.1-0.7\%$ . Therefore, the results tend to indicate that the aerosol particles were~~  
497 ~~less internally mixed in winter among the four seasons at Melpitz. In non-urban location~~  
498 ~~In summer, the less contribution from anthropogenic emissions and the faster aging~~  
499 ~~process as well as SOA formation caused by atmospheric chemistry certainly contribute~~  
500 ~~to make particles more internally mixed. Changes in organic aerosol (OA) composition~~  
501 ~~can be found in Crippa et al. (2014), Poulain et al. (2014), and Chen et al. (2022). In~~  
502 ~~cold seasons, the local pollution (100 km around) is dominated by liquid fuel, biomass,~~  
503 ~~and coal combustions mostly for house heating (van Pinxteren et al., 2016). During~~  
504 ~~winter long-range transport from the eastern wind bring to the station continental air~~  
505 ~~masses which are strongly influence by anthropogenic emissions (in opposition to~~  
506 ~~western marine air masses). These particles are a mixture of different anthropogenic~~  
507 ~~sources emitted all along the transport as well as including some local and regional~~  
508 ~~sources (most house heating). All of them at different aging state cause the overall~~  
509 ~~particles more externally mixed. s, initially externally mixed aerosol particles become~~  
510 ~~an internal mixture on a time scale of ~1 day (Fierce et al., 2016). In winter, the~~  
511 ~~relatively stable weather patterns increase the persistence of aerosol ( $> 5$  days) at~~  
512 ~~Melpitz (Schmale et al., 2018). When tracking an aerosol cluster, the prolonged mixing~~

513 ~~time should promote the aging process, leading to an internal mixture. However, we~~  
514 ~~observed a less internally mixed aerosol particle population in winter. A plausible~~  
515 ~~explanation is mixing in of local pollution.~~

516 As mentioned above,  $\kappa_{\text{CCN}}$  (and  $(D_{75} - D_{25})/D_c$ ) vs.  $D_p$  relationships determine the  
517 relationship between  $\kappa_{\text{CCN}}$  (and  $(D_{75} - D_{25})/D_c$ ) and SS. Monodisperse CCN  
518 measurements provide the size-resolved  $\kappa$  and  $(D_{75} - D_{25})/D_c$ . At a given SS condition,  
519  $\kappa_{\text{CCN}}$  represents the  $\kappa$  of particles at  $D_p = D_c$ , and the same is true for  $(D_{75} - D_{25})/D_c$ .  
520 ~~Essentially, the relationship between  $\kappa_{\text{CCN}}$  and SS is determined by the  $\kappa_{\text{CCN}}$  vs.  $D_p$~~   
521 ~~relationship. Identically, the relationship between  $(D_{75} - D_{25})/D_c$  and SS depends on the~~  
522  ~~$(D_{75} - D_{25})/D_c$  vs.  $D_p$  relationship. Monodisperse CCN measurements provide the size-~~  
523 ~~resolved  $\kappa$  and  $(D_{75} - D_{25})/D_c$ . At a given SS condition,  $\kappa_{\text{CCN}}$  represents the  $\kappa$  of particles~~  
524 ~~at  $D_p = D_c$ , and the same is true for  $(D_{75} - D_{25})/D_c$ . It should be noted that our~~  
525 ~~monodisperse CCN measurements only provide the size-resolved  $\kappa$  and  $(D_{75} - D_{25})/D_c$~~   
526 ~~within  $D_p$  of ~40–200 nm. As shown in Figure 7a6a,  $\kappa_{\text{CCN}}$  increases with  $D_p$  at  $D_p$  range~~  
527 ~~of ~40 to 100 nm, whereas  $\kappa_{\text{CCN}}$  almost stays constant at  $D_p$  of 100 to 200 nm for all~~  
528 ~~seasons. Additionally, the increase  $\kappa_{\text{CCN}}$  with  $D_p$  varies with season. The  $\kappa_{\text{CCN}}$  vs.  $D_p$~~   
529 ~~relationship is fitted by a power-law function at each season. ~~Fit results are presented~~~~  
530 ~~in Table 5. In summer, there is the lowest slope parameter ~~of 0.19~~ in the  $\kappa_{\text{CCN}}$  vs.  $D_p$~~   
531 ~~power-law fit, meaning that the  $\kappa_{\text{CCN}}$  is least sensitive to  $D_p$ . Compared to the cold~~  
532 ~~seasons, the anthropogenic emissions linked to house heating strongly reduce in~~  
533 ~~summer which affect the smaller particles, and the dominant small particles ( $D_p < 100$~~   
534 ~~nm) are associated to NPF and the SOA formation. NPF is a complex process which~~  
535 ~~depends on the availability of condensing material ( $\text{H}_2\text{SO}_4$  and organic), as well as pre-~~  
536 ~~existing particles (coagulation and condensation sink parameters). Therefore, same~~

537 condensing material on the gas phase can either condense on pre-existing particles  
538 (usually larger than 100 nm and then detected by ACSM) or lead to NPF formation. A  
539 direct consequence of it is a probable smaller effect of the size dependent chemical  
540 composition of the particles. This might explain why  $\kappa_{CCN}$  at SS of 0.1% and 0.7 % are  
541 closer, i.e., the weaker sensitive of  $\kappa_{CCN}$  to  $D_p$  in summer, meaning that the difference  
542 between the  $\kappa_{CCN}$  at different particle sizes is smallest among the four seasons. Followed  
543 by autumn with the slope parameter of 0.31, the slope parameter is highest in spring  
544 and winter of 0.36–0.37. Therefore, the  $\kappa_{CCN}$  is most sensitive to  $D_p$  in spring and winter.  
545 Figure 7b-6b presents the  $(D_{75} - D_{25})/D_c$  vs.  $D_p$  relationship. As particle size increases,  
546  $(D_{75} - D_{25})/D_c$  decreases at  $D_p$  of ~40 to 200 nm for all seasons, meaning that small  
547 particles are less internally mixed. The reason is that during the aerosol aging process,  
548 not only particle size increases but  $\kappa$  becomes more uniform. The  $(D_{75} - D_{25})/D_c$  vs.  $D_p$   
549 relationship is also fitted well by the a power-law function at each season, with fit  
550 results shown in Table 5. The lowest absolute value of the slope parameter was observed  
551 in summer, indicating that the degree of external mixture was least sensitive to  $D_p$ ,  
552 which could be related to the less mixing between the local emissions and long-range  
553 transport particles in summer. The highest absolute value of the slope parameter was  
554 observed in autumn of 0.42, followed by winter of 0.30 and spring of 0.26, and the  
555 lowest was 0.20 observed in summer. Thus, the difference between the degree of  
556 external mixture at different particle sizes is largest in autumn, followed by winter and  
557 spring, and is smallest in summer.

### 558 **3.3 $N_{CCN}$ prediction at Melpitz**

559  $N_{CCN}$  plays an important role in modeling the formation and evolution of clouds  
560 (Zhao et al., 2012; Fan et al., 2012, 2018). In tThis section, we evaluates the accuracy  
561 of  $N_{CCN}$  predicted from five different schemes. Table 6-3 introduces the five schemes,

562 which can be summarized into two categories ~~of  $N_{CCN}$  prediction approach~~. From  
563 polydisperse CCN measurements, the  $N_{CCN}$  (AR) and SS relationships can be obtained,  
564 and their fitting results can be used to predict  $N_{CCN}$  at the given SS conditions, which  
565 belongs to the 1<sup>st</sup> category, corresponding to the N1 and N2 schemes in Table 3,  
566 respectively. ~~The fit results of  $N_{CCN}$ –SS relationship and AR–SS relationship can predict~~  
567  ~~$N_{CCN}$  at the given SS conditions, which belongs to the 1<sup>st</sup> category approach,~~  
568 ~~corresponding to the 1<sup>st</sup> and 2<sup>nd</sup> schemes in Table 6, respectively.~~ Compared to CCN  
569 measurements, it is generally more common and simpler to obtain the PNSD  
570 measurements; thus, we usually predict  $N_{CCN}$  using the real-time PNSD combined  
571 with the parameterized  $\kappa(D_c)$  CCN activity, which belongs to the 2<sup>nd</sup> category approach.  
572 The 2<sup>nd</sup> category includes the last three schemes (K1, K2, and K3) in Table 3, but they  
573 vary in assuming  $\kappa$ . ~~The last three schemes in Table 6 belong to the 2<sup>nd</sup> category~~  
574 ~~approach, but they vary in assuming  $\kappa$ .~~ The 3<sup>rd</sup> K1 scheme uses a fixed  $\kappa$  of 0.3 without  
575 temporal and size-dependent variations, as recommended for continental aerosol  
576 (Andreae and Rosenfeld., 2008), which is also the median value of  $\kappa_{chem}$  over all data  
577 setting at Melpitz. The 4<sup>th</sup> K2 scheme uses the bulk  $\kappa_{chem}$  calculated from aerosol  
578 chemical composition, which is also non-size-dependent but changes over time. The 5<sup>th</sup>  
579 K3 scheme uses the  $\kappa - D_p$  power-law fit results shown in Table 5 Figure 6a, which are  
580 size-dependent without temporal variations at each season. Applying the  $\kappa - D_p$  power-  
581 law equation into equation 2a,  $D_c$  can be derived as function of SS,

$$D_c = \left( \frac{4 \times A^3}{27 \times coef \times \ln^2(1 + SS/100)} \right)^{\frac{1}{slope+3}} \quad (5)$$

582 where the *slope* and *coef* represent the slope parameter and the coefficient in  $\kappa - D_p$   
583 power-law fit. Subsequently, the predicted  $N_{CCN}$  can be calculated through equation 4.  
584 The 2<sup>nd</sup> category last three schemes all assumed that aerosol particles are internally

585 mixed at a particular  $D_p$ , as used in many previous  $N_{CCN}$  prediction studies (e.g., Deng  
586 et al., 2013; Pöhlker et al., 2016; Wang et al., 2018a).

