**Abstract:** Understanding aerosol particle activation is essential for evaluating aerosol indirect effects (AIEs) on climate. Long-term measurements of aerosol particle activation help to understand the AIEs and narrow down the uncertainties of AIEs simulation. However, they are still scarce. In this study, more than 4-year aerosol comprehensive measurements were utilized at the central European research station Melpitz, Germany, to gain insight into the aerosol particle activation and provide recommendations on improving the prediction of number concentration of cloud condensation nuclei (CCN,  $N_{CCN}$ ). (1) The overall CCN activation characteristics at Melpitz is provided. As supersaturation ( $SS$ ) increases from 0.1% to 0.7%, the median  $N_{CCN}$  increases from 399 to 2144  $\text{cm}^{-3}$ , which represents 10% to 48% of the total particle number concentration with a diameter range of 10 – 800 nm, while the median hygroscopicity factor ( $\kappa$ ) and critical diameter ( $D_c$ ) decrease from 0.27 to 0.19 and from

26 176 to 54 nm, respectively. (2) Aerosol particle activation is highly variable across  
27 seasons, especially at low  $SS$  conditions. At  $SS = 0.1\%$ , the median  $N_{CCN}$  and activation  
28 ratio (AR) in winter are 1.6 and 2.3 times higher than the summer values, respectively.  
29 (3) Both  $\kappa$  and the mixing state are size dependent. As the particle diameter ( $D_p$ )  
30 increases,  $\kappa$  increases at  $D_p$  of  $\sim 40$  to 100 nm and almost stays constant at  $D_p$  of 100 to  
31 200 nm, whereas the degree of the external mixture keeps decreasing at  $D_p$  of  $\sim 40$  to  
32 200 nm. The relationships of  $\kappa$  vs.  $D_p$  and degree of mixing vs.  $D_p$  were both fitted well  
33 by a power-law function. (4) Size-resolved  $\kappa$  improves the  $N_{CCN}$  prediction. We  
34 recommend applying the  $\kappa - D_p$  power-law fit for  $N_{CCN}$  prediction at Melpitz, which  
35 performs better than using the constant  $\kappa$  of 0.3 and the  $\kappa$  derived from particle chemical  
36 compositions and much better than using the  $N_{CCN}$  (AR) vs.  $SS$  relationships. The  $\kappa -$   
37  $D_p$  power-law fit measured at Melpitz could be applied to predict  $N_{CCN}$  for other rural  
38 regions. For the purpose of improving the prediction of  $N_{CCN}$ , long-term monodisperse  
39 CCN measurements are still needed to obtain the  $\kappa - D_p$  relationships for different  
40 regions and their seasonal variations.

## 41 **1. Introduction**

42 The specific subset of aerosol particles that serves as nuclei for the condensation  
43 of water vapor, forming cloud droplets at a given supersaturation ( $SS$ ) condition, is  
44 known as cloud condensation nuclei (CCN). Aerosol particle activation affects the  
45 aerosol and cloud interactions (ACI), thereby changing the cloud microstructure (Zhao  
46 et al., 2012; Jia et al., 2019; Wang et al., 2019), precipitation (Khain, 2009; Wang et al.,  
47 2011; Fan et al., 2012, 2018), radiation (Twomey, 1974, 1977; Albrecht, 1989; Zhao  
48 and Garrett, 2015), and by these effects the global climate (Ramanathan et al., 2001;

49 Rosenfeld et al., 2019). The latest sixth assessment report from IPCC (2021) pointed  
50 out that aerosol indirect effects (AIEs) remain the most considerable uncertainty in  
51 assessing the anthropogenic contribution to present and future climate change.

52 The ambient  $SS$  and aerosol activation ability are both important for predicting the  
53 number concentration of cloud droplets. The classical Köhler theory (Köhler, 1936),  
54 combining the Raoult law with the Kelvin effect, illustrates that the aerosol particle  
55 activation depends on particle size, chemical composition, and the given  $SS$ . Petters and  
56 Kreidenweis (2007) parameterized the Raoult term with a single hygroscopicity factor  
57  $\kappa$  to capture the water activity without needing to know anything about the dissolved  
58 compounds. Different perspectives have been presented on the influence of particle size  
59 and composition on the CCN activation. In terms of a single aerosol particle, the actual  
60 particle size plays a more important role than the chemical composition for activation  
61 because of the different range in which  $\kappa$  and particle diameter ( $D_p$ ) vary and the  
62 reciprocal relationship between  $\kappa$  and the third power of the critical  $D_p$  ( $D_c^3$ ) at a given  
63  $SS$ . As for a population of aerosol particles, Dusek et al. (2006) concluded that particle  
64 number size distribution (PNSD) matters more than the chemical composition  
65 distribution, which has been supported by many experiments. Even sometimes,  
66 assuming a constant  $\kappa$  still predicted CCN number concentration ( $N_{CCN}$ ) well (e.g., Sihto  
67 et al., 2011; Wang et al., 2018a). Andreae and Rosenfeld (2008) reviewed the previous  
68 studies on aerosol particle activation and recommended that for modeling purposes, the  
69 global  $\kappa$  values of  $0.3 \pm 0.1$  and  $0.7 \pm 0.2$  can be representative for continental and marine  
70 aerosol, respectively, which has been widely used to predict  $N_{CCN}$ . The regional  
71 variability should be emphasized because the mean  $\kappa$  measured in urban, rural, and  
72 forest exhibits significant differences. For instance, Sihto et al. (2011) suggested an  
73 average  $\kappa$  of 0.18 to predict the CCN activation well in boreal forest conditions in

74 Hyytiälä, Finland. A fixed  $\kappa$  of 0.31 suffices to calculate the  $N_{CCN}$  in a suburban site  
75 located in the center of the North China Plain (Wang et al., 2018a). The mean  $\kappa$  is 0.5  
76 in a near-coast background station (CESAR Tower) in Netherlands (Schmale et al.,  
77 2018). The median  $\kappa$  ranges from 0.02 to 0.16 at  $SS = 0.1\text{--}1.0\%$  in an urban background  
78 site in Budapest, Hungary (Salma et al., 2021). Therefore, the assumption of a constant  
79  $\kappa = 0.3$  may not be appropriate when trying to predict  $N_{CCN}$  for different continental  
80 regions.

81 Additionally, some experiments, especially conducted on more diverse particulate  
82 sources, have indicated chemistry does play an important role in  $N_{CCN}$  variability (e.g.,  
83 Nenes et al., 2002; Petters and Kreidenweis, 2007; Rose et al., 2010). Not only the bulk  
84 chemical composition with a constant  $\kappa$  should be considered for  $N_{CCN}$  prediction, but  
85 the size-resolved chemical composition (Deng et al., 2011; Wu et al., 2016) and the  
86 mixing state should be applied (Su et al., 2010; Zhang et al., 2014). Information on the  
87 organic aerosol fraction improves  $N_{CCN}$  prediction considerably (Poulain et al., 2010;  
88 Zhang et al., 2016; Kuang et al., 2020). Freshly formed particles are about 1 nm in  
89 diameter (Kulmala et al., 2012), which must grow to tens of nanometers in diameter to  
90 serve as the effective CCN at a relatively high  $SS$  of  $\sim 1\%$  (Dusek et al., 2006) and even  
91 larger than 200 nm to be efficient at  $SS$  less than 0.1% (Deng et al., 2013). Aerosol  
92 chemical composition changes during the growing and aging processes. For instance,  $\kappa$   
93 increases with particle size caused by photochemical processes which enhancing  
94 secondary inorganic species formation and going along with an increase in particle size  
95 (Massling et al., 2009; Zhang et al., 2017; Wang et al., 2018b). On the other hand, in  
96 sulfate dominated new particle formation (NPF) events with subsequent particle growth  
97 by condensation of organic vapors, the  $\kappa$  of small particles may exceed the  $\kappa$  of the  
98 larger ones (Wang et al., 2018a). If the  $\kappa$  of organic aerosol increases from 0.05 to 0.15,

99 the global average aerosol radiative forcing would decrease by  $\sim 1 \text{ W m}^{-2}$ , which is in  
100 the same order of magnitude as the overall climate forcing of anthropogenic aerosol  
101 during the industrialization period (Rastak et al., 2017).

