18 **Abstract**

19 Reactive halogens play a prominent role in the atmospheric chemistry of the Arctic during
20 springtime. Field measurements and modelings studies suggest that halogens are emitted to the
21 atmosphere from snowpack and reactions on wind-blown snow and aerosols. The relative importance of
22 snowpack and blowing snow sources is still debated, both at local scales and regionally throughout the
23 Arctic. To understand implications of these halogen sources on a pan-Arctic scale, we simulate Arctic
24 reactive bromine chemistry in the atmospheric chemical transport model GEOS-Chem. Two mechanisms
25 are included: 1) a blowing snow sea salt aerosol formation mechanism and 2) a snowpack mechanism
26 assuming uniform molecular bromine production from all snow surfaces. We compare simulations
27 including neither mechanism, each mechanism individually, and both mechanisms to examine conditions
28 where one process may dominate or the mechanisms may interact. We compare the models using these
29 mechanisms to observations of bromine monoxide (BrO) derived from multiple-axis differential optical
30 absorption spectroscopy (MAX-DOAS) instruments on O-Buoy platforms on the sea ice and at a coastal
31 site in Utqiagvik, Alaska during spring 2015. Model estimations of hourly and monthly average BrO are
32 improved by assuming a constant yield of 0.1% molecular bromine from all snowpack surfaces on ozone
33 deposition. The blowing snow mechanism increases modeled BrO by providing more bromide-rich

34 aerosol surface area for reactive bromine recycling. The snowpack mechanism led to increased model
35 BrO across the Arctic Ocean with maximum production in coastal regions, whereas the blowing snow
36 mechanism increases BrO in specific areas due to high surface windspeedwind speeds. Our uniform
37 snowpack source has a greater impact on BrO mixing ratios than the blowing snow source. Model results
38 best replicate several features of BrO observations during spring 2015 when using both mechanisms in
39 conjunction, adding evidence that these mechanisms are both active during the Arctic Spring. Extending
40 our transport model throughout the entire year leads to predictions of enhanced fall BrO that are not
41 supported by observations.

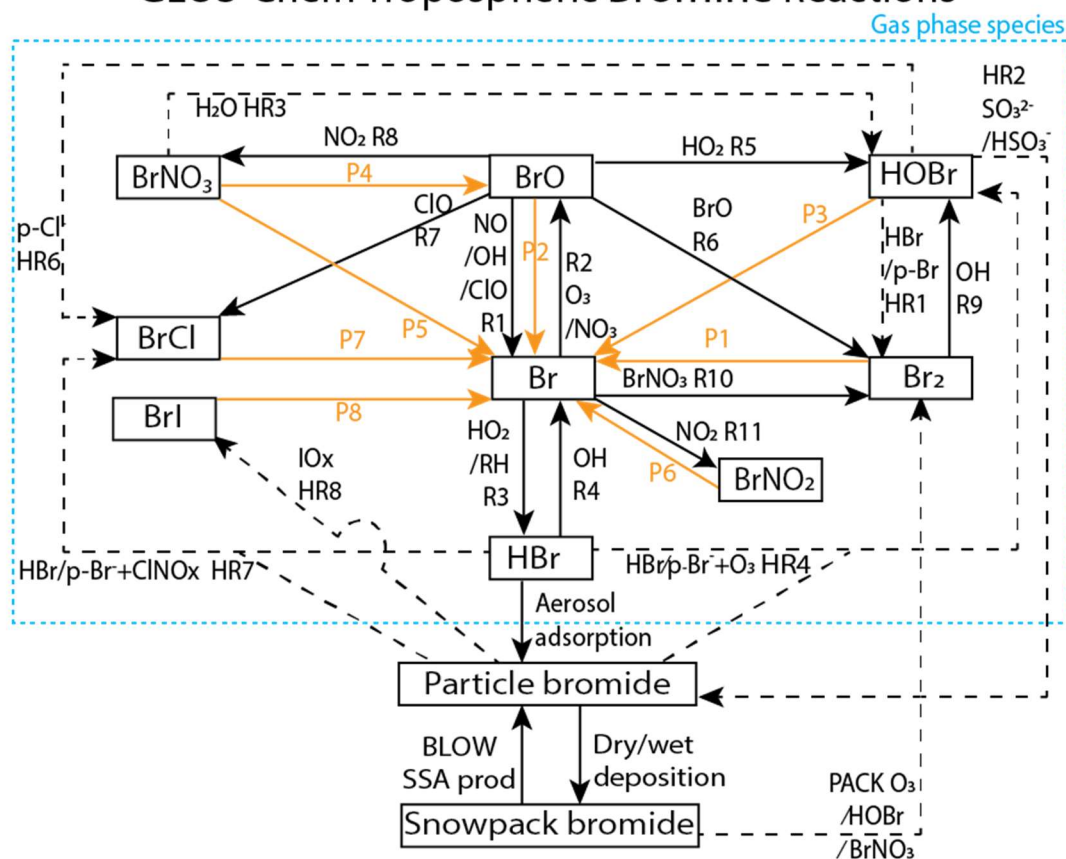

42 **1. Introduction**

43 Simulating Arctic halogen chemistry is a persistent problem for global models because processes
44 appear to differ between the Arctic and middle latitudes (Parrella et al., 2012; Schmidt et al., 2016).
45 Space-based instruments observe large column densities of reactive bromine across swaths of the Arctic
46 Ocean during the Arctic spring (Chance, 1998; Richter et al., 1998; Wagner and Platt, 1998). Increased
47 levels of tropospheric reactive bromine are associated with ozone depletion events (Barrie et al., 1988;
48 Foster et al., 2001; Koo et al., 2012; Halfacre et al., 2014) as well as oxidation of gaseous elemental
49 mercury (Schroeder et al., 1998; Nghiem, 2013; Moore et al., 2014). Bromine radicals have been
50 observed to lead directly to ozone depletion and mercury oxidation (Wang et al., 2019a). Deposition of
51 oxidized mercury to the snowpack can have deleterious effects on the health of Arctic humans and
52 animals (AMAP, 2011). Arctic reactive bromine chemistry impacts tropospheric oxidative chemistry but
53 is not typically accounted for in global models. Model studies have found that reactive halogen chemistry
54 can explain the oxidation of gaseous elemental mercury (Holmes et al., 2010) and reduce radiative forcing
55 from ozone (Sherwen et al., 2016c). Replicating reactive halogen chemistry in models requires inclusion
56 of multi-phase chemical reactions as well as mechanisms affecting sea salt aerosol particle production and
57 chemical reactions within the snowpack.

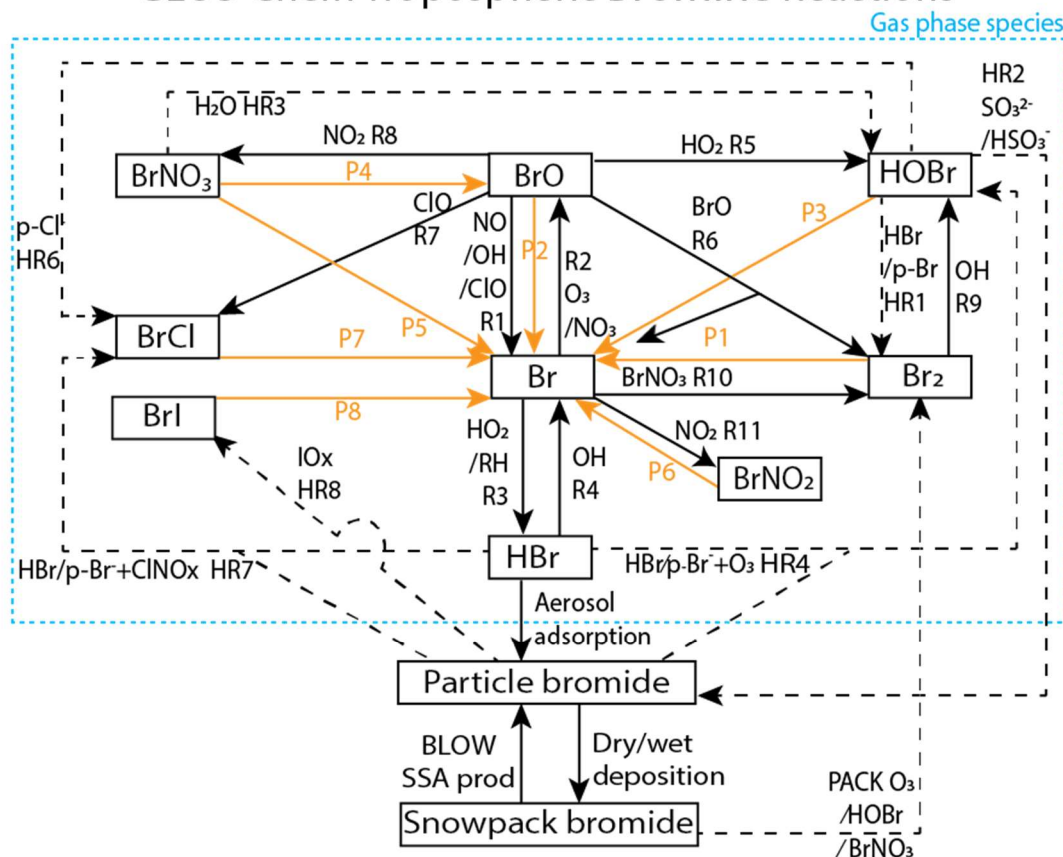

58 These increased levels of tropospheric reactive bromine radicals are a product of heterogeneous
59 photochemical reactions at the interface between air and saline surfaces such as surface snowpack and sea
60 salt aerosols (Saiz-Lopez and von Glasow, 2012; Simpson et al., 2015). Figure 1 depicts the gas-phase,
61 heterogeneous, and photochemical reactions thought to control tropospheric bromine, all of which are
62 included in the model and results presented in this manuscript. Bromine radicals (Br) are produced by
63 photolysis of molecular bromine (P1) or by self-reaction of BrO (R6) and react with ozone to form
64 bromine monoxide (BrO) (R2). Under sunlit conditions, BrO is most often photolyzed back to Br
65 radicals and an oxygen atom (P2) that then most often reforms ozone, resulting in a null cycle. Due to this
66 rapid interchange of Br and BrO, these two compounds form the BrO_x family. If processes other than BrO