587 The prediction results are shown in Figure 87. The linear equation ( $y = kx$ ) is used  
588 to fit the relationship between the predicted  $N_{CCN}$  and the measured one, and its slope  
589 represents the mean ratio of the predicted  $N_{CCN}$  to the measured  $N_{CCN}$ . ~~To make the  
590 results of the predictions comparable for all regression schemes, we also applied a linear  
591 regression to the 1<sup>st</sup> scheme and forced the linear regression through zero for all  
592 schemes.~~ The relative deviation (RD) equals the ratio of the absolute difference between  
593 the predicted  $N_{CCN}$  and the measured one to the measured  $N_{CCN}$ ,

$$RD = \frac{|predicted\ N_{CCN} - measured\ N_{CCN}|}{measured\ N_{CCN}} \quad (6)$$

594 The median RD was used to quantify the deviation between predictions and  
595 measurements of each scheme. The slope and median RD shown in Figure 7 are both  
596 calculated from all five SS conditions for each season. As shown in Figure 7, the N1  
597 and N2 schemes only provide rough estimates of the  $N_{CCN}$  which is reflected in the high  
598 median RD. The results for N1 and N2 schemes are similar in that they both predict the  
599 overall mean  $N_{CCN}$  well (slopes of approximately 1.0) but with large median RDs.  
600 Compared to N1 scheme, the N2 scheme is better because of the lower median RD.  
601 Compared to the 1<sup>st</sup> category (the N1 and N2 schemes), the 2<sup>nd</sup> category (the K1, K2,  
602 and K3 schemes) predicts  $N_{CCN}$  better because of the lower median RD. The results for  
603 K1 and K2 are similar in that they both overestimate  $N_{CCN}$  by approximately 10%  
604 (slopes of approximately 1.1) with similar median RDs. The reason for the  $N_{CCN}$   
605 overestimation is that the constant  $\kappa$  of 0.3 and the real-time bulk  $\kappa_{chem}$  are both greater  
606 than the  $\kappa_{CCN}$  at each season. In winter, the  $\kappa_{CCN}$  was highest and the difference between  
607 the  $\kappa_{CCN}$  and the parameterized  $\kappa$  in K1 and K2 scheme was lowest, causing the best

608 prediction of  $N_{CCN}$  among the four seasons. Owing to the largest difference between the  
609  $\kappa_{CCN}$  and the parameterized  $\kappa$ , the  $N_{CCN}$  prediction was worst in summer for K1 scheme  
610 and in autumn for K2 scheme. The K3 scheme appears to be the best one for  $N_{CCN}$   
611 prediction among the five schemes which is reflected in the lowest median RDs and the  
612 fit slope of  $\sim 1.0$  for different seasons. The evaluations of the five schemes for the  $N_{CCN}$   
613 prediction at each SS condition and each season are provided in Figure S7 in SI.–  
614 i.e.,  $RD = (|predicted\ N_{CCN} - measured\ N_{CCN}|) / measured\ N_{CCN}$ ; a large RD represents a  
615 large deviation between prediction and measurement. The slope and RD shown in  
616 Figure 8 are both calculated from all five SS conditions for each season. As shown in  
617 Figure 8, the 1<sup>st</sup> and 2<sup>nd</sup> schemes only provide rough estimates of the  $N_{CCN}$  on account  
618 of the pretty high RD ranging from 64% to 136%. Compared to the 1<sup>st</sup> category  
619 approach (the 1<sup>st</sup> and 2<sup>nd</sup> schemes), the 2<sup>nd</sup> category approach (the 3<sup>rd</sup>, 4<sup>th</sup>, and 5<sup>th</sup>  
620 schemes) predicts  $N_{CCN}$  better. The predicted  $N_{CCN}$  correlates well with the measured  
621 one for the 3<sup>rd</sup>, 4<sup>th</sup>, and 5<sup>th</sup> schemes with  $R^2 > 0.97$ ; but  $N_{CCN}$  is generally overestimated  
622 for the 3<sup>rd</sup> and 4<sup>th</sup> schemes because the fit slopes range from 1.03 to 1.17 for different  
623 seasons. The 5<sup>th</sup> scheme appears to be the best one for  $N_{CCN}$  prediction among the five  
624 schemes on account of the lowest RD ranging from 11% to 17% and the fit slope of  $\sim 1$   
625 for different seasons. It should be noted that the fit slope shown in Figure 8 represents  
626 the average over all five SS conditions, which could obscure the performance at each  
627 SS condition. Thus, Figure 9 further evaluates the five schemes for the  $N_{CCN}$  prediction  
628 at each SS condition.

629 The K3 scheme provides an improved prediction of  $N_{CCN}$ , which is obvious when  
630 compared to N1 and N2 schemes. Compared to K1 and K2 schemes, the K3 scheme  
631 reduced approximately 10% overestimation of  $N_{CCN}$  because the fitting slope decreased  
632  $\sim 0.1$  on average. We simply evaluate the effects of the 10% overestimation in  $N_{CCN}$  on

633 predictions of cloud radiative forcing and precipitation. The methods are in Text S2 in  
634 SI and Wang et al. (2019). Essentially, an overestimation of  $N_{CCN}$  leads to overestimate  
635 the number concentration of cloud droplet ( $N_C$ ) in models. Theoretically, it can reduce  
636 3.2% overestimation of cloud optical thickness, corresponding to global average  
637 difference of  $1.28 \text{ Wm}^{-2}$  when assuming the cloud shortwave cooling effect of  $40 \text{ Wm}^{-2}$   
638 (Lee et al., 1997), which amounts to approximately one-third of the direct radiative  
639 forcing from a doubling  $\text{CO}_2$ . Additionally, the overestimation in  $N_{CCN}$  (and  $N_C$ ) leads  
640 to underestimate the strength of the autoconversion process in cloud (Liu et al., 2006),  
641 thereby suppressing precipitation. Therefore, although ACSM measurements can derive  
642  $\kappa_{\text{chem}}$  and thus predict  $N_{CCN}$ , the monodisperse CCN measurements are still important  
643 to obtain the  $\kappa - D_p$  relationship and thus improve the predictions of  $N_{CCN}$  (and  $N_C$ ) and  
644 climate.

645 Figure 8 compared the  $\kappa - D_p$  relationship measured at different regions. The  $\kappa -$   
646  $D_p$  relationship measured at Melpitz is similar to that measured at other rural regions  
647 with similar  $\kappa - D_p$  power-law fitting results, e.g., the Vavihill station in Sweden (Fors  
648 et al., 2011) and the Xinken station in China (Eichler et al., 2008). Therefore, the  $\kappa - D_p$   
649 power-law fit measured at Melpitz could be applied to predict  $N_{CCN}$  for these rural  
650 regions. However, it may cause considerable deviations for different aerosol  
651 background regions, e.g., the suburb stations in Xingtai, China (Wang et al., 2018a) and  
652 in Paris, France (Mazoyer et al., 2019), the coast of Barbados (Kristensen et al., 2016),  
653 the amazon rainforest (Pöhlker et al., 2016), and the urban stations in Budapest,  
654 Hungary (Salma et al., 2021) and in Shanghai, China (Ye et al., 2013), because their  $\kappa -$   
655  $D_p$  relationships are different from that measured at Melpitz.

656 When using the  $N_{CCN} - SS$  power-law fit (the 1<sup>st</sup> scheme) to predict  $N_{CCN}$ , it causes  
657 significant overestimations of  $N_{CCN}$  at  $SS = 0.1\%$  with median values ranging from 3%

658 to 29% for different seasons and causes less than 21% underestimations in median at  
659 other larger  $SS$  conditions. Additionally, the prediction results are much uncertain at a  
660 given  $SS$  condition and season, especially at  $SS = 0.1\%$ . For instance, one quarter of the  
661 predicted  $N_{CCN}$  are twice higher than the measured values at  $SS = 0.1\%$  for all datasets.  
662 Thus, this scheme can only be used to provide rough estimations of  $N_{CCN}$ .