102 To obtain the regional parameters of aerosol particle activation, extensive field  
103 campaigns have been conducted worldwide. Besides the significant difference in spatial,  
104 also the temporal variations of aerosol activation characteristics are essential for  $N_{CCN}$   
105 prediction (Andreae and Rosenfeld, 2008). Most of the observations lasted 1–2 months  
106 or even less, mainly focusing on the effects of short-term weather processes or pollution  
107 events on aerosol particle activation, such as the effects of the summer monsoon  
108 (Jayachandran et al., 2020), wet removal (Croft et al., 2009), NPF events (Dusek et al.,  
109 2010; Wu et al., 2015), biomass burning (Rose et al., 2010), and aerosol particle aging  
110 as well as oxidation processes (Zhang et al., 2016, 2017). The long-term CCN  
111 measurements (of at least one full year) are still rarely reported, resulting in insufficient  
112 knowledge concerning the seasonal and annual cycles of aerosol particle activation,  
113 which are also critical for model predictions and evaluations. Burkart et al. (2011)  
114 reported the particle activation in the urban background aerosol of Vienna, Austria,  
115 based on 11-month aerosol and CCN concentration measurements. Paramonov et al.  
116 (2015) reported a synthesis of CCN measurements within the EUCAARI network using  
117 the long-term data collected at 14 locations. Pöhlker et al. (2016) presented the  
118 climatology of CCN properties of a remote central Amazonian rain forest site using 1-  
119 year measurements. Che et al. (2017) provided the aerosol-activation properties in the  
120 Yangtze River Delta, China, based on  $\sim 1$ -year measurements. Using the long-term (of  
121 most  $> 1$  year) aerosol and CCN concentration measurements from 12 sites, Schmale  
122 et al. (2018) presented the spatial differences in aerosol particle activation for various  
123 regional backgrounds. However, systematic studies focusing on the seasonal cycle of

124 size-resolved particle activation and respective CCN predictions are still scarce in the  
125 central European continent. Such a study would be of great help for understanding ACI  
126 and narrowing down the regional uncertainties in climate predictions.

127 In this investigation, more than 4-year comprehensive measurements of aerosol  
128 physical, chemical, and activation properties collected at the ACTRIS (Aerosol, Clouds  
129 and Trace Gases Research Infrastructure, <http://www.actris.eu/>) site Melpitz, Germany,  
130 are utilized. The major objective is to gain insight into the aerosol particle activation  
131 and provide recommendations on methods for  $N_{CCN}$  predictions. We present therefore  
132 the long-term observations and seasonal cycles of various particle activation variables  
133 such as  $N_{CCN}$ , activation ratio, critical diameter, size-resolved  $\kappa$  and mixing state.  
134 Furthermore, we evaluated the accuracy of  $N_{CCN}$  calculated from five different  
135 activation schemes and finally provide recommendations on  $N_{CCN}$  predictions at  
136 Melpitz and for other rural regions.

## 137 **2. Methodology**

### 138 **2.1 Experiment details**

139 Atmospheric aerosol measurements were conducted at the Melpitz observatory  
140 (51.54°N, 12.93°E, 86 m above sea level), 50 km to the northeast of Leipzig, Germany.  
141 The aerosol particles observed at Melpitz can be regarded as representative for the  
142 central European rural background conditions (Birmili et al., 2009). The surroundings  
143 of the site are mostly pastures and forests without significant sources of anthropogenic  
144 emissions. More detailed descriptions of the Melpitz site can be found, for example, in  
145 Poulain et al. (2020).

146 This study focuses on the physicochemical properties and the activation ability of  
147 aerosol particles using the data collected at Melpitz from August 2012 to October 2016.  
148 Figure 1 depicts the experimental setup. All instruments were in the same container

149 laboratory and utilized the same air inlet. Ambient aerosol particles were first pretreated  
150 through a PM<sub>10</sub> Anderson inlet and an automatic aerosol diffusion dryer kept the relative  
151 humidity in sampling lines less than 40% following the ACTRIS recommendations.  
152 Subsequently, the aerosol flow was divided into the different instruments using an  
153 isokinetic splitter. Particle number size distributions (PNSD) were measured using a  
154 Dual-mobility particle size spectrometer (D-MPSS, TROPOS-type; Birmili et al., 1999;  
155 Wiedensohler et al., 2012) with a diameter range of 5 – 800 nm. An aerosol chemical  
156 speciation monitor (ACSM, Aerodyne Inc; Ng et al., 2011) was used to measure the  
157 chemical compositions of the non-refractory submicron aerosol particulate matter  
158 (nitrate, sulfate, chloride, ammonium, and organics). A multi-angle absorption  
159 photometer (MAAP, model 5012, Thermo Scientific; Petzold and Schönlinner, 2004)  
160 was used to measure the particle light absorption coefficients and to estimate the  
161 equivalent black carbon (eBC) mass concentration. For simultaneous measurement of  
162 particle and CCN number size distributions, dried aerosol particles were passed through  
163 the bipolar charger to establish charge equilibrium (Wiedensohler, 1988) and then  
164 through a differential mobility analyzer (DMA) for selecting a monodisperse particle  
165 fraction. After the DMA, the flow was split to pass through a condensation particle  
166 counter (CPC, model 3010, TSI) to measure the total number concentration of the  
167 selected monodisperse condensation nuclei ( $N_{CN}$ ) and through a cloud condensation  
168 nuclei counter (CCNC, model 100, Droplet Measurement Technologies; Roberts and  
169 Nenes, 2005) to measure the  $N_{CCN}$ . Thus, the size dependent activated fraction (AF,  
170  $N_{CCN}/N_{CN}$ ) curve, i.e., the AF at a certain diameter ( $D_p$ ) of dry particles, could be  
171 obtained. The losses in both instruments were checked and it was corrected for in the  
172 inversion routine. The coupling between size selection and CCNC was programmed in  
173 a way that the size resolved measurements started only after the temperature and

174 thereby the *SS* of the CCNC was stabilized. As the diameter scan started after *SS*  
175 stabilization, the measurement itself was the same length at all *SS* conditions. At fully  
176 stabilized CCNC conditions we did one  $D_p$  scan at per *SS* setting. A total of five different  
177 *SS* conditions was set in the CCNC instrument (0.1%, 0.2%, 0.3%, 0.5%, and 0.7%). A  
178 complete *SS* cycle lasted ~2.5 hours and the slight variations in the 2.5h total *SS* cycle  
179 was only due to the waiting time until the temperature of the CCNC was stabilized.

180 All the instrumentation was frequently calibrated within the framework of the  
181 European Center for Aerosol Calibration (ECAC, <https://www.actris-ecac.eu/>). The  
182 ACSM was regularly calibrated according to the manufacturer's recommendations with  
183 350 nm monodispersed ammonium nitrate and ammonium sulfate particles (Freney et  
184 al., 2019). The D-MPSS was calibrated following the recommendations in  
185 Wiedensohler et al. (2018). Throughout the campaign, the CCNC was calibrated once  
186 a year following the procedures outlined in Rose et al. (2008) with using the E-AIM  
187 model (Clegg et al. 1998). The measurement uncertainties of these instruments should  
188 be noted. The uncertainty in the MAAP is within 10% (Müller et al., 2011), and those  
189 in the D-MPSS and CCNC are both on the order of 10% (Wiedensohler et al., 2018;  
190 Rose et al., 2008). For the *SS* setting in CCNC, Gysel and Stratmann (2013) pointed out  
191 that an achievable accuracy in *SS* is 10 % (relative) at  $SS > 0.2\%$ , and less than 0.02 %  
192 (absolute) at the lower *SS*. For the ACSM data, the uncertainty in determining the total  
193 non-refractory mass is 9%. While for the individual chemical components, the  
194 uncertainty is 15% for nitrate, 28% for sulfate, 36% for ammonium, and 19% for  
195 organic matter (Crenn et al., 2015).

196 Due to instrument failures and maintenance operations, missing measurements  
197 occurred during the campaign. Effective data coverage is shown in Figure S1 in  
198 supporting information (SI). Overall, the CCNC, D-MPSS, and ACSM-MAAP

199 captured 45578 AF curves, 103052 PNSDs, and 26876-hour aerosol chemical  
200 measurements, which covered 63%, 92%, and 77% of the campaign time, respectively.  
201 For 42% of the time all these instruments were measuring together.

## 202 **2.2 Methods**

203 Each AF curve ( $N_{CCN}/N_{CN}$  vs.  $D_p$ ) was first corrected for multiply charged particles.  
204 Multiply (mostly doubly) charged particles appear in the AF curve as a plateau or  
205 shoulder at small diameters because they have the same electrical mobility diameter as  
206 singly charged smaller particles (Rose et al., 2008; Henning et al., 2014). To correct for  
207 this, the fraction of multiple charged particles as determined from the D-MPSS  
208 measurements was subtracted from each value of  $N_{CCN}/N_{CN}$  in AF. The PNSD from the  
209 D-MPSS measurements (5 to 800 nm) are needed as the DMA-CCNC size range does  
210 not cover the large particle fraction, which is essential for the correction. Subsequently,  
211 we obtained the corrected AF curves.