67 photolysis (P~~2~~¹) convert BrO back to Br without producing ozone, the imbalance between these other
68 processes and P~~2~~¹ result in net ozone depletion. For example, ozone is depleted through R6 or R7 when
69 BrO reacts with another halogen oxide to form either Br₂ or BrCl, or through other more extended
70 processes. A reactive halogen activating cycle occurs when a BrO radical reacts with a hydroperoxy
71 (HO₂) radical in R5 to form gaseous hypobromous acid (HOBr). Heterogeneous chemistry can occur on a
72 saline surface between HOBr and particulate bromide (p-Br⁻) in HR1 forming Br₂ or particle chloride (p-
73 Cl⁻) in HR6 forming BrCl. For each cycle of reactions P1, R2, R5, and HR1, one hydroperoxy radical is
74 removed from the atmosphere, one bromine ~~atom~~^{radical} is released to the atmosphere, and one ozone
75 molecule is destroyed. This process of activation of particulate bromide to Br₂ by consuming other
76 radicals (e.g. HO₂) is known as the "bromine explosion" (Wennberg, 1999). Ground-based instruments
77 have observed sharp increases in reactive bromine levels over the course of a single day from below 2
78 pmol/mol up to a maximum of 41 pmol/mol (Pöhler et al., 2010). Reactions may also sequester reactive
79 bromine into more stable bromine reservoir species. BrO may react with nitrogen dioxide (NO₂) in R8 to
80 form bromine nitrate (BrNO₃), which can also undergo hydrolysis on ~~a saline aqueous and ice~~^{saline aqueous and ice} surfaces to
81 form HOBr as in HR3.

GEOS-Chem Tropospheric Bromine Reactions

GEOS-Chem Tropospheric Bromine Reactions

83

84 **Figure 1: GEOS-Chem tropospheric bromine reactions.** Tropospheric bromide reservoirs shown in
 85 black boxes, with attached lines indicating reactions. Solid black lines R1-R11 indicate gas phase
 86 chemical reactions, solid orange lines P1-P8 indicate photolysis reactions, and dashed black lines HR1-
 87 HR8 indicate heterogeneous reactions. All gaseous species may undergo ~~wet and~~ dry deposition.
 88 Additional sources of tropospheric bromine include the production of particulate bromide by the BLOW
 89 mechanisms and the production of Br_2 by the PACK mechanism, as well as the degradation of
 90 organobromines to form Br (OR1). Table 3 enumerates the specific species involved in each equation and
 91 shows reaction rates for each respective equation.

92 A potentially important competitor for recycling of reactive bromine through HOBr is its reaction
 93 with sulfur (IV) species, such as the reaction between HSO_3^- and HOBr in HR2 (Chen et al., 2017). To
 94 the extent that this reaction competes with HR1, it can slow the release of bromide from surfaces and
 95 reduce gas-phase reactive bromine (e.g., reduce BrO). Deposition of the HBr formed from HOBr by HR2
 96 can remove reactive bromine from the troposphere. In general, the termination of this chemistry leads to
 97 formation of HBr , which undergoes gas-particulate uptake to particulate bromide (p-Br^-).

98 Ozone deposited to a saline surface can oxidize Br⁻ to form HOBr (similar to p-Br⁻ reactions
99 HR4a and HR4b) which is then converted to Br₂ or another dihalogen (e.g., BrCl). Production of reactive
100 bromine during ozone deposition does not require light and can occur at night (Oum et al., 1998; Artiglia
101 et al., 2017). The production of Br₂ is increased at low pH levels (Halfacre et al., 2019).

102 We define the inorganic bromine family, Br_y, in this manuscript as the sum of the bromine
103 species: Br, BrO, HOBr, BrNO₃, 2xBr₂, BrCl, BrI, and HBr, excluding p-Br⁻. The release of bromine from
104 sea salt aerosol particles was found to be the dominant global source of reactive bromine (Sander et al.,
105 2003; Zhu et al., 2019). Sea salt aerosol particles (SSA) sourced from the bursting of bubbles in oceanic
106 whitecaps and other sources and are one of the most abundant aerosol particle types present in the
107 troposphere (De Leeuw et al., 2011). Due to their abundance, SSA particles greatly increase the surface
108 areaparticulate bromide on aerosol surfaces available for heterogeneous reactive bromine chemistry.
109 Debromination of acidified aerosol increases reactive bromine by 30%, although global models may
110 underestimate Arctic reactive bromine when considering only open ocean-sourced SSA (Schmidt et al.,
111 2016). Initial literature on Arctic reactive bromine chemistry identified aerosol particles as a potential
112 saline surface for reactive bromine photochemistry (Fan and Jacob, 1992; Vogt et al., 1996) and recent
113 studies confirmed that SSA is depleted in bromide (Hara et al., 2018). If one supposes that SSA can only
114 be produced from the open ocean source of SSA, the lack of Arctic Ocean open water during the
115 winter/spring is at odds with observations of high SSA concentrations observed during the winter months
116 in polar regions (Wagenbach et al., 1998; Huang et al., 2018). The formation of SSA from the sublimation
117 of blowing snow particles over the Arctic Ocean was proposed as an alternate SSA production
118 mechanism (Yang et al., 2008, 2010, 2019). Recent field studies have confirmed the direct production of
119 SSA from blowing snow (Frey et al., 2020). A blowing snow SSA mechanism was implemented in the
120 global chemical model GEOS-Chem and was able to explain wintertime SSA enhancements over the
121 Arctic (Huang and Jaeglé, 2017) as well as CALIOP-detected aerosol particle abundance (Huang et al.,
122 2018) and high levels of Arctic BrO detected by satellites in spring (Huang et al., 2020).

123 Snowpack containing bromide salts was also identified as a source of reactive bromine (Tang and
124 McConnell, 1996). Molecular bromine was measured above the snowpack at levels up to 25 pmol/mol
125 (Foster et al., 2001). Field experiments demonstrate that the snowpack emits Br₂, Cl₂, and BrCl, with
126 emission affected by ambient ozone levels, the snowpack ratio of bromide to chloride, and exposure to
127 sunlight (Pratt et al., 2013; Custard et al., 2017). Box modeling found that the flux of reactive bromine
128 from the surface of the Arctic Ocean sea ice is a prerequisite for bromine activation (Lehrer et al., 2004).
129 Box modeling found that both HOBr and BrNO₃ can be converted to Br₂ in the snowpack (Wang and
130 Pratt, 2017). Detailed one dimensional models of the snowpack-air interface find that reactive bromine

131 production can occur in the interstitial air between snowpack grains (Thomas et al., 2011; Toyota et al.,
132 2014), with ozone depletion events arising from snowpack reactive bromine production (Thomas et al.,
133 2011; Toyota et al., 2014; Cao et al., 2016). However, a detailed snowpack model coupled to an
134 atmospheric model would be sensitive to important parameters such as snowpack bromide content and
135 acidity of the air-ice interface that are highly variable across the Arctic (Toom-Sauntry and Barrie, 2002;
136 Krnavek et al., 2012). A mechanism to parameterize the release of molecular bromine from snowpack
137 upon deposition of ozone, HOBr, and BrNO₃ was implemented in the GEM-AQ model and captured
138 many of the observed features of reactive bromine in the Arctic troposphere (Toyota et al., 2011). The
139 mechanisms from Toyota et al. (2011) assumes a 100% yield of molecular bromine on deposition of
140 HOBr or BrNO₃ (see Figure 1 PACK) and a diurnally varying yield of Br₂ on ozone deposition of 7.5%
141 during the daytime (solar elevation angle > 5°) and 0.1% during the nighttime (solar elevation angle < 5°)
142 (see Figure 1 PACK). In the Toyota et al. (2011) parameterization, the daytime yield of Br₂ from ozone
143 was increased to 7.5% to match surface ozone depletion observations and is based on the assumption that
144 photochemical reactions in the snowpack would trigger a bromine explosion and amplify the net release
145 of Br₂ (Toyota et al., 2011). Herrmann et al (2021) implemented the Toyota et al. (2011) mechanism in
146 WRF-Chem and found snowpack Br₂ production was capable of replicating ozone depletion events
147 observed in multiple datasets. Marelle et al. (2021) implemented a surface snowpack mechanism based on
148 Toyota et al. (2011) and a blowing snow [SSA](#) mechanism based on Yang et al. (2008) and Huang and
149 Jaeglé (2017) and found improved prediction of ozone depletion events, the majority of which were
150 triggered by the snowpack mechanism. The Toyota et al. (2011) mechanism was also implemented in the
151 EMAC model and replicated many of the features of reactive bromine events observed by satellite-based
152 GOME sensor (Falk and Sinnhuber, 2018).

153 Field campaigns have directly observed the production of SSA from blowing snow (Frey et al.,
154 2020) as well as production of Br₂ from the snowpack (Pratt et al., 2013) in the environment. This
155 manuscript uses both production mechanisms for the first time in the global chemical model GEOS-
156 Chem. We devised a set of six model runs to test each mechanism individually and together as well as one
157 control run using neither mechanism. We compare BrO simulated in each model run against extensive
158 ground-based observations of BrO made from February to June 2015. This set of modeling scenarios
159 allows identification of the effects of each mechanism on BrO as well as the synergistic effects of both
160 mechanisms working together.