663 When using the real-time  $N_{aero}$  combined with AR- $SS$  power law fit (the 2<sup>nd</sup>  
664 scheme) to predict  $N_{CCN}$ , the performances are slightly better than those of the 1<sup>st</sup>  
665 scheme. The median overestimations of  $N_{CCN}$  are less than 17% at  $SS = 0.1\%$  for all  
666 seasons, while the median underestimations of  $N_{CCN}$  range from 12% to 35% at  $SS =$   
667  $0.2\% - 0.7\%$  for all seasons. Similarly, the prediction results remain a high uncertainty  
668 at a given  $SS$  condition and season. Thus, this scheme also provides rough estimations  
669 on  $N_{CCN}$ .

670 When assuming the real-time PNSD combined with a constant  $\kappa$  of 0.3 (the 3<sup>rd</sup>  
671 scheme) to predict  $N_{CCN}$ , it causes overestimations of  $N_{CCN}$  in most cases. The median  
672 of the overestimation ranges from 3% to 30% at  $SS = 0.1\% - 0.7\%$  for different seasons.  
673 As shown in Figure 7a, a constant  $\kappa$  of 0.3 is almost greater than the  $\kappa_{CCN}$  of all particles  
674 with the diameter ranging from 40 to 200 nm, except for the accumulation-mode  
675 particles ( $D_p$  of 100 to 200 nm) in spring and winter. Therefore, besides the well-  
676 predicted  $N_{CCN}$  at  $SS = 0.1\%$  and  $0.2\%$  in spring and winter,  $N_{CCN}$  is overestimated at  
677 assuming a constant  $\kappa$  of 0.3 as shown in Figure 9c. The largest overestimation occurs  
678 at  $SS = 0.1\%$  in summer (30% in median) because of the low  $\kappa_{CCN}$  (0.22 in average)  
679 combined with the low measured  $N_{CCN}$  ( $347 \text{ cm}^{-3}$  in average). Although the largest  
680 median overestimation reaches to 30%, which is numerically similar to the largest  
681 median overestimation of the 1<sup>st</sup> scheme (29%) and the largest median underestimation  
682 of the 2<sup>nd</sup> scheme (35%), the uncertainties of the 3<sup>rd</sup> scheme are much lower than those

683 of the 1<sup>st</sup> and 2<sup>nd</sup> schemes. For example, when using 3<sup>rd</sup> scheme, one-quarter of the ratio  
684 of the predicted  $N_{CCN}$  to the measured  $N_{CCN}$  are larger than 1.31 at  $SS = 0.1\%$  for all  
685 datasets as shown in Figure 9c, while the ratio is  $\sim 2.0$  for both the results of 1<sup>st</sup> and 2<sup>nd</sup>  
686 scheme as shown in Figures 9a and 9b. Thus, the 3<sup>rd</sup> scheme has better predictions on  
687  $N_{CCN}$  compared to the 1<sup>st</sup> and 2<sup>nd</sup> schemes.—

688 When assuming the real time PNSD combined with the real time bulk  $\kappa_{chem}$  (the  
689 4<sup>th</sup> scheme) to predict  $N_{CCN}$ , it also causes clear overestimations of  $N_{CCN}$  in most cases,  
690 like the prediction results calculated from the 3<sup>rd</sup> scheme. The median overestimations  
691 are within 7% to 21% at  $SS = 0.1\%$ – $0.7\%$  for different seasons. The reason for the  
692 overestimation is that the  $\kappa_{chem}$  is greater than  $\kappa_{CCN}$  measured at all the five  $SS$   
693 conditions. For instance, the mean  $\kappa_{CCN}$  over all datasets ranges from 0.20 to 0.28 at  $SS$   
694  $= 0.1\%$ – $0.7\%$ , whereas the mean  $\kappa_{chem}$  over all datasets is 0.36. The largest  
695 overestimation also occurs at  $SS = 0.1\%$  in summer with 21% in median. Compared to  
696 the 3<sup>rd</sup> scheme, the uncertainty of the  $N_{CCN}$  prediction at a given  $SS$  condition and season  
697 is lower in the 4<sup>th</sup> scheme. Considering the median overestimations of the predicted  
698  $N_{CCN}$  at different seasons and  $SS$  conditions and the uncertainty of the predicted  $N_{CCN}$  at  
699 each given season and  $SS$  condition, we conclude that the performances of the 4<sup>th</sup>  
700 scheme are better than the 3<sup>rd</sup> scheme.

701 When assuming the real time PNSD combined with the  $\kappa - D_p$  power law fit (the  
702 5<sup>th</sup> scheme) to predict  $N_{CCN}$ , it can predict the  $N_{CCN}$  well at each  $SS$  condition for all  
703 seasons. At  $SS = 0.1\%$ , it causes less than 10% overestimation in median for  $N_{CCN}$   
704 prediction for all seasons; at  $SS = 0.2\%$ – $0.7\%$ , the median overestimation ranges from  
705  $-3\%$  to 6% for all seasons. The uncertainty of the  $N_{CCN}$  prediction at a given  $SS$  condition  
706 and season is also smallest among the five schemes, especially at relatively high  $SS$   
707 conditions (e.g., 0.5% and 0.7%). For instance, at  $SS = 0.7\%$  for all datasets, when using

708 the 5<sup>th</sup> scheme, one-quarter of the ratio of the predicted  $N_{CCM}$  to the measured  $N_{CCM}$  are  
709 larger than 1.10, while the ratio ranges from 1.18 to 1.38 for other four schemes.  
710 Therefore, the 5<sup>th</sup> scheme provides the best  $N_{CCM}$  prediction among the five schemes.

711 Overall, the performance for  $N_{CCM}$  prediction is gradually getting better from the  
712 1<sup>st</sup> to the 5<sup>th</sup> scheme shown in Table 6. The classic  $N_{CCM}$ - $SS$  and  $AR$ - $SS$  power-law fits  
713 shown in Table 3 can only be used to provide rough estimates of the  $N_{CCM}$ . At Melpitz,  
714 using a constant  $\kappa$  of 0.3 or the bulk  $\kappa_{chem}$  both causes significant overestimations of  
715  $N_{CCM}$  with about 30% in median, especially at  $SS = 0.1\%$  in summer. The  $\kappa$ - $D_p$  power-  
716 law fit at each season shown in Table 5 is recommended applying for  $N_{CCM}$  prediction  
717 at Melpitz, which can narrow down the prediction deviation (ratio of the predicted  $N_{CCM}$   
718 to the measured  $N_{CCM}$  minus 1) within 10% in median. Additionally, as shown in Figure  
719 10, the  $\kappa$ - $D_p$  power-law fit measured at Melpitz is similar to that measured at other  
720 rural and continental regions with similar aerosol background conditions, e.g., the  
721 Vavihill station in Sweden (Fors et al., 2011) and the Xinken station in China (Eichler  
722 et al., 2008), and is also valid for some urban (Ye et al., 2013) and suburb regions  
723 (Mazoyer et al., 2019). Therefore, the  $\kappa$ - $D_p$  power-law fit measured at Melpitz could  
724 be applied to predict  $N_{CCM}$  for these regions. However, it may cause considerable  
725 deviations for different aerosol background regions, e.g., the polluted suburb station in  
726 Xingtai, China (Wang et al., 2018a), the coast of Barbados (Kristensen et al., 2016), the  
727 amazon rainforest (Pöhlker et al., 2016), and the urban station in Budapest, Hungary  
728 (Salma et al., 2021), because their  $\kappa$ - $D_p$  relationships are different from that measured  
729 at Melpitz.