212 Each corrected AF curve was fitted with a sigmoid function,

$$AF = a + b / \left( 1 + \exp \left( - \frac{D_p - D_c}{\sigma_s} \right) \right) \quad (1)$$

213 Where  $a$  is the offset from 0 in the y direction and  $b$  is the height of the upper plateau  
214 of the sigmoidal function,  $D_c$  is the critical diameter, and  $\sigma_s$  is a measure for the width  
215 of the sigmoid function. This AF fit was multiplied with the PNSD to gain the CCN  
216 number size distribution and by integrating the total number of CCN, i.e.,  $N_{CCN}$ .

217 The critical diameter ( $D_c$ ) of dry particles,  $\kappa$ , and mixing state at each  $SS$  condition  
218 can be derived from the AF fit results. Affected by aerosol mixing, the AF rises  
219 gradually from 0 to the max ( $\sim 1$ ) rather than displaying an intermittent mutation.  $D_c$  is  
220 defined as the diameter of the dry particles from which 50% of the particles are activated  
221 at the given  $SS$ .

222 The shape of the AF curve, i.e., the relative width of the AF, represents the degree  
 223 of external mixture, which can be quantified by the ratio of  $(D_{75} - D_{25})/D_c$  (Jurányi et  
 224 al., 2013).  $D_{75}$  and  $D_{25}$  are the diameters at which 75% and 25% of the particles are  
 225 activated at the given  $SS$ . Internal mixture implies that all particles with any given dry  
 226 size have equal  $\kappa$  with  $(D_{75} - D_{25})/D_c = 0$ , whereas a distribution of different  $\kappa$  at a  
 227 given particle size can be observed for externally mixed aerosol with higher  $(D_{75} -$   
 228  $D_{25})/D_c$  values. Note that the particle composition varying at different sizes is not  
 229 defined as external mixing in this study. Jurányi et al. (2013) confirmed the reliability  
 230 of this approach by comparing the  $\kappa$  distributions derived from parallel monodisperse  
 231 CCN measurements and HTDMA measurements.

232 According to the derivation of  $\kappa$ -Köhler theory (Petters and Kreidenweis, 2007),  
 233 the  $\kappa$  can be calculated from  $D_c$  at a given  $SS$ :

$$\kappa = \frac{4A^3}{27D_c^3 \ln^2(1 + SS/100)} \quad (2a)$$

234 with

$$A = \frac{4\sigma_{s/a}M_w}{RT\rho_w} \quad (2b)$$

235 where  $\sigma_{s/a}$  is the droplet surface tension (assumed to be that of pure water,  $0.0728 \text{ Nm}^{-2}$ ),  
 236  $M_w$  the molecular weight of water,  $R$  the universal gas constant,  $T$  the absolute  
 237 temperature,  $\rho_w$  the density of water, and  $A$  can be considered a function of  $T$ . Thus, the  
 238 size-resolved  $\kappa$  (pair of  $\kappa$  and  $D_c$ ) can be obtained at each  $SS$  cycle. Our monodisperse  
 239 CCN measurements provide the size-resolved  $\kappa$  within  $D_p$  ( $D_c$ ) of  $\sim 40\text{--}200 \text{ nm}$ , which  
 240 depends largely on the  $SS$  setting of 0.1% to 0.7%. Note that equation 2a is derived from  
 241 an approximation of  $\kappa$ -Köhler equation and when  $\kappa$  is less than 0.2, it causes a slight  
 242 bias in calculating  $\kappa$  (Petters and Kreidenweis, 2007). Additionally, the debate about

243 the importance of  $\sigma_{s/a}$  changes and the connected bulk/surface partitioning on activation  
244 of aerosols is on ongoing (e.g., Ovadnevaite et al., 2017; Vepsäläinen et al., 2022),  
245 which is not focused on in this study.

246 Besides deriving it from the monodisperse CCN measurements,  $\kappa$  can be derived  
247 from the ACSM and MAAP chemical composition measurements ( $\kappa_{chem}$ ) using the  
248 Zdanovskii–Stokes–Robinson (ZSR) mixing rule (Zdanovskii, 1948; Stokes and  
249 Robinson, 1966) combined with  $\kappa$ -Köhler theory:

$$\kappa_{chem} = \sum_i \varepsilon_i \kappa_i \quad (3)$$

250 where  $\kappa_i$  and  $\varepsilon_i$  mean the  $\kappa$  and volume fraction for each component, respectively, and  
251  $i$  is the number of the component in the mixture. The  $\varepsilon_i$  was derived from its measured  
252 component  $i$  mass concentration and density ( $\rho_i$ ). A simple ion-pairing scheme (Gysel  
253 et al., 2007) was used in this study with the  $\kappa_i$  and  $\rho_i$  values listed in Table 1 (Wu et al.,  
254 2015). A  $\kappa$  of 0.1 is used for particulate organics (Dusek et al., 2010; Gunthe et al., 2009,  
255 2011). For black carbon, we use a  $\kappa$  of 0 (Rose et al., 2011; Schmale et al., 2018).

256 The CCN number size distribution is a part of the particle number size distribution  
257 (PNSD), which approximately corresponds to the part of PNSD with  $D_p > D_c$  when  
258 assuming particles to be internally mixed (Figure S2 in SI). The assumption of the  
259 internal mixing could be reasonable because the median values of the parameter  $b$  and  
260  $(D_{75} - D_{25})/D_c$  are 1.0 and 0.18. Thus,  $D_c$  plays a critical role on diagnosing  $N_{CCN}$  in  
261 models, which can be derived from  $\kappa$  parameterization at a given  $SS$ . When  $\kappa$  is obtained,  
262  $D_c(\kappa, SS)$  is calculated from equation 2a. And, assuming an internal mixture, the  
263 predicted  $N_{CCN}$  is the integration of the PNSD from  $D_c$ , that is,

$$Predicted N_{CCN} = \int_{D_c}^{800} PNSD(D_p) dD_p \quad (4)$$

## 264 **3. Results**

### 265 **3.1 Aerosol activation characteristics**

266 As  $SS$  increases, the CCN number size distribution broadens towards smaller  
267 particle sizes (Figure S3 in SI), causing an increase in  $N_{CCN}$  and activation ratio (AR,  
268 i.e., ratio of  $N_{CCN}$  to total aerosol number concentration with a diameter range of 10 to  
269 800 nm,  $N_{aero}$ ). At Melpitz, the median  $N_{CCN}$  and AR increase from 399 to 2144  $\text{cm}^{-3}$   
270 and 0.10 to 0.48 when  $SS$  increases from 0.1% to 0.7%. As shown in Figure 2, the  $N_{CCN}$   
271 measured at Melpitz is slightly higher than that measured in more remote rural  
272 background stations, e.g., in Vavihill, Sweden (Fors et al., 2011), Hyytiälä, Finland  
273 (Paramonov et al., 2015), Southern Great Plains, USA (Liu and Li, 2014),  
274 Mahabaleshwar, India (Singla et al., 2017). However, compared to the  $N_{CCN}$  measured  
275 in polluted regions (e.g., Rose et al., 2010; Deng et al., 2011; Kim et al., 2014; Varghese  
276 et al., 2016), the Melpitz  $N_{CCN}$  is much lower.

277 Figure 3a presents the  $N_{CCN}$  vs.  $SS$  and AR vs.  $SS$  relationships at each season and  
278 all datasets at Melpitz. The two relationships are similar, and both can be fitted well  
279 with using a power-law function (Twomey, 1959). The fit was also performed with an  
280 error function (Pöhlker et al., 2018) and the fitted parameters are in SI (Table S2). Over  
281 the whole period, the median values of the slope parameter and the coefficient in the  
282  $N_{CCN}$ - $SS$  power-law fit are 2851  $\text{cm}^{-3}$  and 0.75, respectively, which are within the range  
283 of values for continental aerosol (slope parameter of 600–3500  $\text{cm}^{-3}$  and coefficient of  
284 0.4–0.9) reported in Seinfeld and Pandis (2016). The slope parameters in the power-law  
285 fitting represent the sensitivity of the  $N_{CCN}$  and AR to the variation in  $SS$ , which are  
286 highest in summer and lowest in winter. The seasonal variations of  $N_{CCN}$  and AR at  $SS$   
287 = 0.1% and 0.7% are shown in Figure 3b. In summer, the median  $N_{CCN}$  and AR are both  
288 lowest at  $SS = 0.1\%$ , which contributed to the largest sensitivity of  $N_{CCN}$  and AR to  $SS$ ,

289 i.e., the largest slope parameter in the power-law fitting among the four seasons.  
290 Additionally, the shape of the PNSD contributed to explain the sensitivity of  $N_{CCN}$  and  
291 AR to  $SS$ . The PNSD in summer was steepest in the 40-200 nm size range among the  
292 four seasons (Figure S4 in SI). Thus, in summer, a small shift in  $D_c$  will change the  
293  $N_{CCN}$  and AR much more than those in winter where the PNSD looks broader, causing  
294 the strong sensitivity of  $N_{CCN}$  and AR to  $SS$ .