161 2. Data sources and methods

162 2.1 MAX-DOAS observation platforms

163 Multiple axis differential optical absorption spectroscopy (MAX-DOAS) remotely measures the
164 vertical profile of BrO (Hönninger and Platt, 2002; Carlson et al., 2010; Frieß et al., 2011; Peterson et al.,
165 2015; Simpson et al., 2017). BrO is commonly used as a proxy for total tropospheric reactive bromine
166 (Chance, 1998; Richter et al., 1998; Wagner and Platt, 1998; Theys et al., 2011; Choi et al., 2012). MAX-
167 DOAS instruments were mounted on all of the fifteen floating autonomous platforms (O-Buoys) deployed
168 in the Arctic sea ice as a part of the National Science Foundation-funded Arctic Observing Network
169 project (Knepp et al., 2010). Since MAX-DOAS requires sunlight to operate, measurements are not
170 available in winter. Spring observations on the O-Buoys typically begin in April when there is enough O-
171 Buoy solar power to defrost the MAX-DOAS viewport. Figure 2 shows the O-Buoys active during 2015.
172 O-Buoy 10 was deployed into sea ice in fall 2013 and measured reactive halogen chemistry in spring
173 2014 and 2015. Most O-Buoys were destroyed in the summer, crushed between fragments of melting sea
174 ice. However, O-Buoy 10 survived summer 2014 in an intact ice floe, survived the winter of 2014-15,
175 and re-started MAX-DOAS observations in April 2015. O-Buoys 11 and 12 were deployed in fall 2014
176 and also re-started observing BrO in April 2015. Figure 2 shows the GPS-derived tracks of the O-Buoys
177 for their full deployment and highlights the O-Buoy locations from April to June 2015 when the BrO
178 observations considered in this analysis were gathered. A MAX-DOAS instrument of the same design
179 was deployed at the Barrow Arctic Research Center (BARC) on the coast of the Arctic Ocean located at
180 156.6679°W, 71.3249°N near Utqiagvik, AK (Simpson, 2018), also shown in Figure 2. Unlike the O-
181 Buoy MAX-DOAS systems, which were powered by batteries and solar panels, the BARC MAX-DOAS
182 was powered from local utilities and was able to defrost its viewport to gather BrO observations earlier in
183 the year, including February and March 2015. The BARC MAX-DOAS data was compared with two O-
184 Buoy style MAX-DOAS instruments deployed on Icelander platforms (deployed on top of sea ice instead
185 of within) and measurements from the various MAX-DOAS systems were found to be comparable
186 (Simpson et al., 2017). The reactive bromine season ends when the BrO slant column densities fall below
187 the instrument detection limit and do not recover, which we call the seasonal end date (Burd et al., 2017).
188 All O-Buoy and BARC (Utqiagvik) data are available at arcticdata.io (Simpson et al., 2009) (Simpson,
189 2018). More information on the time periods of spring BrO observations can be found in Swanson et al.
190 (2020) and Burd et al. (2017). For comparison to the MAX-DOAS BrO observations, GEOS-Chem model
191 simulations are sampled along the GPS-derived paths of O-Buoys 10, 11 and 12 as well as at BARC.

192

193 **Figure 2: Locations of MAX-DOAS BrO observations used in this work.**

194 Blue lines show the drift tracks of O-Buoys, with green showing the locations with valid BrO
 195 measurements in spring 2015. Location of Barrow Arctic Research Center (BARC) in Utqiagvik indicated
 196 by green dot. ~~Inset map shows~~ True color MODIS imagery on 1 April 2015 shows typical sea ice
 197 coverage (NASA 2015). Inset map shows location of map grid within northern hemisphere.

198 2.2 MAX-DOAS profile retrieval

199 Vertical profiles of BrO were derived from MAX-DOAS observations by means of optimal
200 estimation inversion procedures detailed in Peterson et al. (2015) with settings detailed in Simpson et al.
201 (2017). The HeiPro optimal estimation algorithm (Frieß et al., 2006, 2019) is used to retrieve a vertical
202 profiles of BrO between the surface and 4km from the MAX-DOAS observations. Examination of the
203 averaging kernels from each MAX-DOAS retrieval finds the retrieved vertical profile of BrO is best
204 represented by two quantities: the vertical column density of BrO in the lowest 200 m, and the vertical
205 column density of BrO in the lowest 2000 m of the troposphere referred to in this manuscript as BrO_{LTcol}
206 (Peterson et al., 2015). ~~We approximate surface mixing ratio by assuming well mixed constant
207 distribution of BrO throughout the lowest 200 m. This mixing ratio is reported as BrO_{pptv200} (Simpson et al
208 2009, Simpson 2018).~~ It was shown in Peterson et al. (2015) that these two quantities were largely
209 independent of each other, were fairly insensitive to variations in the assumed prior profile, and
210 represented the ~2-3 degrees of freedom for signal indicated by the optimal estimation retrieval. ~~An
211 important consideration of this method is that when the visibility is poor, the MAX-DOAS is unable to
212 traverse the lowest 2000m AGL and the BrO_{LTcol} cannot be measured accurately. Therefore, our quality-
213 control algorithm eliminates BrO_{LTcol} observations when the degrees of freedom for signal in the lofted
214 (200m - 2000m AGL) layer were below 0.5 (Simpson et al., 2017). The average fitting error (1 σ error) of
215 BrO_{LTcol} during spring 2015 was 5.6×10^{12} molecules/cm².~~

216 2.3 SSA production from open ocean

217 Seafoam from breaking waves and bursting of bubbles forms aerosol droplets suspended in the
218 marine boundary layer (Lewis and Schwartz, 2004). We calculate emission of sea salt aerosol particles
219 from the open ocean as a function of wind speed and sea surface temperature (SST) using the mechanism
220 initially described in Jaeglé et al. (2011) and updated with decreased emissions over cold (SST < 5°C)
221 ocean waters (Huang and Jaeglé, 2017). Two separate SSA tracers are transported: accumulation mode
222 SSA ($r_{dry} = 0.01-0.5 \mu\text{m}$) and coarse mode SSA ($r_{dry} = 0.5-8 \mu\text{m}$). Sea salt bromide is emitted assuming
223 bromine content of 2.11×10^{-3} kg Br per kg of dry SSA (primarily NaCl) based on the mean ionic
224 composition of sea water (Sander et al., 2003). Bromide content is tracked separately on accumulation
225 mode SSA and on coarse mode SSA. Freshly emitted SSA is alkaline and can be titrated to a pH of 5 by
226 uptake of acid gases SO₂, H₂SO₄, and HNO₃ (Alexander et al., 2005). Heterogeneous chemical reactions
227 can convert SSA-transported bromide into gaseous reactive bromine species in the atmosphere. We run
228 our open ocean SSA calculations at 0.5° latitude x 0.625° longitude spatial resolution using the
229 harmonized emissions component (HEMCO) for highest possible detail (Keller et al., 2014; Lin et al.,
230 2021) including cold water corrections used in Jaeglé et al. (2011) . Production of SSA from open oceans
231 ~~which can lead to Arctic reactive bromine recycling on advected open ocean SSA within GEOS-Chem~~

232 [followed by advection can lead to reactive bromine recycling over Arctic Ocean sea ice](#). Each of our
233 model runs reads the dataset generated offline by HEMCO rather than spend computational time
234 replicating open ocean SSA emissions. We call our control run using only open ocean SSA emissions
235 BASE.

236 2.4 Blowing snow SSA production

237 Snow can be lofted from the snowpack into the lowest layers of the troposphere by high
238 [windspeedwind speeds](#), where it can undergo saltation (bouncing leading to fragmentation) and
239 sublimation to form SSA (Yang et al., 2008, 2010; Frey et al., 2020). This process is modeled as a
240 function of humidity, ambient temperature, [windspeedwind speed](#), and the salinity of the blowing snow
241 (Yang et al., 2008, 2010). [We assume that snowpack exists on all sea ice surfaces during the Arctic](#)
242 [Spring after snow accumulation during winter on sea ice of all ages](#). Three thresholds must be met for
243 SSA production from blowing snow (Dery and Yau, 1999; Déry and Yau, 2001). A temperature threshold
244 restricts SSA production from blowing snow to temperatures below freezing. The humidity threshold is
245 based on relative humidity with respect to ice. Sublimation from snow crystals cannot occur if the air is
246 saturated, and no SSA is produced if RH_{ice} is greater than 100%. The [windspeedwind speed](#) threshold
247 requires [ten-meter10-m](#) wind speed to be greater than a threshold value defined in Equation 1 for any
248 production of SSA (Dery and Yau, 1999; Déry and Yau, 2001).

$$249 U_t = 6.975 + 0.0033(T_s + 27.27)^2 \quad (1)$$

250 The wind speed threshold (U_t) is dependent on surface temperature (T_s) in Celsius with a minimum
251 threshold of 6.975 m/s at $-27.27 \text{ }^\circ\text{C}$ and a maximum threshold at $0 \text{ }^\circ\text{C}$ of 9.429 m/s. The [ten-meter10-](#)
252 [m windspeedwind speed](#) threshold is the most stringent and often controls the production of SSA from
253 blowing snow.

254 Production of blowing snow ~~and~~ SSA is highly sensitive to surface [windspeedwind speed](#). We
255 use the highest resolution surface [windspeedwind speed](#) dataset to ensure the most accurate modeling of
256 SSA and reactive bromine. The MERRA-2 Global Reanalysis Product has a 0.5° latitude x 0.625°
257 longitude resolution which is typically re-gridded to a lower resolution for global chemical modeling.
258 Previous use of the snowpack blowing snow [SSA](#) mechanism ~~has simulated blowing snow used with~~
259 MERRA-2 data re-gridded to either $2^\circ \times 2.5^\circ$ or $4^\circ \times 5^\circ$ latitude and longitude (Huang and Jaeglé, 2017;
260 Huang et al., 2018, 2020). Re-gridding to coarser spatial resolution may smooth out the highest ~~ten-~~
261 [meter10-m windspeedwind speeds](#) by averaging them with lower [windspeedwind speeds](#) in the grid cell.
262 The Utqiagvik MERRA-2 [ten-meter10-m windspeedwind speeds](#) at different spatial resolutions are
263 shown in Supplemental Figures S1, S2 and S3 to illustrate this effect. Average Utqiagvik [ten-meter10-m](#)
264 [windspeedwind speeds](#) for 2015 are 5.3 m/s at $2^\circ \times 2.5^\circ$ resolution and 5.5 m/s at $0.5^\circ \times 0.625^\circ$ resolution.