730 Additionally, it should be noted that the main size dependence of  $\kappa$  occurs at  $D_p$  of  
731 ~40 to 100 nm as shown in Figure 7a, which would be for  $SS$  larger than 0.2%. At  $D_p$   
732 of 100 to 200 nm corresponding to  $SS$  less than 0.2%,  $\kappa$  almost stays constant. The mean

733 value of  $\kappa$  is close to 0.3 for spring and winter, and that's where deviations in Figure 9e  
734 are small. However, the mean value of  $\kappa$  overestimates the  $\kappa$  for  $SS$  larger than 0.2% at  
735 each season. We further compare the  $N_{CCN}$  predictions between using the seasonally  
736 mean value of  $\kappa$  over  $D_p$  of 100 to 200 nm and the  $\kappa$ - $D_p$  power law fit. As shown in  
737 Figure 11, at  $SS = 0.1$  and 0.2%, the seasonally mean  $\kappa$  value over  $D_p$  of 100 to 200 nm  
738 and  $\kappa$ - $D_p$  power law fit both predict the  $N_{CCN}$  well at each season, while the mean  $\kappa$   
739 value leads to significant overestimation of  $N_{CCN}$  within 10% on average at  $SS = 0.3$ ,  
740 0.5, and 0.7%. Therefore, to predict the  $N_{CCN}$  at a relatively low  $SS$  of less than 0.2%  
741 (e.g., in fog and shallow stratiform cloud), the mean  $\kappa$  value over  $D_p$  of 100 to 200 nm  
742 also works well. The mean value plus/minus one standard deviation are  $0.32 \pm 0.09$ ,  
743  $0.24 \pm 0.07$ ,  $0.26 \pm 0.09$ ,  $0.32 \pm 0.10$  and  $0.28 \pm 0.09$  for spring, summer, autumn, winter,  
744 and all datasets, respectively.

#### 745 4. Conclusions

746 Aerosol particle activation plays an important role in determining  $N_C$  the number  
747 concentration of cloud droplets, thereby affecting cloud microphysics, precipitation  
748 processes, radiation, and climate. To reduce the uncertainties and gain more confidence  
749 in the simulations on AIEs, long-term measurements on aerosol activation  
750 characteristics are essential; however, they are still rarely reported. Based on more  
751 than 4-year comprehensive measurements conducted at the central European ACTRIS  
752 site Melpitz, Germany, this study presents a systematic seasonal analysis of aerosol  
753 activation characteristics and  $N_{CCN}$  predictions.

754 Over the whole period at Melpitz, the mean-median  $N_{CCN}$  and AR increased from  
755 399 to 2144 cm<sup>-3</sup> and 0.10 to 0.48 13 to 2477 cm<sup>-3</sup> and 0.11 to 0.52 with  $SS$  increasing  
756 from 0.1% to 0.7%, respectively. Aerosol activation characteristics are highly variable  
757 across seasons, especially at relatively low  $SS$  conditions. For instance at  $SS = 0.1\%$ ,

758 the median  $N_{CCN}$  and AR in winter are 1.6 and 2.3 times higher than the summer values,  
759 respectively. Aerosol particle activation depends on its physical and chemical properties.  
760 In summer, the highest  $N_{aero}$ , smallest  $GMD$ , steepest PNSD in 40-200 nm size range,  
761 and lowest  $\kappa_{chem}$  all contribute to the lowest AR and  $N_{CCN}$  among the four seasons, and  
762 the reverse holds true in winter.

763 ~~At  $SS = 0.1\%$ , the seasonal mean  $N_{CCN}$  is  $681 \text{ cm}^{-3}$  in winter, which is almost~~  
764 ~~twice higher than the summer value ( $347 \text{ cm}^{-3}$ ); the seasonal mean AR is 0.18 in winter,~~  
765 ~~which is three times higher than the summer value (0.06). Aerosol particle activation~~  
766 ~~depends on its physical and chemical properties. Affected by the frequent NPF events,~~  
767 ~~in summer, the mean  $N_{aero}$  is highest ( $6224 \text{ cm}^{-3}$ ) and the mean  $GMD$  is smallest (50~~  
768 ~~nm) among the four seasons. On the contrary in winter, the mean  $N_{aero}$  is lowest ( $3686$~~   
769  ~~$\text{cm}^{-3}$ ) and the mean  $GMD$  is largest (58 nm). In summer, the mean  $f_{org}$  (56%) is highest~~  
770 ~~among the four seasons, corresponding to the lowest  $\kappa_{chem}$  with a mean value of 0.29;~~  
771 ~~in winter, the mean  $f_{nitrate}$  (36%) is highest among the four seasons, which might explain~~  
772 ~~the highest mean  $\kappa_{chem}$  (0.40). Therefore, in winter, the highest  $\kappa_{chem}$ , largest  $GMD$ , and~~  
773 ~~the lowest  $N_{aero}$  cause the highest AR at each  $SS$  condition among the four seasons.~~

774 Both  $\kappa$  and the mixing state are size-dependent, thereby varying with  $SS$ . The  
775 median  $\kappa_{CCN}$  decreases from 0.27 to 0.19 as  $SS$  increases from 0.1% to 0.7%, which  
776 was less than the median bulk  $\kappa_{chem}$ . The mean  $\kappa$  is 0.28, 0.28, 0.24, 0.21, and 0.20 at  
777  $SS = 0.1\%$ ,  $0.2\%$ ,  $0.3\%$ ,  $0.5\%$ , and  $0.7\%$ , respectively.  $D_e$  depends on  $\kappa$  at a given  $SS$   
778 condition. The seasonal trend of  $\kappa_{CCN}$  was similar to that of  $\kappa_{chem}$ , especially at relatively  
779 low  $SS$  conditions. The lowest  $\kappa_{CCN}$  and  $\kappa_{chem}$  were observed in summer, which related  
780 to the highest organics mass fraction in particles. Aerosol particles were more internally  
781 mixed in summer and spring whereas less internally mixed in winter and autumn. In  
782 cold seasons, the increasing anthropogenic emissions linked to house heating mixed

783 with the aged particles from long-range transport, which could decrease the degree of  
784 internal mixing of particles. As  $D_p$  increases,  $\kappa_{CCN}$  increases at  $D_p$  range of ~40 to 100  
785 nm and almost stays constant at  $D_p$  range of 100 to 200 nm, whereas the  $(D_{75} - D_{25})/D_c$   
786 monotonically decreases. The relationships of  $(D_{75} - D_{25})/D_c$  vs.  $D_p$  and  $\kappa$  vs.  $D_p$  are  
787 both fitted well by a power-law function for each season.

788 The mean  $D_e$  is 177, 112, 91, 67, and 54 nm at  $SS = 0.1\%$ ,  $0.2\%$ ,  $0.3\%$ ,  $0.5\%$ , and  
789  $0.7\%$ , respectively. For different seasons, the seasonal mean  $\kappa$  varies from 0.23 to 0.32  
790 at  $SS = 0.1\%$ , and 0.19 to 0.21 at  $SS = 0.7\%$ ; the seasonal mean  $D_e$  varies from 168 nm  
791 to 187 nm at  $SS = 0.1\%$ , and 53 nm to 55 nm at  $SS = 0.7\%$ . The degree of external  
792 mixture is quantified by the  $(D_{75} - D_{25})/D_e$ , which ranges from 0.17 to 0.25 in average  
793 over the whole period at  $SS = 0.1-0.7\%$ . In summer, aerosol particles were extremely  
794 close to being internally mixed with  $(D_{75} - D_{25})/D_e$  ranging from 0.14 to 0.18 at  $SS =$   
795  $0.1-0.7\%$ ; in winter, particles were less internally mixed among the four seasons with  
796  $(D_{75} - D_{25})/D_e$  ranging from 0.24 to 0.36 at  $SS = 0.1-0.7\%$ . As  $D_p$  increases,  $\kappa$  increases  
797 at  $D_p$  of ~40 to 100 nm and almost stays constant at  $D_p$  of 100 to 200 nm), and  $(D_{75} -$   
798  $D_{25})/D_e$  decreases for all seasons. The relationships of  $(D_{75} - D_{25})/D_e$  vs.  $D_p$  and  $\kappa$  vs.  
799  $D_p$  are both fitted well by the power law function for each season.

800 Five activation schemes are evaluated on the  $N_{CCN}$  predictions. Compared to using  
801 the classic  $N_{CCN} - SS$  or  $AR - SS$  power-law fits to predict  $N_{CCN}$ , the prediction is better  
802 by using the real-time PNSD combined with the parameterized  $\kappa$ , including a constant  
803  $\kappa$  of 0.3, the bulk  $\kappa_{chem}$ , and the  $\kappa - D_p$  power-law fit. However, assuming a constant  $\kappa$   
804 of 0.3 recommended for continental aerosol (Andreae and Rosenfeld., 2008) or the bulk  
805  $\kappa_{chem}$  calculated from aerosol chemical composition both cause significant  
806 overestimations of the  $N_{CCN}$  with approximately 10% in median for all  $SS$  conditions,  
807 which theoretically cause 3.2% overestimation of cloud optical thickness, amounting to

808 approximately one-third of the direct radiative forcing from a doubling CO<sub>2</sub> (Lee et al.,  
809 1997). And, the strength of the autoconversion process in cloud could be  
810 underestimated (Liu et al., 2006). with about 30% in median, especially at SS = 0.1%  
811 in summer. Generally, the performances of the latter (the bulk  $\kappa_{\text{chem}}$ ) are slightly better  
812 than the former (a constant  $\kappa$  of 0.3) on account of the lower uncertainty at each given  
813 season and SS condition. Size-resolved  $\kappa$  improves the  $N_{CCN}$  prediction. We recommend  
814 applying the  $\kappa - D_p$  power-law fit for  $N_{CCN}$  prediction, which obtains the best prediction  
815 among the five schemes.