295 To explain the seasonal variations in aerosol activation characteristics, we  
296 investigated the PNSD and chemical compositions as shown in Figure 4. In summer,  
297 affected by the frequent NPF events (Ma et al., 2015; Wang et al., 2017), the Aitken-  
298 mode particles with  $D_p < 100$  nm accounted for the largest portion of the PNSD (Figure  
299 S4 in SI), resulting in the highest  $N_{aero}$  and the smallest geometric mean diameter  
300 ( $GMD = \exp\left(\frac{\sum_i n_i \times \ln D_i}{N_{aero}}\right)$ ) among the four seasons. Additionally, in summer, there was  
301 the lowest bulk  $\kappa_{chem}$  with median value of 0.24 corresponding to the highest organic  
302 mass fraction (56% of total mass), which could be related to the strong formation of the  
303 secondary organic aerosol (SOA). Therefore, the  $N_{CCN}$  and AR both kept relatively low  
304 values in summer, especially at low  $SS$  conditions (e.g., at  $SS = 0.1\%$ ). On the contrary  
305 in winter, the relatively low number concentration of Aitken-mode particles caused the  
306 lowest  $N_{aero}$  and the largest  $GMD$  among the four seasons, which could be owing to the  
307 rare NPF events. Meanwhile, in winter, low temperatures favored the particulate phase  
308 of nitrate (Poulain et al., 2011), causing the highest nitrate mass fraction (31% of total  
309 mass) among the four seasons, which might explain the highest  $\kappa_{chem}$  (median value of  
310 0.34). Taking all three together, the lowest  $N_{aero}$ , the largest  $GMD$ , as well as the highest  
311  $\kappa_{chem}$ , contribute to the highest AR value in winter at each  $SS$  condition. The  
312 relationships between  $\kappa_{chem}$  and each particle component, and the correlations among  
313 seasonal median values of  $N_{aero}$ ,  $GMD$ , and  $\kappa_{chem}$  are in SI (Text S1, Figures S5 and S6).

314 Additionally, no significant yearly trends of the CCN activation characteristics are  
315 found during the 4-year measurements and the results are provided in SI (Text S2 and  
316 Figure S7).

### 317 **3.2 Size-resolved particle hygroscopicity factor and mixing state**

318 The hygroscopicity factor and the mixing state directly influence the  $D_c$  and the  
319 shape of the AF curve, thereby changing the  $N_{CCN}$  at a given  $SS$  condition. Affected by  
320 the variations of particle composition, these two parameters are not constant and both  
321 vary with particle size and season.

322 Figure 5a shows monthly median values of  $\kappa_{chem}$  and  $\kappa$  calculated from  
323 monodisperse CCN measurements ( $\kappa_{CCN}$ ) at  $SS$  of 0.1% and 0.7%. Their seasonal  
324 median values are summarized in Table 2. At Melpitz, the median  $\kappa_{CCN}$  decreased from  
325 0.27 to 0.19 as  $SS$  increased from 0.1% to 0.7%, which was less than the median  
326 bulk  $\kappa_{chem}$  of 0.3. The seasonal variation of  $\kappa_{CCN}$  at  $SS$  of 0.1% is similar to that of  $\kappa_{chem}$ ,  
327 whereas the seasonal trend in  $\kappa_{CCN}$  is much weaker at  $SS = 0.7\%$ . Essentially, the  
328 relationship between  $\kappa_{CCN}$  and  $SS$  is determined by the  $\kappa_{CCN}$  vs.  $D_p$  relationship. The  
329  $\kappa_{CCN}$  at  $SS$  of 0.1% and 0.7% correspond to the median  $D_c$  (i.e.,  $D_p$ ) of 176 and 54 nm,  
330 respectively. As the ACSM is sensitive to particle mass rather than number  
331 concentration, the bulk composition is dominated by the contribution of the larger  
332 particles. In the median volume size distribution of particle, the peak diameter was at  
333  $\sim 300$  nm (Poulain et al., 2020). Thus,  $\kappa_{chem}$  may be representative for the larger particles  
334 rather than for the smaller particles. Owing to the positive correlation between  $\kappa$  and  
335  $D_p$  (Figure 6a), the  $\kappa_{chem}$  representing for the larger particles could be greater than the  
336  $\kappa_{CCN}$  for the smaller particles. Figure 5b depicts the monthly variation of  $D_c$  at  $SS$  of  
337 0.1% and 0.7%, which shows the opposite trend to  $\kappa_{CCN}(SS)$  because of the negative

338 correlation of  $D_c^3(SS)$  vs.  $\kappa(SS)$  shown in equation 2a. Compared to the  $D_c$  at lower  $SS$   
339 conditions (e.g., 0.1%),  $D_c$  has a more significant seasonal trend at higher  $SS$  conditions  
340 (e.g., 0.7%). At  $SS = 0.7\%$ , the low  $\kappa_{CCN}$  caused the large  $D_c$  in summer, whereas the  
341 high  $\kappa_{CCN}$  caused the small  $D_c$  in spring and winter.

342 The monthly trend of the external-mixing degree  $((D_{75} - D_{25})/D_c)$  is shown in  
343 Figure 5c. Jurányi et al. (2013) pointed out that the  $(D_{75} - D_{25})/D_c$  ranged from 0.08 to  
344 0.12 for ammonium sulfate calibration measurements at  $SS = 0.1-1.0\%$ , which  
345 indicated an internal mixture within measurement accuracy. For our measurements, the  
346 median  $(D_{75} - D_{25})/D_c$  over all datasets range from 0.15 to 0.20 at  $SS = 0.1-0.7\%$ . The  
347 median  $(D_{75} - D_{25})/D_c$  was low in summer and spring and high in winter and autumn.  
348 The results tend to indicate that the aerosol particles at Melpitz were more internally  
349 mixed in summer and spring whereas less internally mixed in winter and autumn. In  
350 summer, the less contribution from anthropogenic emissions and the faster aging  
351 process as well as SOA formation caused by atmospheric chemistry certainly contribute  
352 to make particles more internally mixed. Changes in organic aerosol (OA) composition  
353 can be found in Crippa et al. (2014), Poulain et al. (2014), and Chen et al. (2022). In  
354 cold seasons, the local pollution (100 km around) is dominated by liquid fuel, biomass,  
355 and coal combustions mostly for house heating (van Pinxteren et al., 2016). During  
356 winter long-range transport from the eastern wind bring to the station continental air  
357 masses which are strongly influence by anthropogenic emissions (in opposition to  
358 western marine air masses). These particles are a mixture of different anthropogenic  
359 sources emitted all along the transport as well as including some local and regional  
360 sources (most house heating). All of them at different aging state cause the overall  
361 particles more externally mixed.