265 The maximum Utqiagvik ~~10-m ten-meter windspeed~~ wind speed at MERRA-2 2x2.5 is 16.3 m/s, while the
266 maximum ~~windspeed~~ wind speed at MERRA-2 0.5°x0.625° is 19.3 m/s. These extremely high
267 ~~windspeed~~ wind speed events are more common at higher spatial resolution and can contribute an outsized
268 amount of SSA to the marine boundary layer. Supplemental Figure S4 shows the measured ~~ten-meter~~ 10-
269 m windspeed wind speed at BARC, along with daily average threshold ~~windspeed~~ wind speed (Equation
270 1). Spikes in daily averaged ~~windspeed~~ wind speed at BARC in April can contribute to SSA formation and
271 justify the use of high-resolution MERRA-2 wind speed data.

272 Snow salinity is influenced by snow age and the material underlying the snow (Krnavek et al.,
273 2012). The median surface snowpack salinity near Utqiagvik was measured at 0.67 practical salinity units
274 (PSU)PSU for 2-3 weeks old sea ice, 0.12 PSU for thicker first year ice, and 0.01 PSU for multi-year ice
275 (MYI) (Krnavek et al., 2012). Snow salinity is also a function of snow depth above sea ice, with blowing
276 surface snow having much lower salinity than snow at depth that is in contact with the sea ice (Frey et al.,
277 2020). Domine et al. (2004) measured median salinity at 0.1 PSU on snowpack over first year ice and
278 0.02 PSU on snowpack over multi-year ice. In this analysis we use a salinity of 0.1 PSU on first-year sea
279 ice as in Huang et al. (2020). The production of reactive bromine from sea ice types is entirely dependent
280 on PSU in this parameterization. Previous modeling efforts have used 0.01 PSU for MYI (Huang et al.,
281 2018) and underestimate BrO production in high Arctic areas with increased MYI coverage. The bromide
282 content of surface snow over MYI is enriched by deposition of SSA and trace gases, and MYI regions
283 may play a role in springtime halogen chemistry (Peterson et al., 2019). Previous analysis of O-Buoy data
284 found no statistically significant differences in springtime BrO between regions of the Arctic (Swanson et
285 al., 2020). We use 0.05 PSU for snowpack on MYI as in Huang et al. (2020).

286 Another important parameter for SSA formation is the number of SSA particles formed from each
287 blowing snowflake. A value of 5 particles per snowflake was used in Huang and Jaeglé (2017) based on
288 wintertime observations of supermicron and sub-micron SSA at Barrow. Values of 1 and 20 particles per
289 snowflake have been tested (Yang et al., 2019) but it is unclear which value was more realistic. We use a
290 particle formation value of 5 particles per snow grain as in Huang et al. (2020).

291 Snowpack may be enriched or depleted in bromide compared to seawater, which is thought to be
292 an effect of atmospheric deposition or release of bromine from snowpack (Krnavek et al., 2012).
293 Snowpack enrichment due to atmospheric deposition is less pronounced when snowpack salinity is high,
294 with snowpack containing 1000 $\mu\text{M Na}^+$ (approximately 0.06 PSU) or more never exceeding twice the
295 seawater ratio of bromine to chloride (Krnavek et al., 2012). Domine et al. (2004) found an increased
296 enrichment factor of five times seawater in snow with a salinity of 100 $\mu\text{M Cl}^-$ (approximately 0.006
297 PSU). We use a snowpack enrichment factor of bromide five times that of seawater as in Huang et al.

298 (2020) where this enrichment best agreed with GOME-2 observations. However, we note that a bromide
299 enrichment factors five times seawater exceeds enrichment factors of two measured in snowpack with a
300 salinity of 0.1 PSU (Krnavek et al., 2012).

301 Our choice of model input settings is similar to Huang et al. (2020) but we will be running the
302 blowing snow SSA mechanism in HEMCO at a 0.5° latitude x 0.625° longitude spatial resolution. The
303 model run using the results of our high-resolution blowing snow SSA HEMCO simulation is called
304 BLOW.

305 **2.5 Snowpack emissions of molecular bromine**

306 We base our Br₂ emissions scheme on Toyota et al. (2011) and Marelle et al. (2021), which
307 prescribe a yield of Br₂ upon snowpack deposition of ozone, BrNO₃ and HOBr. In other modeling studies,
308 this simplified deposition-based mechanism captured the synoptic-scale behavior of reactive bromine
309 production across the Arctic (Toyota et al., 2011; Falk and Sinnhuber, 2018; Herrmann et al., 2021;
310 Marelle et al., 2021). These modeling studies used different yields of Br₂ upon deposition over land
311 snowpack, multi-year ice, and first year ice, restricting the production of molecular bromine from ozone
312 deposition to first year ice surfaces. None of these studies were coupled to a snowpack model tracking
313 snow bromide, and effectively assume an infinite bromide reservoir with Br₂ production limited only by
314 the deposition flux and Br₂ yield.

315 Field studies indicate that snowpack over multi-year ice, first-year ice, and land regions may
316 contribute to reactive bromine chemistry. Krnavek et al. (2012) found snow bromide content spanning six
317 orders of magnitude, with individual samples taken from multi-year ice, first-year ice, and land regions
318 showing variability of up to three orders of magnitude for each region. Analysis of variance in
319 tropospheric BrO from 2011-2016 found no statistically significant differences in tropospheric BrO
320 between different regions of the Arctic (Swanson et al., 2020). Both coastal snowpack and multi-year ice
321 regions may produce reactive bromine. Molecular bromine production has been observed from coastal
322 snowpack on exposure to ozone (Pratt et al., 2013; Custard et al., 2017). Airborne sampling has observed
323 enhanced BrO up to 200 km inland (Peterson et al., 2018). Snow above multi-year sea ice regions is
324 depleted in bromide, indicating that it may play a role in Arctic bromine chemistry (Peterson et al., 2019).

325 Our modeling study tests the hypothesis that all snow has a uniform ability to produce molecular
326 bromine, effectively assuming an infinite bromide reservoir with Br₂ production limited only by the
327 deposition flux. We differ from previous model parameterizations in allowing uniform Br₂ production
328 upon snowpack deposition of ozone, BrNO₃ and HOBr over all sea ice surfaces and selected coastal
329 snowpack regions. We expect higher predictions of snowpack molecular bromine production than recent

330 modeling efforts (Herrmann et al., 2021; Marelle et al., 2021) in which ozone deposition over land and
331 multi-year ice surfaces did not produce molecular bromine.

332 **2.5.1 Snowpack Br₂ production over sea ice**

333 We assume a uniform production of Br₂ on deposition to snowpack over oceanic ice whether the
334 ice is first-year sea or multi-year sea ice. We use MERRA-2 fractional ocean ice coverage fields, which
335 introduces some artifacts. MERRA-2 classifies the freshwater Great Lakes as ocean, but sea ice and
336 snowpack on those frozen lakes is unlikely to have sufficient bromide to support large Br₂ fluxes due to
337 its distance from the ocean. Therefore, we specifically prohibit snowpack Br₂ emissions in the Great
338 Lakes region (between 41° N and 49° N latitude and 75° W and 93° W longitude). This choice is in
339 agreement with McNamara et al. (2020), who found road salt derived aerosol particles are responsible for
340 80-100% of atmospheric ClNO₂ in Michigan with no ~~mention of~~strong indication for a source of reactive
341 halogens from nearby Great Lakes.

342 **2.5.2 Snowpack Br₂ production over land**

343 We wish to only enable production of Br₂ over land if the snowpack is sufficiently enriched in
344 bromide. Snowpack over land surfaces and glaciers may be enriched in bromide by oceanic SSA sources
345 (Jacobi et al., 2012, 2019). The distance that SSA may be transported inland from the coast is limited by
346 geographical features such as mountains. Based on direct observations of reactive bromine chemistry up
347 to 200 km from the Alaskan coastline (Peterson et al., 2018), we include unlimited production of Br₂ from
348 specific land grid cells within 200 km of the coast upon deposition of ozone, HOBr, and BrNO₃. We only
349 allow the fraction of each grid cell that is within 200 km of the coastline (Group and Stumpf, 2021) to
350 produce molecular bromine. We further restrict snowpack Br₂ emissions to locations that are less than 500
351 m above sea level, because higher elevation locations are unlikely to be enriched by sea spray. This
352 altitude screen eliminates Br₂ emissions from coastal mountains such as the Alaskan Rockies, the Brooks
353 Range in Alaska, and the Scandinavian Mountains as well as from the Greenland Plateau. Halogen
354 chemistry may occur over the Greenland ice sheet (Stutz et al., 2011) contrary to this screen, but this will
355 have minimal impact on the regions of interest in this manuscript.

356 Our final screen is based on the average snow depth in each land grid cell. Both modeling studies
357 (Thomas et al., 2011; Toyota et al., 2014) and field studies (Domine et al., 2004; Pratt et al., 2013;
358 Custard et al., 2017; Frey et al., 2020) agree that bromine chemistry can occur in the better ventilated and
359 illuminated top of the snowpack. Regions with less than 10 cm of snowpack may not have sufficient
360 snow for reactive bromine chemistry, thus we only produce snowpack Br₂ when the average snow depth
361 in a land grid cell is 10 cm or greater. This screen prevents molecular bromine production in the lower
362 latitude regions with minimal snow coverage and is necessary because ozone deposition to plants in

363 snow-free grid cells often exceeds the slow deposition of ozone to snowpack and would not be expected
 364 to produce Br₂.