816 The  $\kappa - D_p$  power-law fit presented in this study could apply to other rural regions.  
817 However, it may cause considerable deviations for different aerosol background regions.  
818 For instance, using the  $\kappa - D_p$  power-law fit measured in urban Budapest (Salma et al.,  
819 2021) for predicting Melpitz  $N_{CCN}$ , it could cause a 39% underestimation of  $N_{CCN}$  in  
820 median for all SS conditions. Additionally, the seasonal difference of the  $\kappa - D_p$   
821 relationship needs to be considered carefully for  $N_{CCN}$  prediction. At Melpitz, if the  $\kappa -$   
822  $D_p$  power-law fit measured in summer was used for predicting  $N_{CCN}$  in winter, it could  
823 cause a 13% underestimation of  $N_{CCN}$  in median for all SS conditions. Although the  $\kappa -$   
824  $D_p$  relationships are similar measured in rural stations, but when comparing the different  
825 urban stations (e.g., shanghai vs. Budapest in Figure 8), these relationships are clearly  
826 different and the reasons for the difference are still unclear. Thus, long-term  
827 monodisperse CCN measurements are still needed not only to obtain the  $\kappa - D_p$   
828 relationships for different regions and for different seasons, but furtherly investigate the  
829 reasons for the difference of the  $\kappa - D_p$  relationships measured at same type of regions.  
830 Finally for the purpose of predicting  $N_{CCN}$ , the measurements of monodisperse CCN  
831 and particle chemical compositions are more expected, compared to the polydisperse

832 CCN measurements.

833 ~~At Melpitz, using the real time PNSD combined with the  $\kappa$ - $D_p$  power law fit~~  
834 ~~could narrow down the uncertainty of  $N_{CCN}$  prediction within 10% in median for all SS~~  
835 ~~conditions (0.1–0.7%) and seasons. The  $\kappa$ - $D_p$  power law fit presented in this study~~  
836 ~~could apply to other rural and continental regions with similar aerosol background~~  
837 ~~conditions. To our knowledge, the  $\kappa$ - $D_p$  power law fit is the first time applied to~~  
838 ~~predict  $N_{CCN}$ . Additionally, the mean  $\kappa$  value over  $D_p$  of 100 to 200 nm also works well~~  
839 ~~to predict  $N_{CCN}$  at a relatively low SS of less than 0.2%.~~

840

$A$	comprehensive parameter for $\sigma_{s/a}$ , $M_w$ , $R$ , $T$ , and $\rho_w$ in equation (2b)
$a$	lower limit for calculating critical diameters at the set-nominal supersaturations in equation (1)
ACI	aerosol and cloud interactions
ACSM	aerosol chemical species monitor
ACTRIS	Aerosol, Clouds and Trace Gases Research Infrastructure
AF	activated fraction, i.e., $N_{CCN}/N_{CN}$
AIEs	aerosol indirect effects
AR	activation ratio, i.e., $N_{CCN}/N_{aero}$
$b$	upper limit for calculating critical diameters at the set-nominal supersaturations in equation (1)
BC	black carbon
CN	condensation nuclei
CCN	cloud condensation nuclei
CCNC	cloud condensation nuclei counter
$coef$	coefficient in $\kappa - D_p$ power-law fit
CPC	condensation particle counter
$D_p$	diameter of the dry particle
$D_c$	critical diameter of the dry particle
$D_X$	$D$ at which X % of the particles are activated
$(D_{75} - D_{25})/D_c$	degree of external mixture
D-MPSS	Dual-mobility particle size spectrometer
DMA	differential mobility analyzer
eBC	equivalent black carbon
$f_{BC}$	mass fraction of BC in submicron aerosol
$f_{nitrate}$	mass fraction of nitrate in submicron aerosol
$f_{org}$	mass fraction of organics in submicron aerosol
$f_{sulfate}$	mass fraction of sulfate in submicron aerosol
GMD	geometric mean diameter of PNSD
$M_w$	molecular weight of water
$N_{aero}$	number concentration of aerosol with <u>a <math>D_p</math> ranging range of</u> 10 to 800 nm
$N_C$	<u>number concentration of cloud droplet</u>
$N_{CN}$	number concentration of CN
$N_{CCN}$	number concentration of CCN
NPF	new particle formation
<u>OA</u>	<u>organic aerosol</u>
PM <sub>10</sub>	particulate matter with the $D_p < 10 \mu\text{m}$
PNSD	particle number size distribution
$R$	universal gas constant
$R^2$	coefficient of determination
RD	relative deviation between the predicted $N_{CCN}$ and the measured one
<u>SI</u>	<u>Supporting information</u>

$SS$	supersaturation
<u>SOA</u>	<u>secondary organic aerosol</u>
$T$	temperature
$\sigma_s$	represent the shape of the sigmoid function
$\sigma_{s/a}$	droplet surface tension
$\kappa$	hygroscopicity factor of aerosol particle
$\kappa_i$	$\kappa$ of each component
$\kappa_{CCN}$	$\kappa$ calculated from the monodisperse CCN measurements
$\kappa_{chem}$	$\kappa$ calculated from the aerosol chemical measurements
$\varepsilon_i$	volume fraction of each component
$\rho_w$	density of the liquid water

1280

Figure 2. Relationship between CCN number concentration ( $N_{CCN}$ ) and supersaturation ( $SS$ ) measured at Melpitz and other stations.

1281

1282 **Figure 3. Seasonal variations of (a) CCN number-size distributions and activation ratios (AR) at five**

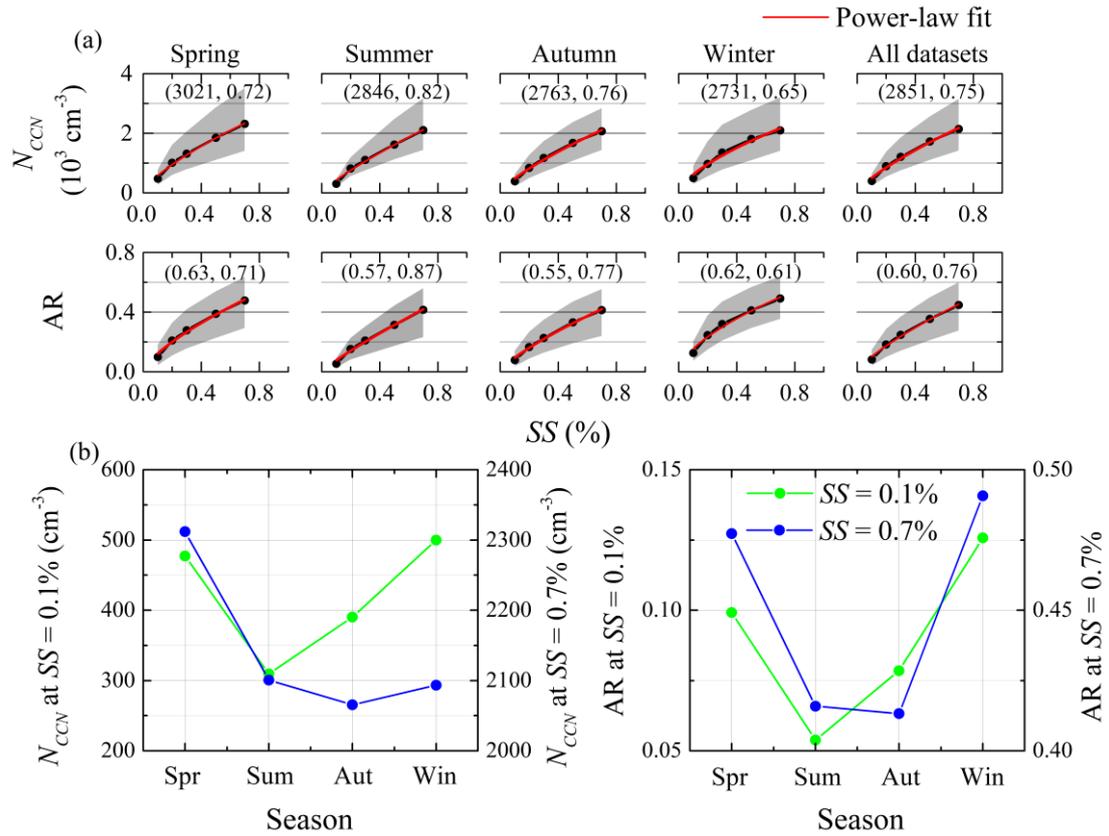

1283 **different supersaturation (SS) conditions, (b) relationship between AR and SS for different seasons,**

1284 **and (c) relationship between CCN number concentration ( $N_{CCN}$ ) and SS for different seasons. Error**