362 As mentioned above,  $\kappa_{CCN}$  (and  $(D_{75} - D_{25})/D_c$ ) vs.  $D_p$  relationships determine the

363 relationship between  $\kappa_{\text{CCN}}$  (and  $(D_{75} - D_{25})/D_c$ ) and  $SS$ . Monodisperse CCN  
364 measurements provide the size-resolved  $\kappa$  and  $(D_{75} - D_{25})/D_c$ . At a given  $SS$  condition,  
365  $\kappa_{\text{CCN}}$  represents the  $\kappa$  of particles at  $D_p = D_c$ , and the same is true for  $(D_{75} - D_{25})/D_c$ . As  
366 shown in Figure 6a,  $\kappa_{\text{CCN}}$  increases with  $D_p$  at  $D_p$  range of  $\sim 40$  to 100 nm, whereas  $\kappa_{\text{CCN}}$   
367 almost stays constant at  $D_p$  of 100 to 200 nm for all seasons. Additionally, the increase  
368  $\kappa_{\text{CCN}}$  with  $D_p$  varies with season. The  $\kappa_{\text{CCN}}$  vs.  $D_p$  relationship is fitted by a power-law  
369 function at each season. In summer, there is the lowest slope parameter in the  $\kappa_{\text{CCN}}$  vs.  
370  $D_p$  power-law fit, meaning that the  $\kappa_{\text{CCN}}$  is least sensitive to  $D_p$ . Compared to the cold  
371 seasons, the anthropogenic emissions linked to house heating strongly reduce in  
372 summer which affects the smaller particles, and the dominant small particles ( $D_p < 100$   
373 nm) are associated to NPF and the SOA formation. NPF is a complex process which  
374 depends on the availability of condensing material ( $\text{H}_2\text{SO}_4$  and organic), as well as pre-  
375 existing particles (coagulation and condensation sink parameters). Therefore, same  
376 condensing material on the gas phase can either condense on pre-existing particles  
377 (usually larger than 100 nm and then detected by ACSM) or lead to NPF formation. A  
378 direct consequence of it is a probable smaller effect of the size dependent chemical  
379 composition of the particles. This might explain why  $\kappa_{\text{CCN}}$  at  $SS$  of 0.1% and 0.7 % are  
380 closer, i.e., the weaker sensitive of  $\kappa_{\text{CCN}}$  to  $D_p$  in summer. Figure 6b presents the  $(D_{75} -$   
381  $D_{25})/D_c$  vs.  $D_p$  relationship. As particle size increases,  $(D_{75} - D_{25})/D_c$  decreases at  $D_p$  of  
382  $\sim 40$  to 200 nm for all seasons, meaning that small particles are less internally mixed.  
383 The reason is that during the aerosol aging process, not only particle size increases but  $\kappa$   
384 becomes more uniform. The  $(D_{75} - D_{25})/D_c$  vs.  $D_p$  relationship is also fitted well by a  
385 power-law function at each season. The lowest absolute value of the slope parameter  
386 was observed in summer, indicating that the degree of external mixture was least  
387 sensitive to  $D_p$ , which could be related to the less mixing between the local emissions

388 and long-range transport particles in summer.

### 389 **3.3 $N_{CCN}$ prediction at Melpitz**

390  $N_{CCN}$  plays an important role in modeling the formation and evolution of clouds.  
391 In this section, we evaluate the accuracy of  $N_{CCN}$  predicted from five schemes. Table 3  
392 introduces the five schemes, which can be summarized into two categories. From  
393 polydisperse CCN measurements, the  $N_{CCN}$  (AR) and  $SS$  relationships can be obtained,  
394 and their fitting results can be used to predict  $N_{CCN}$  at the given  $SS$  conditions, which  
395 belongs to the 1<sup>st</sup> category, corresponding to the N1 and N2 schemes in Table 3,  
396 respectively. Compared to CCN measurements, it is generally more common and  
397 simpler to obtain the PNSD measurements. Thus, we usually predict  $N_{CCN}$  using the  
398 real-time PNSD combined with the parameterized  $\kappa(D_c)$ , which belongs to the 2<sup>nd</sup>  
399 category. The 2<sup>nd</sup> category includes the last three schemes (K1, K2, and K3) in Table 3,  
400 but they vary in assuming  $\kappa$ . The K1 scheme used a fixed  $\kappa$  of 0.3 without temporal and  
401 size-dependent variations, as recommended for continental aerosol (Andreae and  
402 Rosenfeld., 2008), which is also the median value of  $\kappa_{chem}$  over all data setting at  
403 Melpitz. The K2 scheme used the bulk  $\kappa_{chem}$  calculated from aerosol chemical  
404 composition, which is also non-size-dependent but changes over time. The K3 scheme  
405 used the  $\kappa - D_p$  power-law fit results shown in Figure 6a, which are size-dependent  
406 without temporal variations at each season. Applying the  $\kappa - D_p$  power-law equation  
407 into equation 2a,  $D_c$  can be derived as function of  $SS$ ,

$$D_c = \left( \frac{4 \times A^3}{27 \times coef \times \ln^2(1 + SS/100)} \right)^{\frac{1}{slope+3}} \quad (5)$$

408 where the *slope* and *coef* represent the slope parameter and the coefficient in  $\kappa - D_p$   
409 power-law fit. Subsequently, the predicted  $N_{CCN}$  can be calculated through equation 4.  
410 The 2<sup>nd</sup> category assumed that aerosol particles are internally mixed at a particular  $D_p$ ,

411 as used in many previous  $N_{CCN}$  prediction studies (e.g., Deng et al., 2013; Pöhlker et al.,  
412 2016; Wang et al., 2018a).

413 The prediction results are shown in Figure 7. The linear equation ( $y = kx$ ) is used  
414 to fit the relationship between the predicted  $N_{CCN}$  and the measured one, and its slope  
415 represents the mean ratio of the predicted  $N_{CCN}$  to the measured  $N_{CCN}$ . The relative  
416 deviation (RD) equals the ratio of the absolute difference between the predicted  $N_{CCN}$   
417 and the measured one to the measured  $N_{CCN}$ ,

$$RD = \frac{|predicted\ N_{CCN} - measured\ N_{CCN}|}{measured\ N_{CCN}}. \quad (6)$$

418 The median RD was used to quantify the deviation between predictions and  
419 measurements of each scheme. The slope and median RD shown in Figure 7 are both  
420 calculated from all five  $SS$  conditions for each season. As shown in Figure 7, the N1  
421 and N2 schemes only provide rough estimates of the  $N_{CCN}$  which is reflected in the high  
422 median RD. The results for N1 and N2 schemes are similar in that they both predict the  
423 overall mean  $N_{CCN}$  well (slopes of approximately 1.0) but with large median RDs.  
424 Compared to N1 scheme, the N2 scheme is better because of the lower median RD.  
425 Compared to the 1<sup>st</sup> category (the N1 and N2 schemes), the 2<sup>nd</sup> category (the K1, K2,  
426 and K3 schemes) predicts  $N_{CCN}$  better because of the lower median RD. The results for  
427 K1 and K2 are similar in that they both overestimate  $N_{CCN}$  by approximately 10%  
428 (slopes of approximately 1.1) with similar median RDs. The reason for the  $N_{CCN}$   
429 overestimation is that the constant  $\kappa$  of 0.3 and the real-time bulk  $\kappa_{chem}$  are both greater  
430 than the  $\kappa_{CCN}$  at each season. In winter, the  $\kappa_{CCN}$  was highest and the difference between  
431 the  $\kappa_{CCN}$  and the parameterized  $\kappa$  in K1 and K2 scheme was lowest, causing the best  
432 prediction of  $N_{CCN}$  among the four seasons. Owing to the largest difference between the  
433  $\kappa_{CCN}$  and the parameterized  $\kappa$ , the  $N_{CCN}$  prediction was worst in summer for K1 scheme

434 and in autumn for K2 scheme. The K3 scheme appears to be the best one for  $N_{CCN}$   
435 prediction among the five schemes which is reflected in the lowest median RDs and the  
436 fit slope of  $\sim 1.0$  for different seasons. The evaluations of the five schemes for the  $N_{CCN}$   
437 prediction at each  $SS$  condition and each season are provided in Figure S8 in SI.

438 The K3 scheme provides an improved prediction of  $N_{CCN}$ , which is obvious when  
439 compared to N1 and N2 schemes. Compared to K1 and K2 schemes, the K3 scheme  
440 reduced approximately 10% overestimation of  $N_{CCN}$  because the fitting slope decreased  
441  $\sim 0.1$  on average. We simply evaluate the effects of the 10% overestimation in  $N_{CCN}$  on  
442 predictions of cloud radiative forcing and precipitation. The methods are in Text S3 in  
443 SI and Wang et al. (2019). Essentially, an overestimation of  $N_{CCN}$  leads to overestimate  
444 the number concentration of cloud droplet ( $N_C$ ) in models. Theoretically, it can reduce  
445 3.2% overestimation of cloud optical thickness, corresponding to global average  
446 difference of  $1.28 \text{ Wm}^{-2}$  when assuming the cloud shortwave cooling effect of  $40 \text{ Wm}^{-2}$   
447 <sup>2</sup> (Lee et al., 1997), which amounts to approximately one-third of the direct radiative  
448 forcing from a doubling  $\text{CO}_2$ . Additionally, the overestimation in  $N_{CCN}$  (and  $N_C$ ) leads  
449 to underestimate the strength of the autoconversion process in cloud (Liu et al., 2006),  
450 thereby suppressing precipitation. Therefore, although ACSM measurements can derive  
451  $\kappa_{\text{chem}}$  and thus predict  $N_{CCN}$ , the monodisperse CCN measurements are still important  
452 to obtain the  $\kappa - D_p$  relationship and thus improve the predictions of  $N_{CCN}$  (and  $N_C$ ) and  
453 climate.