365 2.5.3 Diurnal yield of Br₂ on ozone deposition

366 We choose two alternate assumptions for the yield of Br₂ during the day. Toyota et al. (2011)
 367 initially assumed a constant yield of Br₂ from ozone deposition of 0.1% based on laboratory observations
 368 of nighttime bromine activation on ozone deposition (Oum et al., 1998; Wren et al., 2010, 2013) and then
 369 adjusted the daytime yield of Br₂ on ozone deposition to 7.5% to better match surface ozone mixing ratios
 370 measured at coastal stations. This increased daytime yield value was chosen based on the assumption that
 371 photochemistry may trigger an autocatalytic cycle leading to a 75-fold increase in Br₂ yield. The
 372 PHOTOPACK runs uses the increased daytime Br₂ yield of 7.5% when the solar elevation angle is 5° or
 373 greater. Previous implementations of the snowpack mechanism (Toyota et al., 2011; Herrmann et al.,
 374 2021; Marelle et al., 2021) predict ozone deposition velocities over Arctic sea ice on the order of 0.01
 375 cm/s. Our model predicts similar ozone deposition rates over polar open ocean of 0.009 cm/s (Pound et
 376 al., 2020), but our model currently predicts the deposition velocity of ozone over Arctic sea ice between
 377 0.02 cm/s and 0.1 cm/s based on the month (see Supplemental Figure S5), with higher values influenced
 378 by proximity to the coast as described in Bariteau et al. (2010).- Thus, our PHOTOPACK run may predict
 379 much higher Br emissions than previous snowpack predictions despite the same yield values due to
 380 differences in deposition. To match our magnitude of Br₂ production with previous implementations of
 381 the snowpack mechanism (Toyota et al., 2011; Herrmann et al., 2021; Marelle et al., 2021) we add two
 382 PACK runs with a constant Br₂ yield on ozone deposition of 0.1% based on yield values in Toyota et al.
 383 (2011). Both PACK and PHOTOPACK runs assume 100% conversion of deposited HOBr and BrNO₃ to
 384 Br₂. Table 1 shows further model run yield details.

385 Table 1 Model run settings

386 Sea salt aerosol particles are produced from blowing snow as detailed in Section 2.5. Daytime is defined
 387 as when the solar elevation angle is greater than 5°, nighttime is defined as when the solar elevation angle
 388 is less than 5°.

Model Run	Blowing snow SSA produced	Millimoles Br yielded per mole O3 deposited (daytime)	Millimoles Br yielded per mole O3 deposited (nighttime)
BASE	FALSE	0	0
BLOW	TRUE	0	0
PACK	FALSE	1	1
BLOW+PACK	TRUE	1	1
PHOTOPACK	FALSE	75	1
BLOW+PHOTOPACK	TRUE	75	1

389

390 2.6 GEOS-Chem chemistry and transport model

391 The GEOS-Chem global atmospheric chemistry and transport model (Bey et al., 2001) simulates
392 emissions, transport, and chemistry of atmospheric trace gases and aerosols, including halogens. The
393 chemical mechanism in GEOS-Chem 12.9.3 (<http://www.geos-chem.org>, last access 29 October 2019,
394 DOI:10.5281/zenodo.3974569) includes HO_x-NO_x-VOC-O₃-halogen-aerosol tropospheric chemistry
395 (Mao et al., 2013; Fischer et al., 2014; Fisher et al., 2016; Travis et al., 2016; Wang et al., 2021). The
396 model has been regularly and consistently updated to reflect current understanding of heterogeneous and
397 gas-phase halogen chemistry.

398 Halogens in the troposphere may be sourced from photooxidation of halocarbons, emissions of
399 iodine from the ocean surface, downward transport of halogens from the stratosphere, and release of
400 halogens through heterogeneous chemistry on SSA. Figure 1 shows a simplified version of the GEOS-
401 Chem reaction scheme focusing on tropospheric bromine reactions and reservoirs. Heterogeneous
402 reactions for release of reactive bromine from aerosol surfaces were added to GEOS-Chem (Parrella et
403 al., 2012) and have been updated to include multiphase reactions [involving cloud aerosols](#) and [inter-](#)
404 [halogen](#) reactions between bromine, chlorine and iodine species (Schmidt et al., 2016; Sherwen et al.,
405 2016a; Wang et al., 2019b) as well as input from the stratosphere (Eastham et al., 2014). Recent updates
406 also include reactions between sulfur (IV) species and HOBr, which lead to a 50% decrease in Br_y due to
407 the scavenging of HOBr on aerosol surfaces containing sulfur (Chen et al., 2017). These HOBr-sulfur(IV)
408 reactions are critical in moderating tropospheric BrO in the mid latitudes (Zhu et al., 2019). In GEOS-
409 Chem 12.9 the halogen chemical mechanism was modified extensively to include chlorine chemistry as
410 detailed in Wang et al. (2019b) with update halogen-sulfur (IV) rates (Liu et al., 2021) as well as
411 improved cloud pH calculation from Shah et al. (2020). For the simulations here, GEOS-Chem uses the
412 Modern-Era Retrospective Analysis for Research and Applications, version 2 (MERRA-2) assimilated
413 meteorological fields (Gelaro et al., 2017) re-gridded from native resolution of 0.5°x0.625° latitude and
414 longitude to 2°x2.5° using a reduced vertical grid of 47 layers.

415 We initialize our model in October 2014 from a full-chemistry benchmark file, allowing for 6
416 months of spinup before our period of interest spanning from March to November 2015. We run six
417 different model simulations with settings detailed in Table 1. The base model (BASE) includes the
418 halogen sources described above but no Arctic-specific halogen sources. The BLOW simulation adds
419 SSA production from blowing snow following Huang et al (2020) but using a more recent version of
420 GEOS-Chem. The PACK simulation adds snowpack Br₂ emissions using a constant yield from O₃
421 deposition. The PHOTOPACK simulation also emits Br₂ from snowpack but increases the Br₂ yield from

422 O₃ deposition under sunlight. These blowing snow [SSA](#) and snowpack sources are combined in the
423 BLOW+PACK and BLOW+PHOTOPACK simulations.

424 **2.7 Comparing GEOS-Chem results to MAX-DOAS vertical column densities**

425 GEOS-Chem simulates BrO mixing ratios for each of its 47 atmospheric layers. Reducing the
426 vertical resolution of the more-resolved GEOS-Chem predictions to be comparable to the coarser MAX-
427 DOAS data is necessary for appropriate comparison (Rodgers and Connor, 2003). To compare the
428 GEOS-Chem profiles with these two grid-coarsened quantities, we grid-coarsen the averaging kernels
429 produced by the HeiPro retrieval algorithm using Supplemental Equation S1 from Payne et al. (2009) to
430 the partial column averaging kernels shown in Figure 3. We use the average of all April averaging kernels
431 that pass our quality criteria (>0.5 DOFS in the lofted layer), which generally represents non-cloudy
432 conditions. We calculate modeled BrO_{LTcol} by applying the partial column averaging kernels shown in
433 Figure 3 to the GEOS-Chem modeled vertical BrO profiles.

434 Figure 3 shows the average partial column averaging kernel for the surface layer (0-200m AGL)
435 has near unit sensitivity to BrO at the ground, decaying to about 0.5 at 200m AGL then to zero at about
436 400m AGL, as desired. The sensitivity of the BrO_{LTcol} is near unity from about the surface to 600m AGL,
437 then slowly decays with 0.5 sensitivity at 2000m AGL. The resulting sensitivity to mid-tropospheric BrO
438 means that free-tropospheric BrO produced by the GEOS-Chem model contributes to modeled BrO_{LTcol},
439 albeit at 50% or lower sensitivity, even if the GEOS-Chem-predicted free-tropospheric BrO is above the
440 nominal 2000m top of the integration window. The residual sensitivity of the BrO_{LTcol} averaging kernel
441 above 2000m is caused by the limited ability of ground-based MAX-DOAS to distinguish the true altitude
442 of BrO at non-tangent geometries (higher viewing elevation angles) that are required to view BrO at these
443 higher altitudes. Figure 3 shows that BrO above 4 km makes only a small contribution to the modeled
444 BrO_{LTcol}, which was not included in the BrO_{LTcol}.

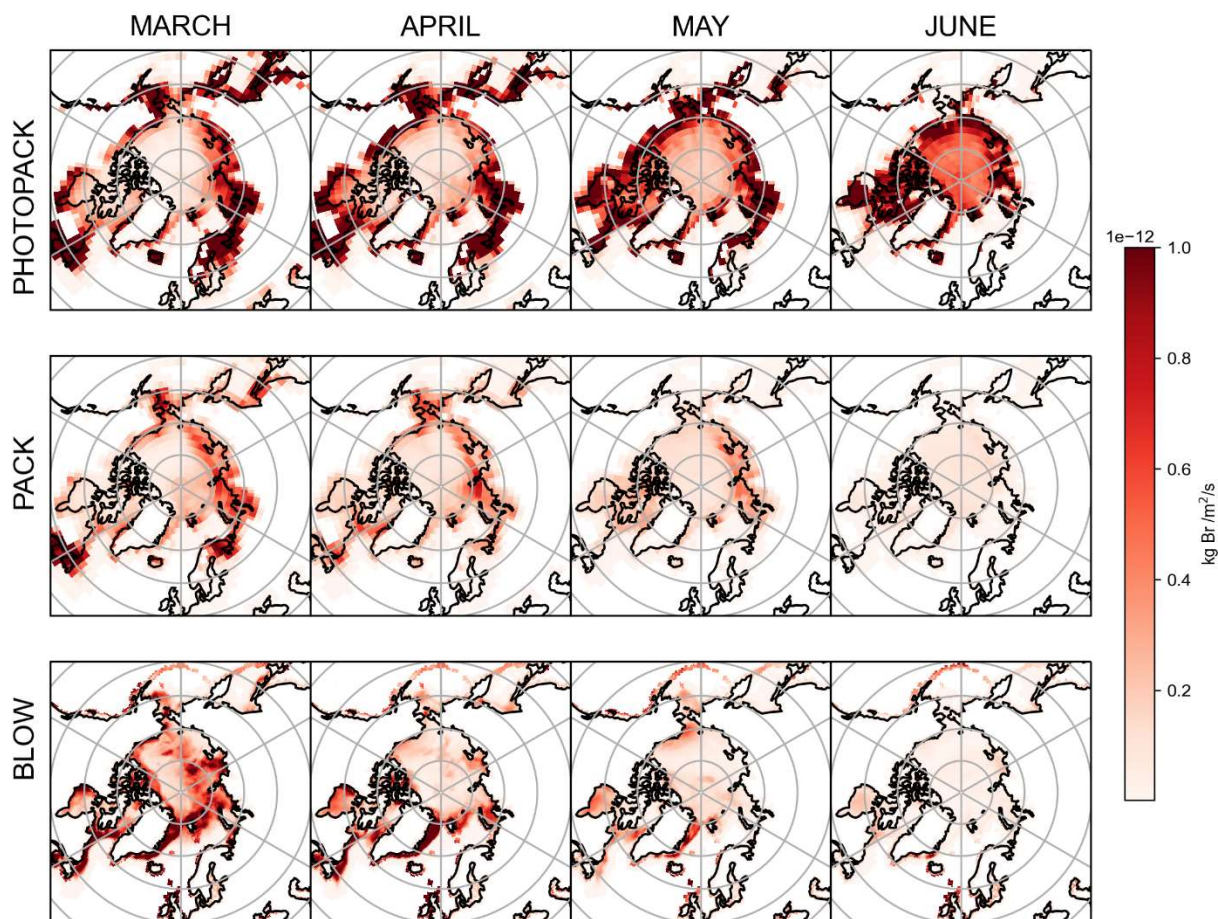

445

446 **Figure 3: Averaging kernels showing the sensitivity of retrieved $\text{BrO}_{\text{LTcol}}$ and retrieved BrO_{surf} to**
 447 **BrO at a range of altitudes.**