1285 **bar means one standard deviation. Red lines and blue lines are the fittings for AR vs. SS and  $N_{CCN}$**

1286 **vs. SS with using the power-law function and the error function, respectively. Fitting results are**

1287 **shown in Table 3.**

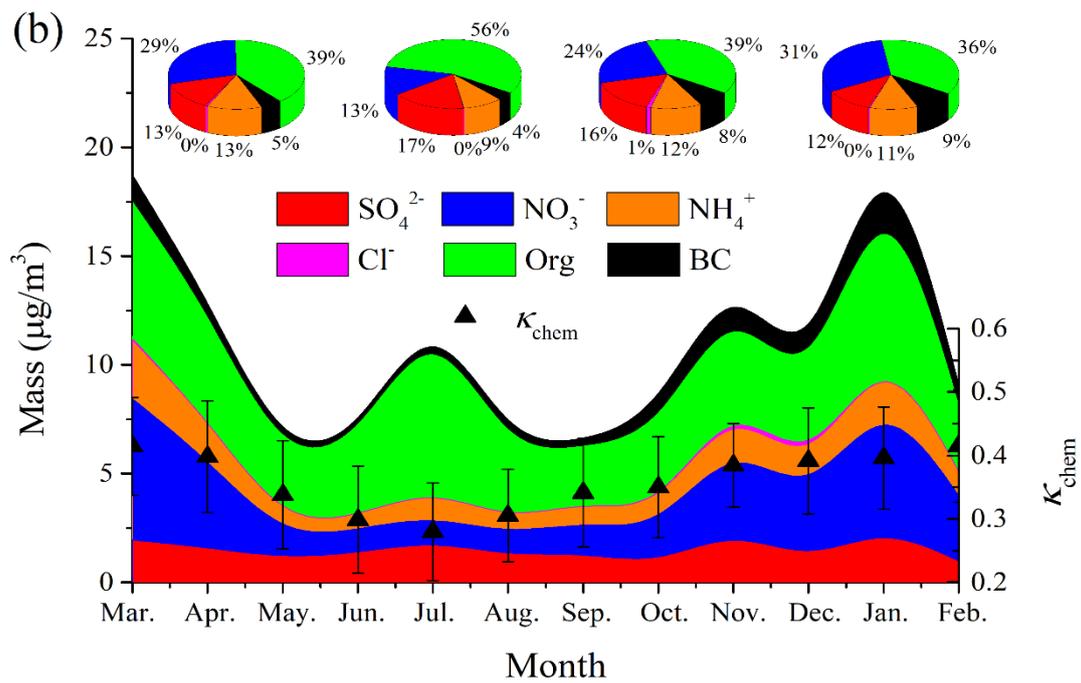

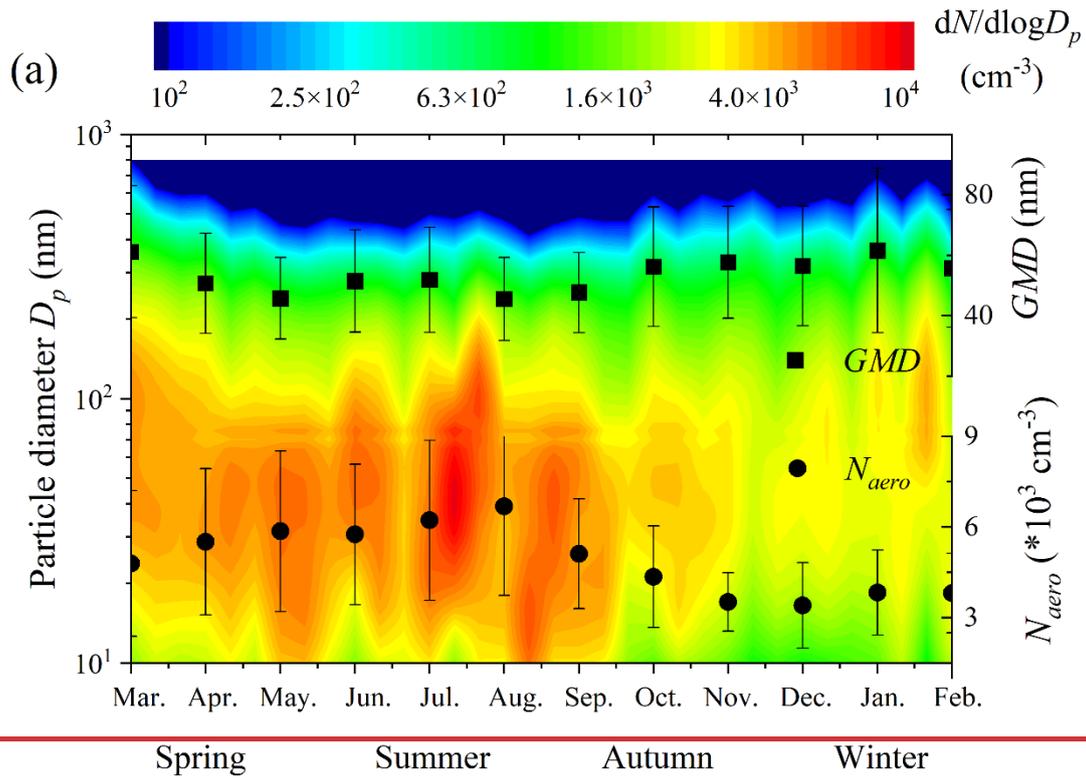

1288

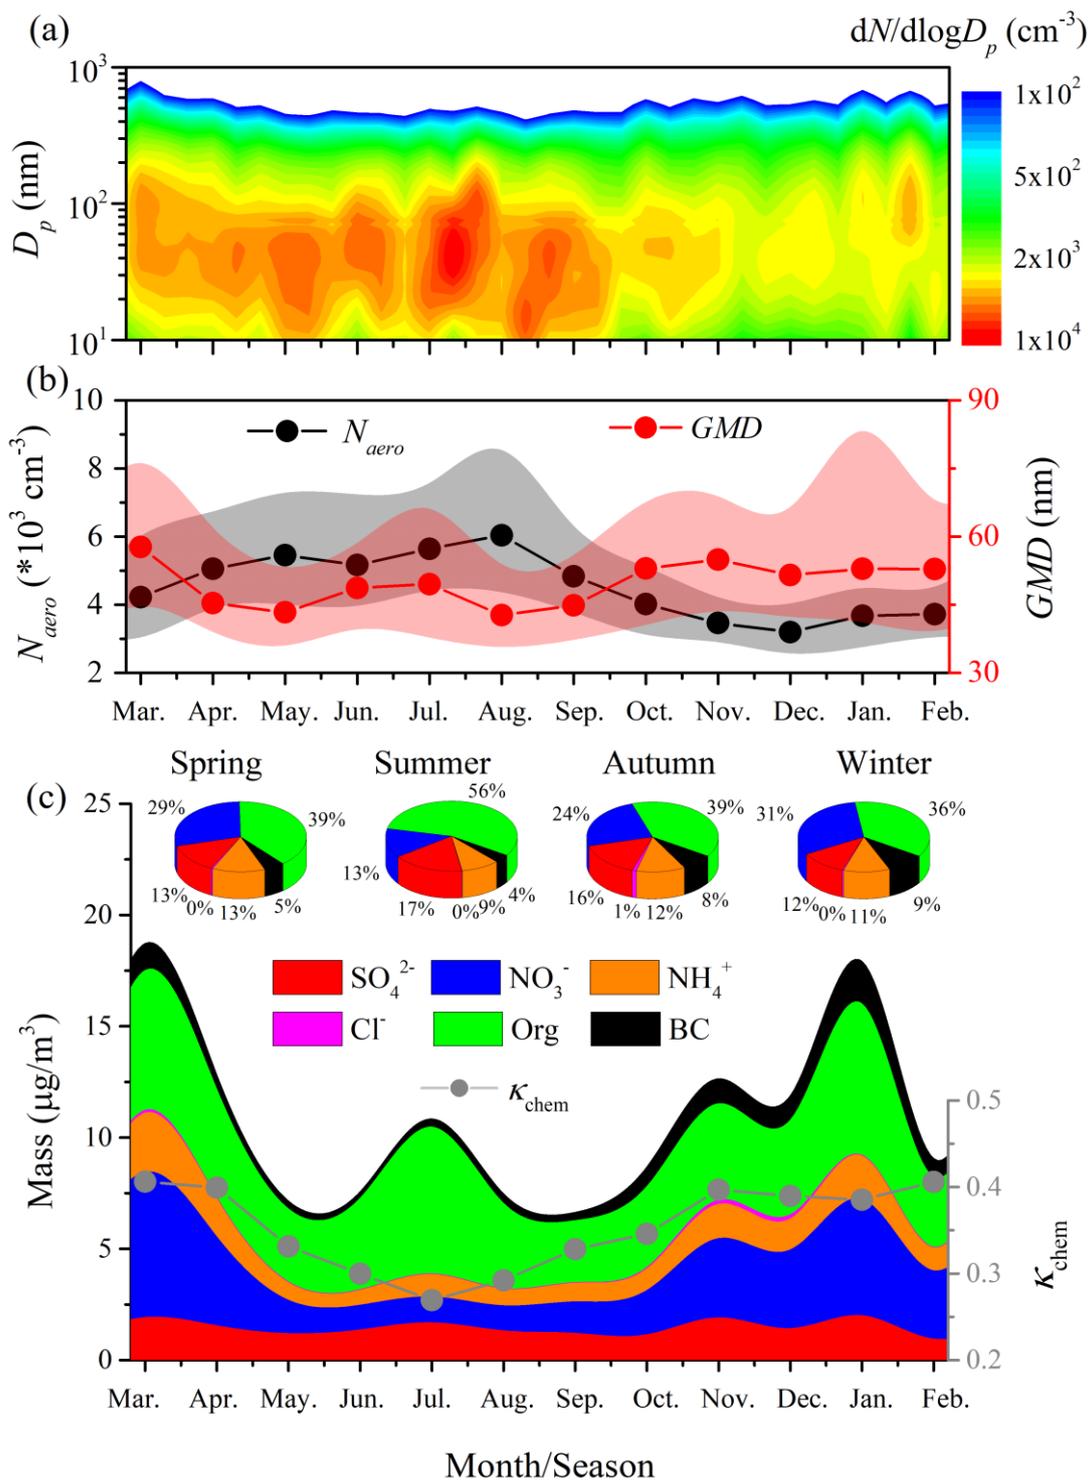

1289 Figure 3. (a) Relationships between CCN number concentration ( $N_{CCN}$ ) and supersaturation ( $SS$ ),  
 1290 and relationship between activation ratios ( $AR$ ) and  $SS$  for different seasons. (b) Seasonal trends of  
 1291  $N_{CCN}$  and  $AR$  at  $SS = 0.1\%$  and  $0.7\%$ . Dots represent the median values of  $N_{CCN}$  and  $AR$ . Shaded  
 1292 areas represent the values in the range from 25<sup>th</sup> to 75<sup>th</sup> percent. Red lines are power-law fittings for  