454 Figure 8 compared the  $\kappa - D_p$  relationship measured at different regions. The  $\kappa -$   
455  $D_p$  relationship measured at Melpitz is similar to that measured at other rural regions  
456 with similar  $\kappa - D_p$  power-law fitting results, e.g., the Vavihill station in Sweden (Fors  
457 et al., 2011) and the Xinken station in China (Eichler et al., 2008). Therefore, the  $\kappa - D_p$   
458 power-law fit measured at Melpitz could be applied to predict  $N_{CCN}$  for these rural

459 regions. We conducted a CCN closure test to support this conclusion. Due to lacking  
460 the data of PNSD and CCN measurements at Vavihill and Xinken stations, we applied  
461 the  $\kappa - D_p$  power-law fitting measured at the two rural stations (green and purple lines  
462 in Figure 8) to predict the  $N_{CCN}$  at Melpitz. Good prediction results were obtained with  
463 mean deviations of  $\sim 1\%$  (Figure S9 in SI). However, it may cause considerable  
464 deviations for different aerosol background regions, e.g., the suburb stations in Xingtai,  
465 China (Wang et al., 2018a), Xinzhou, China (Chen et al., 2022), and Paris, France  
466 (Mazoyer et al., 2019), the coast of Barbados (Kristensen et al., 2016), the amazon  
467 rainforest (Pöhlker et al., 2016), and the urban stations in Budapest, Hungary (Salma et  
468 al., 2021), Guangzhou, China (Chen et al., 2022), and Shanghai, China (Ye et al., 2013),  
469 because their  $\kappa - D_p$  relationships are different from that measured at Melpitz.

#### 470 **4. Conclusions**

471 Aerosol particle activation plays an important role in determining  $N_C$ , thereby  
472 affecting cloud microphysics, precipitation processes, radiation, and climate. To reduce  
473 the uncertainties and gain more confidence in the simulations on AIEs, long-term  
474 measurements of aerosol activation characteristics are essential. However, they are still  
475 rarely reported. Based on more than 4-year comprehensive measurements conducted at  
476 the central European ACTRIS site Melpitz, Germany, this study presents a systematic  
477 seasonal analysis of aerosol activation characteristics and  $N_{CCN}$  predictions.

478 Over the whole period at Melpitz, the median  $N_{CCN}$  and AR increased from 399 to  
479  $2144 \text{ cm}^{-3}$  and 0.10 to 0.48 with  $SS$  increasing from 0.1% to 0.7%, respectively. Aerosol  
480 activation characteristics are highly variable across seasons, especially at relatively low  
481  $SS$  conditions. For instance at  $SS = 0.1\%$ , the median  $N_{CCN}$  and AR in winter are 1.6 and  
482 2.3 times higher than the summer values, respectively. Aerosol particle activation  
483 depends on its physical and chemical properties. In summer, the highest  $N_{aero}$ , smallest

484 *GMD*, and lowest  $\kappa_{\text{chem}}$  all contribute to the lowest AR and  $N_{\text{CCN}}$  among the four seasons,  
485 and the reverse holds true in winter. Additionally, in summer, the steepest PNSD in 40-  
486 200 nm size range and the lowest  $\kappa_{\text{chem}}$  causes the strongest sensitivity of  $N_{\text{CCN}}$  and AR  
487 to *SS* even though the spread in  $\kappa_{\text{CCN}}$  is narrowest.

488 Both  $\kappa$  and the mixing state are size-dependent, thereby varying with *SS*. The  
489 median  $\kappa_{\text{CCN}}$  decreases from 0.27 to 0.19 as *SS* increases from 0.1% to 0.7%, which  
490 was less than the median bulk  $\kappa_{\text{chem}}$ . The seasonal trend of  $\kappa_{\text{CCN}}$  was similar to that of  
491  $\kappa_{\text{chem}}$ , especially at relatively low *SS* conditions. The lowest  $\kappa_{\text{CCN}}$  and  $\kappa_{\text{chem}}$  were  
492 observed in summer, which related to the highest organics mass fraction in particles.  
493 Aerosol particles were more internally mixed in summer and spring whereas less  
494 internally mixed in winter and autumn. In cold seasons, the increasing anthropogenic  
495 emissions linked to house heating mixed with the aged particles from long-range  
496 transport, which could decrease the degree of external mixing of particles. As  $D_p$   
497 increases,  $\kappa_{\text{CCN}}$  increases at  $D_p$  range of ~40 to 100 nm and almost stays constant at  $D_p$   
498 range of 100 to 200 nm, whereas the  $(D_{75} - D_{25})/D_c$  monotonically decreases. The  
499 relationships of  $(D_{75} - D_{25})/D_c$  vs.  $D_p$  and  $\kappa$  vs.  $D_p$  are both fitted well by a power-law  
500 function for each season.

501 Five activation schemes are evaluated on the  $N_{\text{CCN}}$  predictions. Compared to using  
502 the classic  $N_{\text{CCN}} - SS$  or  $AR - SS$  power-law fits to predict  $N_{\text{CCN}}$ , the prediction is better  
503 by using the real-time PNSD combined with the parameterized  $\kappa$ , including a constant  
504  $\kappa$  of 0.3, the bulk  $\kappa_{\text{chem}}$ , and the  $\kappa - D_p$  power-law fit. However, assuming a constant  $\kappa$   
505 of 0.3 recommended for continental aerosol (Andreae and Rosenfeld., 2008) or the bulk  
506  $\kappa_{\text{chem}}$  calculated from aerosol chemical composition both cause significant  
507 overestimations of the  $N_{\text{CCN}}$  with approximately 10% in median for all *SS* conditions,

508 which theoretically cause 3.2% overestimation of cloud optical thickness, amounting to  
509 approximately one-third of the direct radiative forcing from a doubling CO<sub>2</sub> (Lee et al.,  
510 1997). And, the strength of the autoconversion process in cloud could be  
511 underestimated (Liu et al., 2006). Size-resolved  $\kappa$  improves the  $N_{CCN}$  prediction. We  
512 recommend applying the  $\kappa - D_p$  power-law fit for  $N_{CCN}$  prediction, which obtains the  
513 best prediction among the five schemes.

514 The  $\kappa - D_p$  power-law fit presented in this study could apply to other rural regions.  
515 However, it may cause considerable deviations for different aerosol background regions.  
516 For instance, using the  $\kappa - D_p$  power-law fit measured in urban Budapest (Salma et al.,  
517 2021) for predicting Melpitz  $N_{CCN}$ , it could cause a 39% underestimation of  $N_{CCN}$  in  
518 median for all  $SS$  conditions. Additionally, the seasonal difference of the  $\kappa - D_p$   
519 relationship needs to be considered carefully for  $N_{CCN}$  prediction. At Melpitz, if the  $\kappa -$   
520  $D_p$  power-law fit measured in summer was used for predicting  $N_{CCN}$  in winter, it could  
521 cause a 13% underestimation of  $N_{CCN}$  in median for all  $SS$  conditions. Although the  $\kappa -$   
522  $D_p$  relationships are similar measured in rural stations, but when comparing the different  
523 urban stations (e.g., shanghai vs. Budapest in Figure 8), these relationships are clearly  
524 different and the reasons for the difference are still unclear. Thus, long-term  
525 monodisperse CCN measurements are still needed not only to obtain the  $\kappa - D_p$   
526 relationships for different regions and for different seasons, but furtherly investigate the  
527 reasons for the difference of the  $\kappa - D_p$  relationships measured at same type of regions.  
528 Finally for the purpose of predicting  $N_{CCN}$ , the measurements of monodisperse CCN  
529 and particle chemical compositions are more expected, compared to the polydisperse  
530 CCN measurements.