448 Each line represents a row of the averaging kernel matrix. BrO_{surf} is the column from the surface to 200 m
 449 and $\text{BrO}_{\text{LTcol}}$ is the column up to 2000 m.

450 Although it has been suggested in the literature (von Clarmann and Glatthor, 2019) that averaged
 451 averaging kernels can cause problems, we do not report data when there are clouds and thus are only
 452 using the more consistent averaging kernels that occur under clear sky conditions. We use other criteria
 453 related to vertical visibility to identify clear skies. As described in Peterson et al. (2015), the information
 454 content (DOFS) in the lofted layer is nearly linearly related to the aerosol optical depth. We find that the

455 slant column density of the O₂-O₂ collisional dimer (aka O₄) observed at 20° elevation angle is correlated
 456 with the lofted DOFS (Supplemental Figure S6). From this correlation we find that observations of clear
 457 sky conditions have 20° elevation angle O₄ dSCD > 10⁴³ molecule²cm⁻⁵ and use this cut to distinguish
 458 clear sky versus clouds. To assure that GEOS-Chem results are only compared to the clear-sky
 459 observational data, we apply this clear sky screen to the measured-modeled BrO_{LTcol} timeseries. The use
 460 of this screen also assists in minimizing variability in the averaging kernels and thus allowing the April
 461 averaged partial column averaging kernels (Figure 3) to be applied for clear skies at any time of the year.

462

463 **Figure 4: Mean snowpack Br₂ emissions and p-Br⁻ by month, as simulated by GEOS-Chem.**

464 The top row shows emissions of Br₂ in the PHOTOPACK run, the middle row shows the emissions of
 465 Br₂ in the PACK run, and the bottom row shows emissions of p-Br⁻ from adding the BLOW mechanism.

466 3. Examining reactive bromine in the Arctic spring

467 3.1 Snowpack Br₂ emissions

468 The top two rows of Figure 4 shows PHOTOPACK and PACK average snowpack Br₂ emissions
 469 for each spring month. The emission of Br₂ in PHOTOPACK increases over the Arctic Ocean in May and

470 June, when the sun is above the horizon for up to 24 hours per day and ozone deposition yield is almost
471 always at the photo-enhanced level of 7.5%. Notably, Br₂ emissions over the Arctic Ocean in the
472 PHOTOPACK and BLOW+PHOTOPACK runs are highest in June when the sun is nearly always five
473 degrees above the horizon and surface temperatures may drop below freezing. The PACK emissions are
474 lower than the PHOTOPACK Br₂ emissions by an order of magnitude and shows a seasonal cycle with a
475 high BrO_{LTcol} in April and May with a decrease in May and June. While our ozone deposition velocities
476 (see Supplemental Figure S5) over Arctic sea ice are much higher than previous estimates of an
477 approximate magnitude of 0.01 cm/s (Toyota et al., 2011), the PHOTOPACK run highlights that a 75-
478 fold increase in daytime Br₂ yield can lead to predictions of increased Br₂ production over the North Pole
479 in June. Monthly satellite observations show that BrO reaches a minimum over the Arctic Ocean in June
480 (Richter et al., 1998).

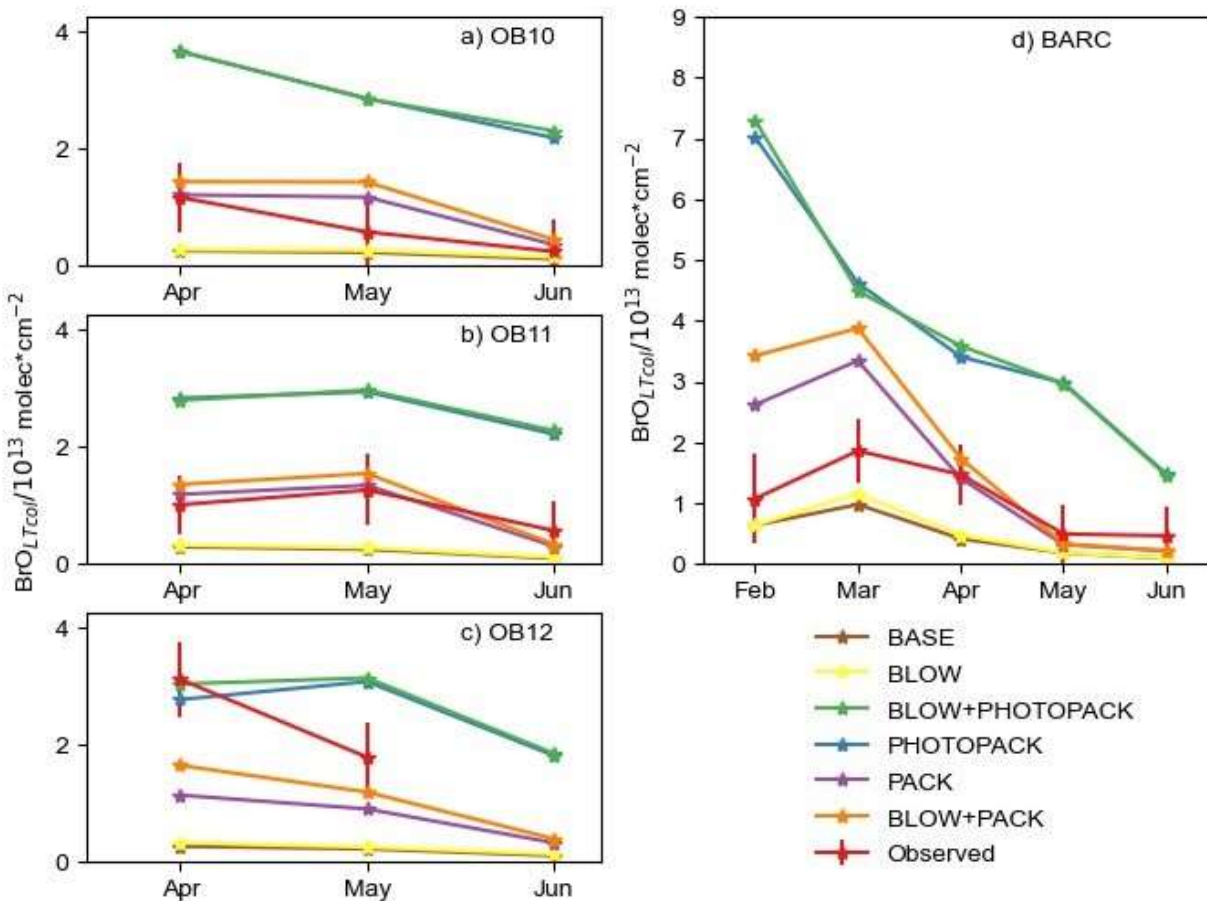

481 Coastal land regions within 200 km of the coastline have some of the highest modeled snowpack
482 Br₂ emissions (see Figure 4 rows 1 and 2). ~~Dry deposition velocities are lower over ice covered ocean~~
483 ~~than open ocean due to the higher likelihood of a stable surface boundary layer over the ice covered~~
484 ~~ocean (Toyota et al., 2016). This remains true within~~ Within GEOS-Chem, as deposition rates are greatest
485 over land, less rapid over ice-covered ocean, and lowest over open ocean (see Supplemental Figure S5).
486 Lower dry deposition velocities over the ice-covered Arctic Ocean lead to decreased deposition and
487 conversion to Br₂. In GEOS-Chem, ozone mixing ratios and deposition are over three orders of magnitude
488 larger than BrNO₃ and HOBr mixing ratios and deposition over the Arctic Ocean, and ozone deposition
489 contributes more than half of total Br₂ emitted in the PACK and BLOW+PACK runs. Our snowpack
490 mechanism assumes that all ozone deposited to the surface of a grid cell reacts with the snowpack cover
491 and produces Br₂. This assumption is more appropriate in the barren snow-covered coastal tundra but may
492 be less accurate in areas where deposition to vegetation dominates. This nonconservative approach may
493 lead to overestimation of Br₂ emissions from snowy vegetated surfaces. Our screens for snowpack
494 emissions described in section 1.3.5 tried to minimize these effects but may not work perfectly due to
495 finite grid cell resolution and other challenges. Increased Br₂ emissions observed in Figure 4 in northern
496 Europe may also be partially driven by increased local mixing ratios of ozone and NO_x over industrialized
497 regions such as the Kola Peninsula.