 1293  $N_{CCN}$  (and  $AR$ ) vs.  $SS$ . Two parameters of the fitting results are shown in brackets.

1294

1295

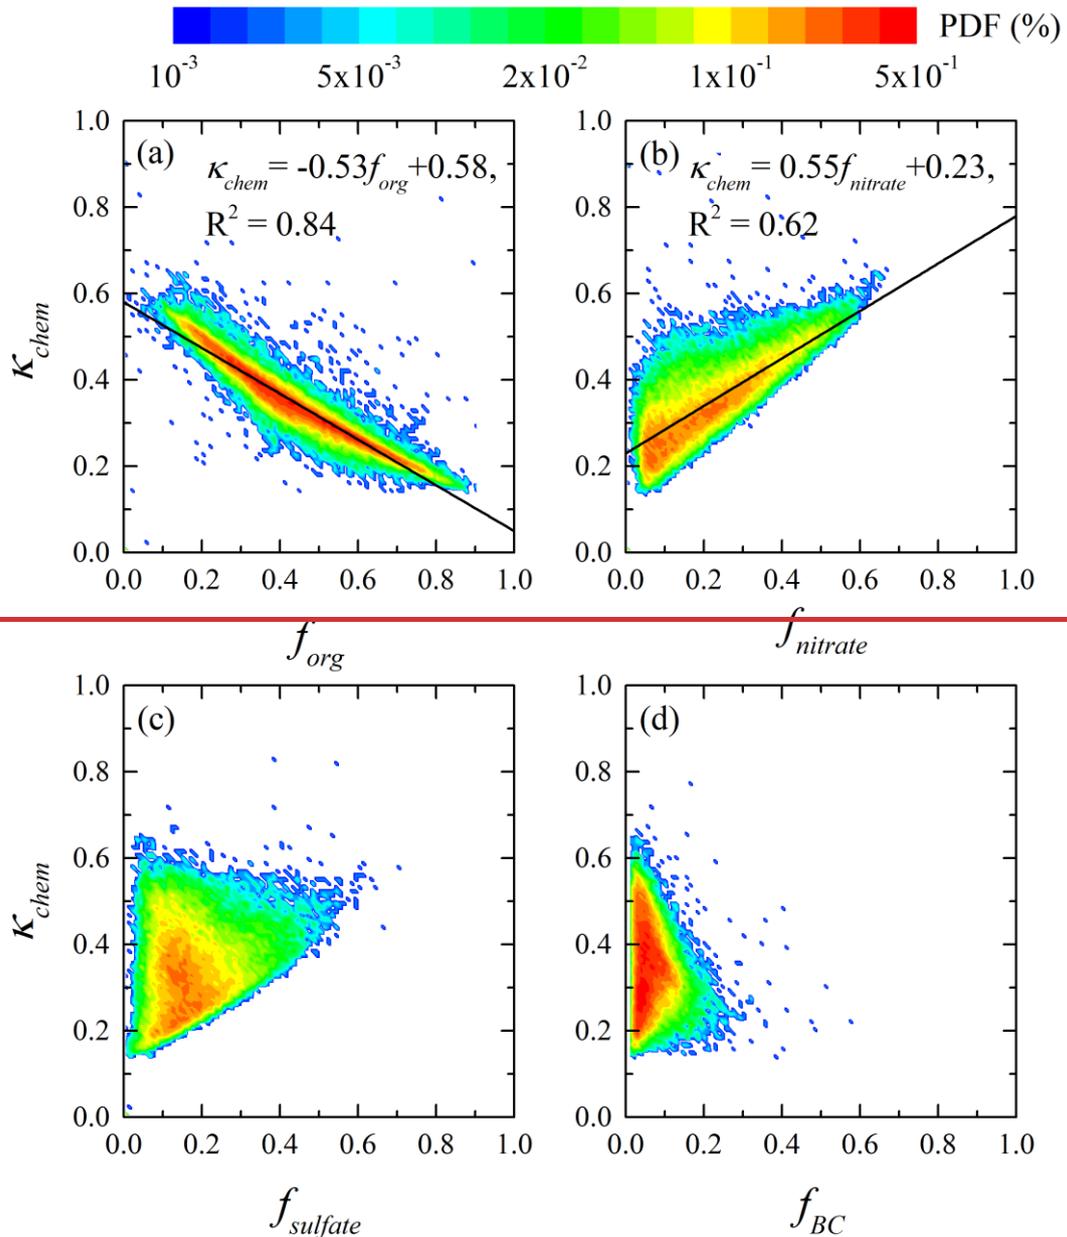

1296

1297

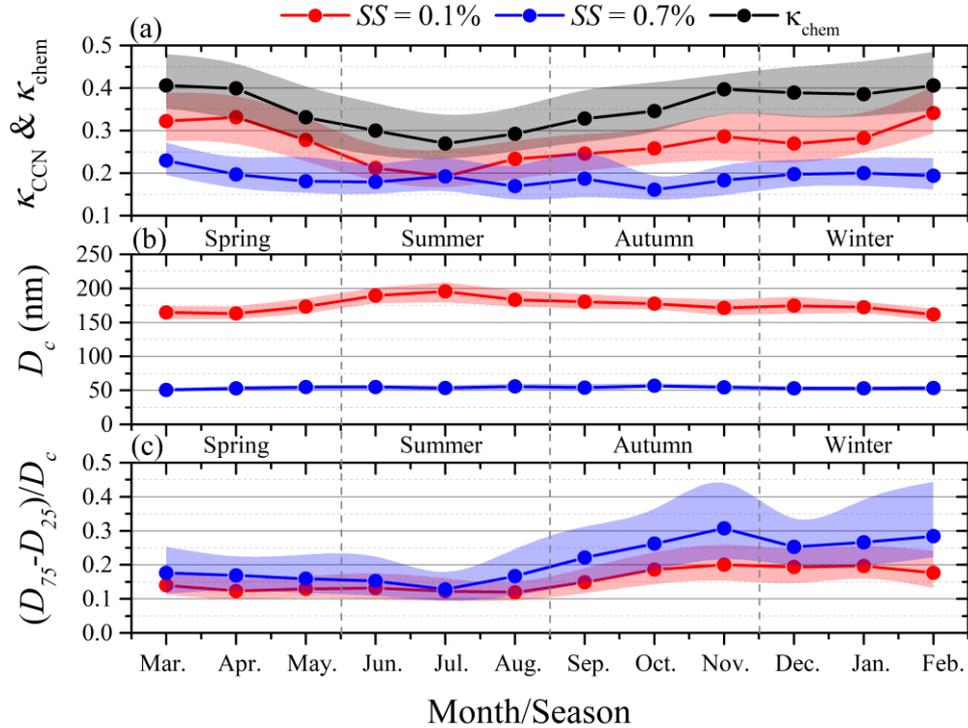

1298 Figure 4. Seasonal variations of (a) aerosol particle number size distribution ( $dN_{aero}/d\log D_p$  vs.  $D_p$ ,  
 1299  $D_p$  is particle diameter), (b) total aerosol number concentration with a  $D_p$  range of 10 to 800 nm  
 1300 ( $N_{aero}$ ) and geometric mean diameter of the particles ( $GMD$ ), and (c) mass concentration and ratio  
 1301 of each component in aerosol particle with  $D_p$  less than 1  $\mu\text{m}$  and the hygroscopicity factor  
 1302 calculated from the chemical composition ( $\kappa_{chem}$ ). Dots represent the median values. Shaded areas