531

532 **Appendix Notation list**

$A$	comprehensive parameter for $\sigma_{s/a}$ , $M_w$ , $R$ , $T$ , and $\rho_w$ in equation (2b)
$a$	lower limit for calculating critical diameters at the set-nominal supersaturations in equation (1)
ACI	aerosol and cloud interactions
ACSM	aerosol chemical species monitor
ACTRIS	Aerosol, Clouds and Trace Gases Research Infrastructure
AF	activated fraction, i.e., $N_{CCN}/N_{CN}$
AIEs	aerosol indirect effects
AR	activation ratio, i.e., $N_{CCN}/N_{aero}$
$b$	upper limit for calculating critical diameters at the set-nominal supersaturations in equation (1)
BC	black carbon
CN	condensation nuclei
CCN	cloud condensation nuclei
CCNC	cloud condensation nuclei counter
$coef$	coefficient in $\kappa - D_p$ power-law fit
CPC	condensation particle counter
$D_p$	diameter of the dry particle
$D_c$	critical diameter of the dry particle
$D_X$	$D$ at which X % of the particles are activated
$(D_{75} - D_{25})/D_c$	degree of external mixture
D-MPSS	Dual-mobility particle size spectrometer
DMA	differential mobility analyzer
eBC	equivalent black carbon
$f_{BC}$	mass fraction of BC in submicron aerosol
$f_{nitrate}$	mass fraction of nitrate in submicron aerosol
$f_{org}$	mass fraction of organics in submicron aerosol
$f_{sulfate}$	mass fraction of sulfate in submicron aerosol
GMD	geometric mean diameter of PNSD
$M_w$	molecular weight of water
$N_{aero}$	number concentration of aerosol with a $D_p$ range of 10 to 800 nm
$N_C$	number concentration of cloud droplet
$N_{CN}$	number concentration of CN
$N_{CCN}$	number concentration of CCN
NPF	new particle formation
OA	organic aerosol
PM <sub>10</sub>	particulate matter with the $D_p < 10 \mu\text{m}$
PNSD	particle number size distribution
$R$	universal gas constant
$R^2$	coefficient of determination
RD	relative deviation between the predicted $N_{CCN}$ and the measured one
SI	Supporting information

$SS$	supersaturation
SOA	secondary organic aerosol
$T$	temperature
$\sigma_s$	represent the shape of the sigmoid function
$\sigma_{s/a}$	droplet surface tension
$\kappa$	hygroscopicity factor of aerosol particle
$\kappa_i$	$\kappa$ of each component
$\kappa_{CCN}$	$\kappa$ calculated from the monodisperse CCN measurements
$\kappa_{chem}$	$\kappa$ calculated from the aerosol chemical measurements
$\varepsilon_i$	volume fraction of each component
$\rho_w$	density of the liquid water

533

534 ***Data availability.***

535 The data used in this study are available from Silvia Henning ([henning@tropos.de](mailto:henning@tropos.de))

536 upon request and <https://doi.org/10.1594/PANGAEA.938215>.

537 ***Author contributions.***

538 AW, SH and LP designed the research. SH and LP collected the data at Melpitz. YW  
539 performed the data analysis and prepared the paper. All co-authors contributed to  
540 interpretation of the results as well as paper review and editing.

541 ***Competing interests.***

542 The authors declare that they have no conflict of interest.

543 ***Acknowledgments.***

544 This research has been supported by the H2020 research infrastructures (grant nos.  
545 ACTRIS (262254) and ACTRIS-2 (654109)), the European Cooperation in Science and  
546 Technology (grant no. COLOSSAL CA16109), the German Federal Environment  
547 Ministry (BMU) grants F&E 370343200 (German title: “Erfassung der Zahl feiner und  
548 ultrafeiner Partikel in der Außenluft”), 2008–2010, and F&E 371143232 (German title:  
549 “Trendanalysen gesundheitsgefährdender Fein- und Ultrafeinstaubfraktionen unter  
550 Nutzung der im German Ultrafine Aerosol Network (GUAN) ermittelten

551 Immissionsdaten durch Fortführung und Interpretation der Messreihen”), 2012–  
552 2014. This research has received funding from the Deutsche Forschungsgemeinschaft  
553 (*DFG*, German Research Foundation, HE 6770/2), the National Natural Science  
554 Foundation of China under grant numbers 42205072, 42075066, 42075063, 42175099,  
555 and 42005067. The China Scholarship Council (no.202008320513) is acknowledged  
556 for supporting Yuan Wang financially. We thank Achim Grüner and René Rabe for the  
557 careful maintenance of the measurements on site. We also thank Angela Buchholz and  
558 another anonymous reviewer for their helpful comments and suggestions on improving  
559 the paper.

950 Figure 1. Schematic diagram of the experimental setup. D-MPSS — Dual-mobility particle size

951 spectrometer, ACSM — aerosol chemical species monitor, MAAP — multi-angle absorption

952 photometer, DMA — differential mobility analyzer, CPC — condensation particle counter, CCNC

953 — cloud condensation nuclei counter.

954

955

956 Figure 2. Relationship between CCN number concentration ( $N_{CCN}$ ) and supersaturation ( $SS$ )

957 measured at Melpitz and other stations.

958

959

960 Figure 3. (a) Relationships between CCN number concentration ( $N_{CCN}$ ) and supersaturation ( $SS$ ),

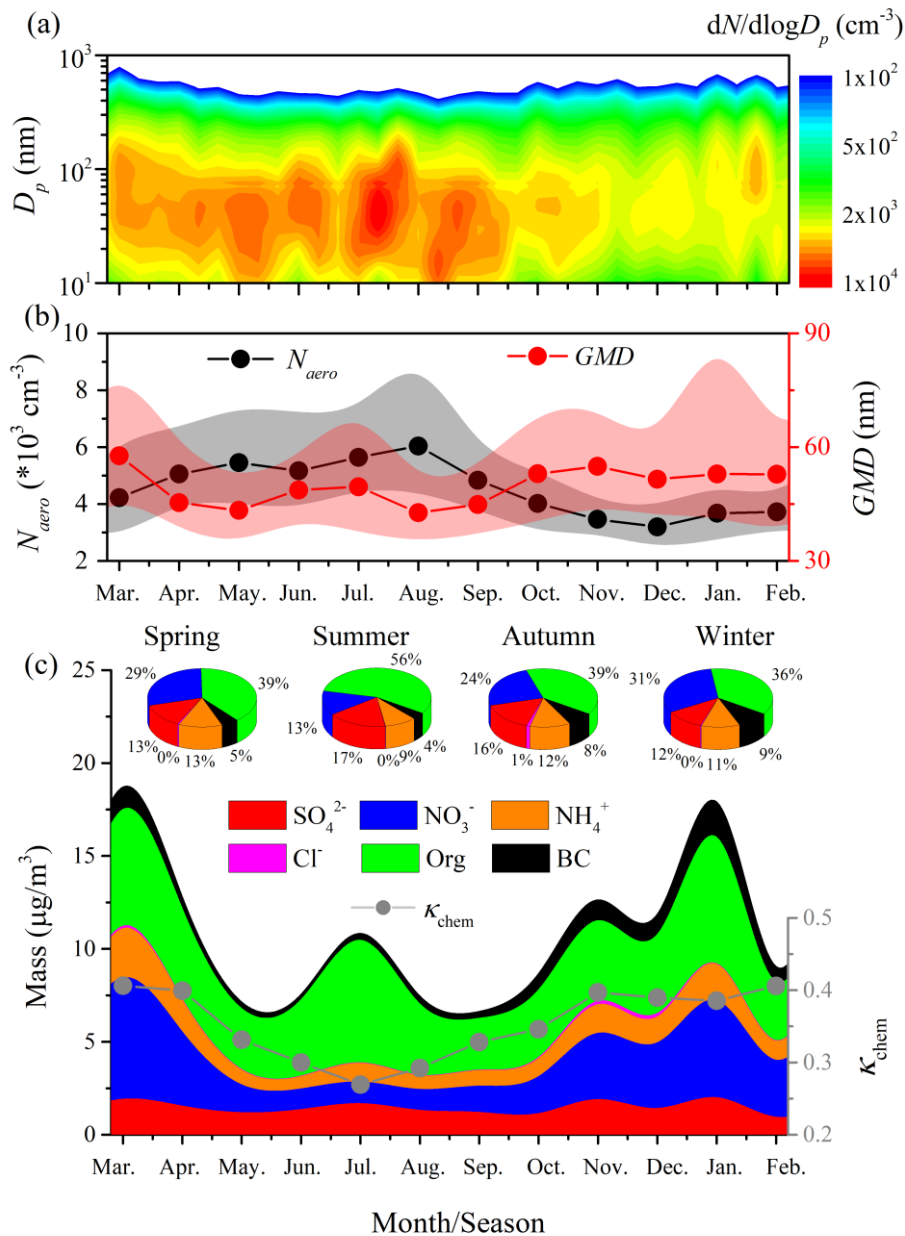

961 and relationship between activation ratios (AR) and  $SS$  for different seasons. (b) Seasonal trends of

962  $N_{CCN}$  and AR at  $SS = 0.1\%$  and  $0.7\%$ . Dots represent the median values of  $N_{CCN}$  and AR. Shaded

963 areas represent the values in the range from 25<sup>th</sup> to 75<sup>th</sup> percent. Red lines are power-law fittings for

964  $N_{CCN}$  (and AR) vs.  $SS$ . Two parameters of the fitting results are shown in brackets.