498 3.2 Blowing ~~s~~Snow ~~p~~Br aerosol bromide emissions

499 The bottom row of Figure 4 shows the total quantity of particulate bromide released by the
500 blowing snow SSA mechanism in the BLOW runs. Emissions over the Arctic Ocean decline each month
501 after the March maximum as rising temperatures increase the ~~windspeed~~wind speed threshold for blowing
502 snow SSA production. Some icy coastal regions with frequently high ~~windspeed~~wind speeds such as the

503 Aleutian Islands south of Alaska and the eastern coast of Greenland continue to emit SSA p-Br⁻ in April,
504 and the extremely high winds in the Aleutians enable SSA production into May. The location of specific
505 high-wind storm systems in spring 2015 may be evident in the darker red spots over the Arctic Ocean,
506 which are particularly noticeable over the Eurasian and Central Arctic in March. These monthly averages
507 are only accurate for the months in spring 2015 and may not be spatially representative of blowing snow
508 SSA production in other years.

509 The impact of the blowing snow SSA emissions on measured BrO is minimal on O-Buoys in the
510 Beaufort Gyre, possibly due to the spatial and seasonal variations in SSA p-Br⁻ emissions. Figure 4 shows
511 that 2015 SSA production was highest in March and April on the Eurasian and Central sector of the
512 Arctic, and thus the O-Buoys deployed as shown in Figure 2 are less exposed to the effects of SSA
513 production than the Arctic as a whole. Particulate bromide must be activated from SSA by heterogeneous
514 reactions as in Figure 1 and Table 3, leading to photochemical cycles that sustain further activation of
515 bromide from SSA. The dearth of sunlight over the Arctic Ocean in early March coincides with the
516 greatest SSA p-Br⁻ production and means that the increased February SSA p-Br⁻ emissions may not lead to
517 a direct increase in BrO.

518

519 **Figure 5: Monthly average BrO_{LTcol} in observations and model**

520 Monthly averages of BrO at a) O-Buoy 10, b) O-Buoy 11, c) O-Buoy 12, and d) BARC at Utqiagvik only
 521 using predictions and observations when dSCDO₄ > 1*10⁴³ molecules²cm⁻⁵. Observations with average 1σ
 522 error shown in red. All units in 10¹³ molecules/cm².

523

524 **3.3 Snowpack Br₂ emissions have more impact than blowing snow SSA on monthly BrO abundance**

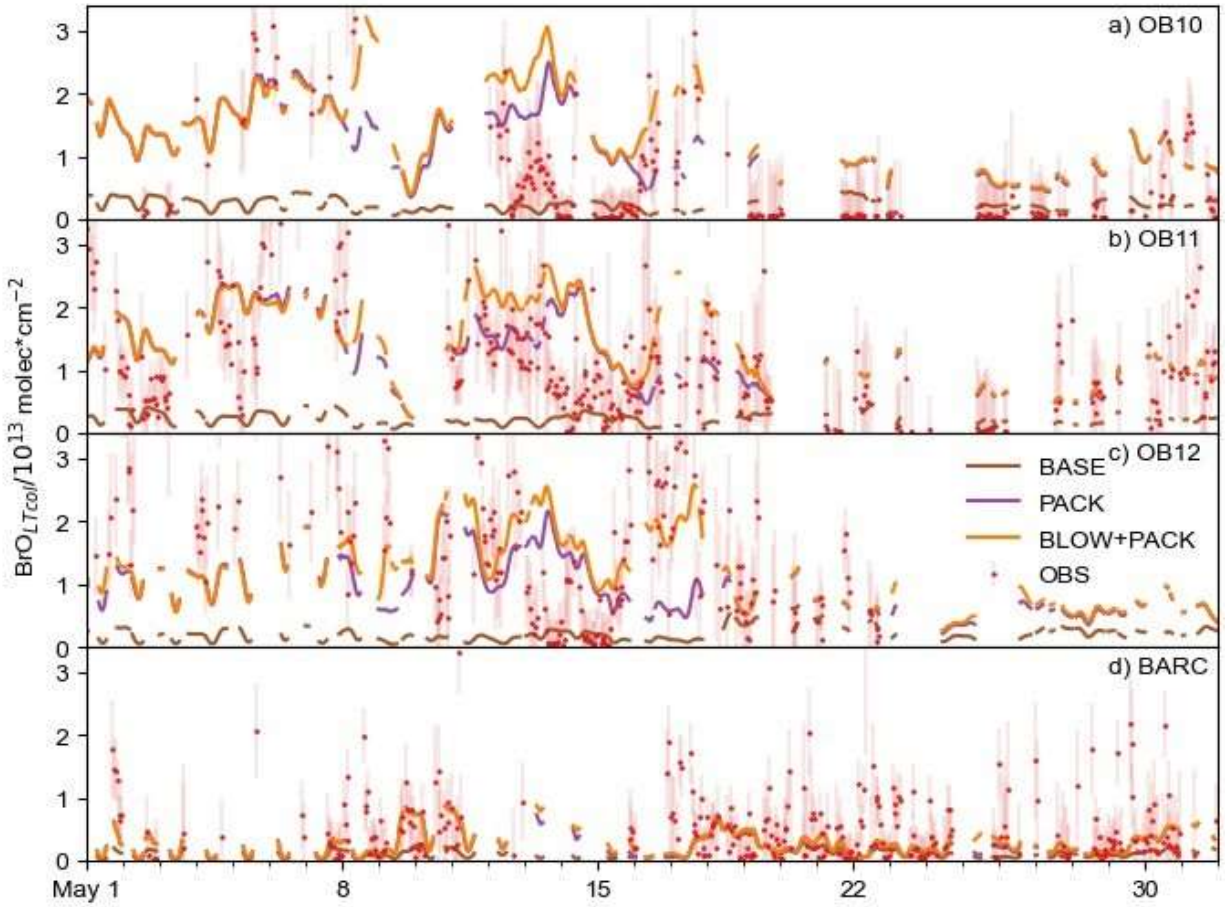

525 Increased levels of bromine have been historically seen at Utqiagvik during February, March,
 526 April and May (Berg et al., 1983). Previous O-Buoy data analysis noted BrO dropping to zero in June
 527 (Burd et al., 2017). Figure 5 shows monthly averaged modeled BrO_{LTcol} at Utqiagvik and on the O-Buoys
 528 for each model configuration. The difference in GEOS-Chem modeled monthly averaged BrO_{LTcol} for O-
 529 Buoy is minimal between the BASE and BLOW runs, the PHOTOPACK and BLOW+PHOTOPACK
 530 runs, and the PACK and BLOW+PACK runs.

531 Both BASE and BLOW runs predict near-zero BrO_{LTcol} on all O-Buoys and during most months
 532 at Utqiagvik. The exception to this is the slight increases in monthly modeled BrO_{LTcol} to 1*10¹³
 533 molecules/cm² in March and April. This BASE increase in BrO_{LTcol} indicates that oceanic SSA rather than
 534 blowing snow SSA can affect modeled BrO at Utqiagvik due to its closer proximity to open ocean regions

535 than the O-Buoys. The increases in BrO from the BASE model due to the addition of BLOW, most
536 evident at Utqiagvik in March 2015, are a result of increased particulate bromide available for activation
537 on aerosol surfaces. The PACK and BLOW+PACK runs show the highest skill in reproducing
538 observations, falling within the monthly average of hourly measured $\text{BrO}_{\text{LTcol}}$ error for 9 of the 13 months
539 plotted in Figure 5. Both PACK and BLOW+PACK replicate the observed monthly pattern on O-Buoy 11
540 and at Utqiagvik especially well. The seasonal pattern of maximum modeled $\text{BrO}_{\text{LTcol}}$ at Utqiagvik in
541 March followed by a decrease to near-zero modeled $\text{BrO}_{\text{LTcol}}$ in May is replicated in both runs despite the
542 overprediction of $\text{BrO}_{\text{LTcol}}$ in February and March. The BLOW+PACK monthly $\text{BrO}_{\text{LTcol}}$ is between
543 $1 \cdot 10^{12}$ molecules/cm² and $1 \cdot 10^{13}$ molecules/cm² higher than PACK monthly $\text{BrO}_{\text{LTcol}}$ due to the addition
544 of blowing snow SSA. This increase is most pronounced in February and March at Utqiagvik when lower
545 temperatures lead to lower threshold windspeedwind speeds and increased SSA production (see
546 Supplemental Figure S4).

547 The inclusion of increased daytime yield of snowpack Br_2 drives monthly average $\text{BrO}_{\text{LTcol}}$ above
548 $3 \cdot 10^{13}$ molecules/cm² in the PHOTOPACK and BLOW+PHOTOPACK runs from February until June,
549 far above peak observed monthly $\text{BrO}_{\text{LTcol}}$ of $2 \cdot 10^{13}$ molecules/cm². The PHOTOPACK and
550 BLOW+PHOTOPACK runs show steady decline in $\text{BrO}_{\text{LTcol}}$ from February to June at Utqiagvik.
551 Predictions of PHOTOPACK and BLOW+PHOTOPACK monthly June $\text{BrO}_{\text{LTcol}}$ above $2 \cdot 10^{13}$
552 molecules/cm² on the O-Buoys is due to increasing photo-assisted local snowpack Br_2 emissions over the
553 Arctic Ocean (see Figure 5). The PHOTOPACK mechanism predicts monthly average $\text{BrO}_{\text{LTcol}}$ within
554 observational error only on O-Buoy 12 in April. Aside from this replication of the sparsely sampled O-
555 Buoy 12 April $\text{BrO}_{\text{LTcol}}$, the PHOTOPACK mechanism overestimates $\text{BrO}_{\text{LTcol}}$. ~~This overprediction of~~
556 ~~$\text{BrO}_{\text{LTcol}}$ by PHOTOPACK and BLOW+PHOTOPACK extends to prediction of unrealistically high~~
557 ~~mixing ratios for all tropospheric bromine species (see Supplemental Figure S7). This overprediction is a~~
558 ~~product of high ozone deposition velocities and daytime conversion rates to Br_2 .~~

559

560

561 **Figure 6: May Hourly BrO_{LTcol} timeseries**

562 Hourly timeseries of BLOW+PACK, PACK, and BASE BrO_{LTcol} on a) O-Buoy 10, b) O-Buoy 11, c) O-
 563 Buoy 12 and d) BARC at Utqiagvik in the 2015 Arctic Spring. O-Buoy observations and error bars in red,
 564 BASE BrO_{LTcol} in brown, PACK BrO_{LTcol} in purple, and BLOW+PACK BrO_{LTcol} in orange. All BrO_{LTcol}
 565 plotted continuously except for gaps where dSCDO₄ > 1*10⁴³ molecules²cm⁻⁵.