1303 represent the values in the range from 25<sup>th</sup> to 75<sup>th</sup> percent. Seasonal variations of (a) aerosol physical  
 1304 and (b) chemical properties.  $dN_{aero}/d\log D$  represents the aerosol number concentration at each bin,  
 1305  $GMD$  is the geometric mean diameter of the particles,  $N_{aero}$  means total aerosol number  
 1306 concentration with diameter ranging 10 to 800 nm,  $\kappa_{chem}$  is the hygroscopicity factor calculated from  
 1307 the chemical composition. Error bar is one standard derivation.

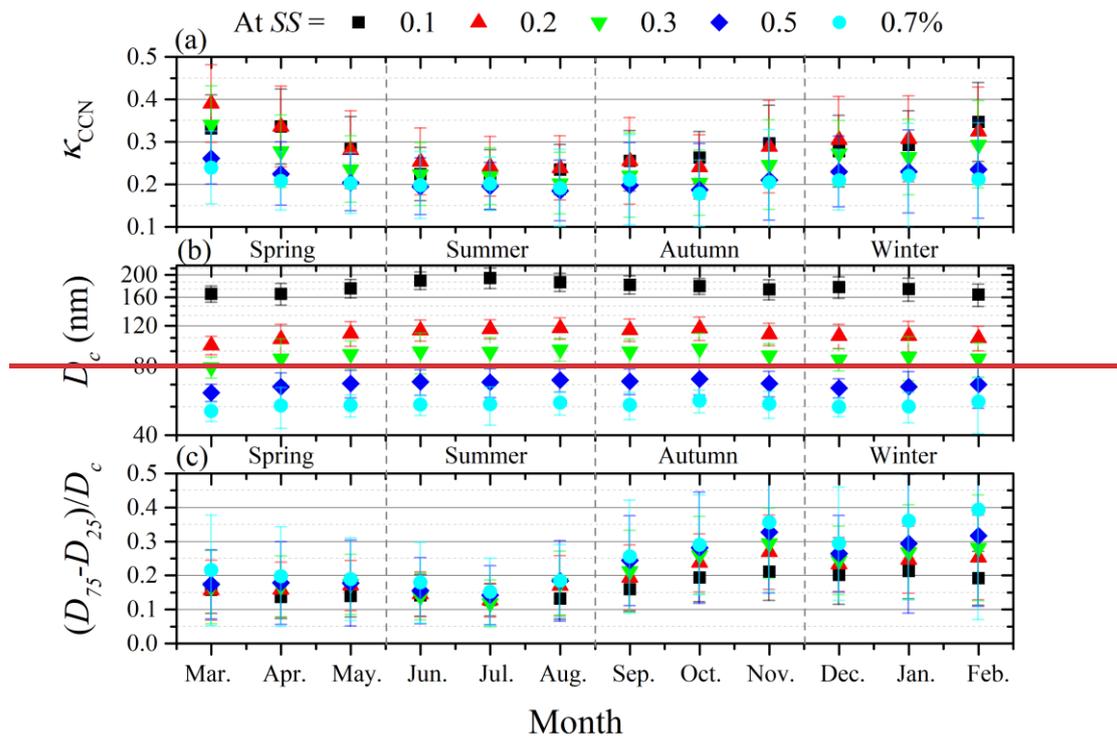

1308 Figure 5. Relationships between (a) aerosol hygroscopicity factor calculated from the chemical  
 1309 composition ( $\kappa_{chem}$ ) and mass fraction of organics ( $f_{org}$ ) in submicron aerosol, (b)  $\kappa_{chem}$  vs. mass  
 1310 fraction of nitrate ( $f_{nitrate}$ ), (c)  $\kappa_{chem}$  vs. mass fraction of nitrate ( $f_{sulfate}$ ), and (d)  $\kappa_{chem}$  vs. mass fraction  
 1311 of black carbon ( $f_{BC}$ ).

1312 of black carbon ( $f_{BC}$ ). Color bar represents the probability density function (PDF). Black lines are  
 1313 linear fit lines.

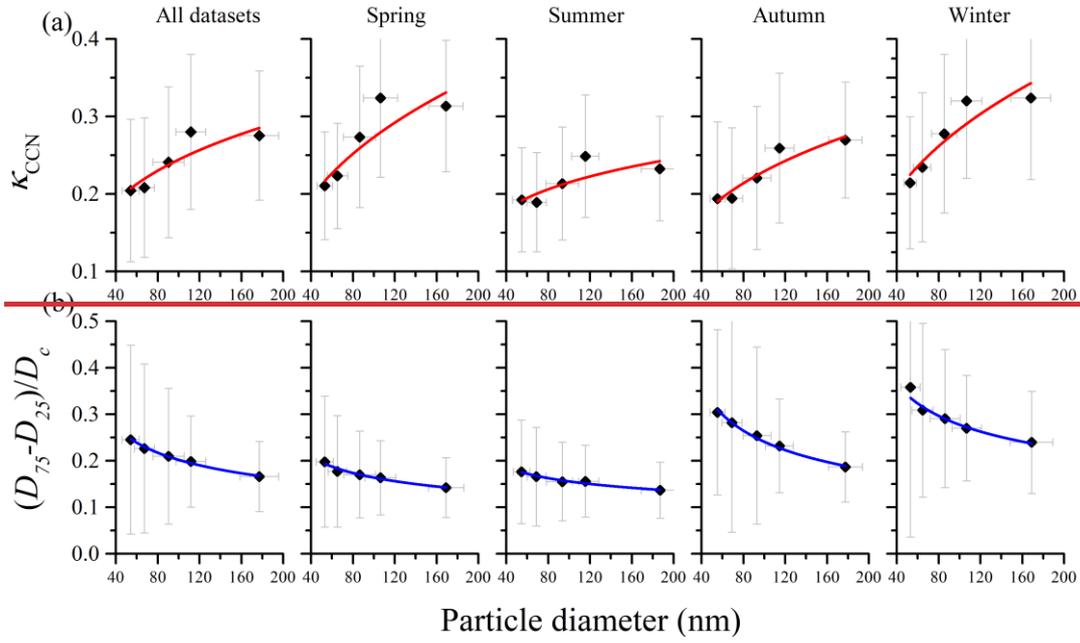

1314  
 1315 Figure 5. Monthly variations of (a) hygroscopicity factor calculated from monodisperse CCN  
 1316 measurements ( $\kappa_{CCN}$ ) at supersaturation ( $SS$ ) of 0.1% and 0.7%, and hygroscopicity factor calculated  
 1317 from particle chemical composition ( $\kappa_{chem}$ ), (b) critical diameter of dry particle for activation ( $D_c$ )  
 1318 at  $SS = 0.1\%$  and 0.7%, and (c) the degree of external mixture ( $(D_{75} - D_{25})/D_c$ ) at  $SS = 0.1\%$  and  
 1319 0.7%. The definitions of  $D_{75}$  and  $D_{25}$  are the  $D_p$  at which 75% and 25% of the particles are activated  
 1320 at the given  $SS$ , respectively. Dots represent the median values. Shaded areas represent the values in  
 1321 the range from 25<sup>th</sup> to 75<sup>th</sup> percent.

1323

1324 ~~Figure 6. Monthly average of (a) hygroscopicity factor calculated from monodisperse CCN~~  
 1325 ~~measurements ( $\kappa_{CCN}$ ), (b) critical diameter of dry particle for activation ( $D_c$ ), and (c) the degree of~~  
 1326 ~~external mixture ( $(D_{75} - D_{25})/D_c$ ) at five different supersaturation (SS) conditions. The definitions~~  
 1327 ~~of  $D_{75}$  and  $D_{25}$  are the  $D_p$  at which 75% and 25% of the particles are activated at the given SS,~~  
 1328 ~~respectively. Error bar is one standard derivation.~~