965

966

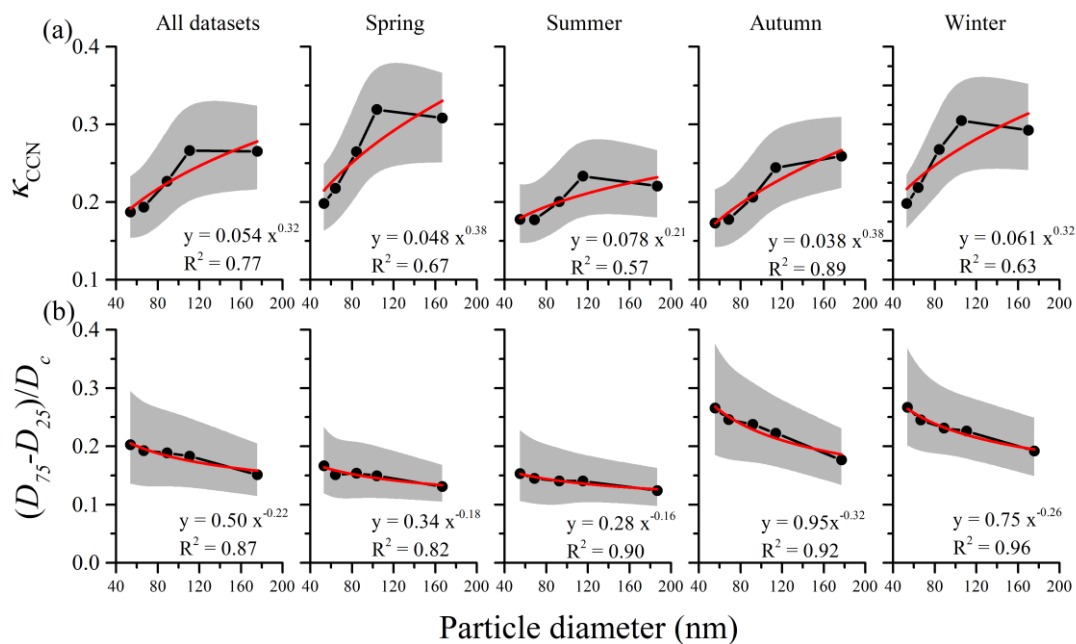

967 Figure 4. Seasonal variations of (a) aerosol particle number size distribution ( $dN_{aero}/d\log D_p$  vs.  $D_p$ ,  
 968  $D_p$  is particle diameter), (b) total aerosol number concentration with a  $D_p$  range of 10 to 800 nm  
 969 ( $N_{aero}$ ) and geometric mean diameter of the particles ( $GMD$ ), and (c) mass concentration and ratio  
 970 of each component in aerosol particle with  $D_p$  less than  $1 \mu\text{m}$  and the hygroscopicity factor  
 971 calculated from the chemical composition ( $\kappa_{chem}$ ). Dots represent the median values. Shaded areas  
 972 represent the values in the range from 25<sup>th</sup> to 75<sup>th</sup> percent.

973

974 Figure 5. Monthly variations of (a) hygroscopicity factor calculated from monodisperse CCN  
 975 measurements ( $\kappa_{\text{CCN}}$ ) at supersaturation ( $SS$ ) of 0.1% and 0.7%, and hygroscopicity factor calculated  
 976 from particle chemical composition ( $\kappa_{\text{chem}}$ ), (b) critical diameter of dry particle for activation ( $D_c$ )  
 977 at  $SS = 0.1\%$  and 0.7%, and (c) the degree of external mixture ( $(D_{75} - D_{25})/D_c$ ) at  $SS = 0.1\%$  and  
 978 0.7%. The definitions of  $D_{75}$  and  $D_{25}$  are the  $D_p$  at which 75% and 25% of the particles are activated  
 979 at the given  $SS$ , respectively. Dots represent the median values. Shaded areas represent the values in  
 980 the range from 25<sup>th</sup> to 75<sup>th</sup> percent.

981

Particle diameter (nm)

982 Figure 6. (a) Relationship between the hygroscopicity factor calculated from monodisperse CCN  
 983 measurements ( $\kappa_{CCN}$ ) and particle diameter ( $D_p$ ), and (b) degree of external mixture ( $(D_{75} - D_{25})/D_c$ )  
 984 vs.  $D_p$  at each season. The definitions of  $D_{75}$  and  $D_{25}$  are the  $D_p$  at which 75% and 25% of the  
 985 particles are activated at the given  $SS$ , respectively. Red lines are power-law fits. Dots represent the  
 986 median values. Shaded areas represent the values in the range from 25<sup>th</sup> to 75<sup>th</sup> percent.  
 987

988

989 Figure 7. Predicted vs. measured CCN number concentration ( $N_{CCN}$ ) for different seasons. The  
 990 Predicted  $N_{CCN}$  is calculated from five different schemes with a detailed introduction shown in Table  
 991 3. Color bar represents the different supersaturation ( $SS$ ) conditions. Black lines are the linear fits.  
 992 The slope and  $R^2$  of the linear regression and the median relative deviation ( $RD$ ) between the  
 993 predicted and measured  $N_{CCN}$  are shown in each panel. Each row represents the results using the  
 994 same scheme in different seasons. Each column represents the results using different schemes in the  
 995 same season.

996

997

998 Figure 8. Relationships between the particle hygroscopicity factor ( $\kappa$ ) and diameter ( $D_p$ ) observed

999 at different stations. Lines are power-law fits of  $\kappa$  vs.  $D_p$ .

1000

1001 Table 1. Densities ( $\rho$ ) and hygroscopicity factor ( $\kappa$ ) for each component.

Species	NH <sub>4</sub> NO <sub>3</sub>	(NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub>	NH <sub>4</sub> HSO <sub>4</sub>	H <sub>2</sub> SO <sub>4</sub>	Organics	BC
$\rho$ (kg m <sup>-3</sup> )	1720	1769	1780	1830	1400	1700
$\kappa$	0.67	0.61	0.61	0.92	0.1	0

1002

1003 Table2. Seasonal median values of hygroscopicity factor derived from the chemical composition  
 1004 ( $\kappa_{\text{chem}}$ ), hygroscopicity factor derived from monodisperse CCN measurements ( $\kappa_{\text{CCN}}$ ), the critical  
 1005 diameter of dry particle for activation ( $D_c$ ), and the degree of external mixture ( $(D_{75} - D_{25})/D_c$ ) at  
 1006 each supersaturation ( $SS$ ) condition. The unit of  $D_c$  is nm.

Parameters	$SS$ (%)	All datasets	Spring	Summer	Autumn	Winter
$\kappa_{\text{chem}}$	-	0.30	0.32	0.24	0.31	0.34
	0.1	0.27	0.31	0.22	0.26	0.29
$\kappa_{\text{CCN}}$	0.2	0.27	0.32	0.23	0.24	0.30
	0.3	0.23	0.26	0.20	0.21	0.27
	0.5	0.19	0.22	0.18	0.18	0.22
	0.7	0.19	0.20	0.18	0.17	0.20
$D_c$	0.1	176	167	187	177	170
	0.2	111	104	116	114	106
	0.3	89	85	93	92	84
	0.5	67	64	69	69	64
	0.7	54	53	55	55	53
$(D_{75} - D_{25})/D_c$	0.1	0.15	0.13	0.12	0.18	0.19
	0.2	0.18	0.15	0.14	0.22	0.23
	0.3	0.19	0.15	0.14	0.24	0.23
	0.5	0.20	0.15	0.14	0.25	0.25
	0.7	0.20	0.17	0.15	0.27	0.27

1007

1008 Table 3. Introduction of five activation schemes. The meaning of the abbreviation can be found in  
 1009 Notation list.

Category	Scheme	Introduction
1 <sup>st</sup> category:	N1	$N_{CCN} - SS$ power-law fits shown in Table 3
$N_{CCN} - SS$ or $AR - SS$ empirical fit	N2	Real-time $N_{aero}$ combined with $AR - SS$ power-law fits shown in Table 3
2 <sup>nd</sup> category:	K1	Real-time PNSD combined with a constant $\kappa$ of 0.3
Real-time PNSD combined with the parameterized $\kappa$	K2	Real-time PNSD combined with the real-time bulk $\kappa_{chem}$
	K3	Real-time PNSD combined with $\kappa - D_p$ power-law fits shown in Figure 6a