566

567 **3.4-BLOW+PACK run best replicates hourly BrO events in mid and late May**

568 The model's hourly predictions of BrO_{LTcol} in May 2015 are shown in Figure 6 for the BASE,
 569 PACK, and BLOW+PACK runs. Figure 6 screens modeled BrO_{LTcol} for times when dSCD O₄ > 1*10⁴³
 570 molecules²cm⁻⁵, while Supplemental Figures S7 and S8 make only direct comparisons between
 571 observations of BrO_{LTcol} on the O-Buoys (S7) and at Utqiagvik (S8) throughout all of Spring 2015. The
 572 O-Buoys show fluctuations in observed BrO_{LTcol} during May and show consistent increased columns of
 573 BrO_{LTcol} from May 10 to May 20. The BASE run never rises above 10¹³ molecules/cm² and underpredicts
 574 most May hourly BrO_{LTcol}, although BASE predicts monthly BrO_{LTcol} on OB10 for two-out-of-three
 575 months May and June. Both PACK and BLOW+PACK runs show better skill in replicating BrO_{LTcol}.
 576 The addition of the snowpack mechanism allows us to predict increased BrO_{LTcol} in late May on O-Buoys

577 10 and 11. This points to the role of surface snowpack in late-season events in agreement with the
578 findings of Burd et al. (2017).

579 We can identify the role of blowing snow SSA by comparing the PACK and BLOW+PACK runs.
580 Both PACK and BLOW+PACK runs underestimate $\text{BrO}_{\text{LTcol}}$ during the first ten days of May. BrO
581 predictions and ~~observations are more active~~ show higher variability and peaks starting on May 10. The
582 blowing snow SSA mechanism increases BLOW+PACK $\text{BrO}_{\text{LTcol}}$ on May 12 and 13. PACK is skilled at
583 replicating observed O-Buoy 11 $\text{BrO}_{\text{LTcol}}$ on both days, and both PACK and BLOW+PACK are within
584 observational $\text{BrO}_{\text{LTcol}}$ error on May 13.

585 A BrO event also occurs on May 13 on O-Buoy 10. While the strength of the O-Buoy 10 BrO
586 event is overestimated by PACK and BLOW+PACK, the shape of that event is ~~duplicated-reproduced~~ in
587 both runs. ~~Examination of the O-Buoy 10 vertical Br_y profile in Supplemental Figure S7 shows surface~~
588 ~~BrO increasing to 2 pmol/mol in the lowest 200 meters of the troposphere on May 10. BrO is mixed~~
589 ~~vertically on May 12 and 13 throughout the lower troposphere, with a linear decrease from surface BrO~~
590 ~~mixing ratios of 3 pmol/mol to 0 pmol/mol at 1200 m altitude. This May 12 $\text{BrO}_{\text{LTcol}}$ event is also~~
591 ~~associated with surface ozone depletion to 15 nmol/mol.~~

592 Observed $\text{BrO}_{\text{LTcol}}$ decreases rapidly on all O-Buoys after May 14, and the model is unable to
593 track this sharp decrease. Rapid changes in $\text{BrO}_{\text{LTcol}}$ may be caused by sharp edges in BrO-enriched
594 airmasses such as those seen by Simpson et al. (2017). GEOS-Chem run at this resolution cannot replicate
595 abrupt changes in BrO, but it does slowly decrease $\text{BrO}_{\text{LTcol}}$ to reach $\text{BrO}_{\text{LTcol}}$ to less than 10^{13}
596 molecules/cm² on May 16. The BLOW+PACK mechanism is skilled in replicating the magnitude and
597 features of a mid-May BrO event on ~~several~~ O-Buoys 10 and 11.

598 Figure 7 shows all Spring 2015 $\text{BrO}_{\text{LTcol}}$ observations on O-Buoys 10, 11, 12, and BARC plotted
599 against PACK $\text{BrO}_{\text{LTcol}}$ and BLOW+PACK $\text{BrO}_{\text{LTcol}}$. The increase in $\text{BrO}_{\text{LTcol}}$ on adding BLOW leads to
600 fewer underpredictions of observations (see bottom right section of Figure 7b). The Pearson correlation
601 coefficient (r) between PACK ~~GE~~ $\text{BrO}_{\text{LTcol}}$ and observed $\text{BrO}_{\text{LTcol}}$ is 0.33, improving to 0.39 on addition of
602 BLOW in the BLOW+PACK run. Other runs show less skill in replicating observations, with a BASE
603 $\text{BrO}_{\text{LTcol}}$ Pearson correlation to observations of 0.19 and a BLOW $\text{BrO}_{\text{LTcol}}$ Pearson correlation to
604 observations of 0.23. We also performed a simple linear regression to determine the relationship between
605 predictions and observations for each run. The slope of the line of best fit improves drastically on addition
606 of PACK, changing from 0.06 for BASE and 0.07 for BLOW to 0.33 for PACK and 0.44 for
607 BLOW+PACK. There is a positive synergistic effect on the slope of the line of best fit when using both
608 BLOW and PACK in combination rather than individually. The use of both BLOW and PACK

609 mechanisms implements literature findings on the processes influencing Arctic reactive bromine and
610 increases correlation between GEOS-Chem predictions and observations.

611

612 **Figure 7: Hourly modeled BrO_{LTcol} versus BrO_{LTcol} observations**

613 Two dimensional histograms showing density of GEOS-Chem predicted BrO_{LTcol} versus all
614 observed Spring 2015 hourly Br_{LTcol}, with a) PACK BrO_{LTcol} shown at left sorted into square bins of 0.2
615 with an Pearson r correlation to observations of 0.33 and b) BLOW+PACK BrO_{LTcol} on the bottom sorted
616 into square bins of 0.2 with Pearson r correlation to observations to 0.39. All units are in molecules/cm 2 .
617 1:1 line drawn in the center in black, with a margin of the average observational error plotted in dashed
618 black lines around the central 1:1 line.

619 **4. Arctic Spring reactive bromine modeling discussion**

620 **4.1 Use of both mechanisms in conjunction leads to best prediction of tropospheric BrO results**

621 Table 2 shows the root mean squared error (RMSE) of each model run as compared to BrO_{LTcol}
622 observations in at each different location in Spring 2015. The PACK and BLOW+PACK runs have the
623 lowest RMSE on O-Buoys 11 and 12, and among the lowest RMSE on O-Buoy 10. Utqiagvik shows the
624 lowest RMSE of $1.25 \cdot 10^{13}$ molec/cm 2 for the BLOW run, although the PACK run is not too far off at
625 $1.57 \cdot 10^{13}$ molec/cm 2 . Despite the fact that BLOW+PACK has a higher RMSE of $1.75 \cdot 10^{13}$ molec/cm 2 at
626 Utqiagvik, the BLOW+PACK run performs the best or near the best of all runs on the O-Buoys and
627 includes both known processes for Arctic reactive bromine production. The PHOTOPACK and
628 BLOW+PHOTOPACK runs with increased daytime yield have a consistently high RMSE of $2.46 \cdot 10^{13}$
629 molec/cm 2 or higher, often double the RMSE of other model runs.

630 Initial implementation of this snowpack mechanism in Toyota et al. (2011) increased the daytime
631 yield of Br $_2$ from ozone depletion-deposition to 7.5% to improve agreement between observed and
632 modeled surface ozone mixing ratios. Toyota et al. (2011) also increased the surface resistance of ozone
633 to 10^{4000} s/m, decreased deposition velocities on Arctic snowpack to approximately 0.01 cm/s. Our

634 model using a constant yield of Br from ozone deposition performs best, despite observations that
 635 sunlight has an effect on reactive bromine recycling in the snowpack (Pratt et al., 2013; Custard et al.,
 636 2017). GEOS-Chem does not explicitly model heterogeneous photochemistry within the snowpack
 637 interstitial space but does include heterogeneous bromine chemistry on aerosol particle surfaces after the
 638 Br₂ is emitted from the snowpack into the lowest model layer. The updates to GEOS-Chem halogen
 639 chemistry (Schmidt et al., 2016; Sherwen et al., 2016b; Chen et al., 2017; Wang et al., 2019b) should be
 640 mechanistically sufficient to model daytime heterogeneous chemistry of reactive bromine on aerosol
 641 surfaces. We note that improvements to GEOS-Chem have increased the explicit modeling of these
 642 photochemical recycling and amplification processes, possibly reducing the need for empirical increases
 643 to daytime yields.

644 Our findings differ from recent implementations of the snowpack mechanism in Herrmann et al.
 645 (2021) and Marelle et al. (2021). While all snowpack mechanisms are based on Toyota et al. (2011),
 646 several large differences in model configuration and mechanism implementation explain these
 647 differences. We allow Br₂ production from ozone deposition over all snow surfaces, leading to much
 648 higher Br₂ production over MYI and coastal regions. Land snowpack can produce Br₂ on exposure to
 649 ozone and sunlight (Pratt et al., 2013; Custard et al., 2017) and Figure 4 shows our coastal snowpack
 650 producing large quantities of Br₂. Tropospheric reactive bromine chemistry has been observed up to 200
 651 km inland from the coast (Peterson et al., 2018). Marelle et al. (2021) underestimates BrO in late March
 652 and overestimates Utqiaġvik BrO in early April. This seasonal pattern may be due to increased daytime
 653 ozone yield on first year ice near Utqiaġvik in April. Herrmann et al. (2021) found that HOBr and BrNO₃
 654 deposition was more important in driving snowpack Br₂ production and that the daytime yield of 7.5%
 655 Br₂ on ozone deposition underpredicted BrO. We find that ozone contributes slightly more than HOBr
 656 and BrNO₃ because we allow for Br₂ production on ozone deposition over multi-year ice and coastal
 657 snowpack regions. The temporal scale of this manuscript spans the entire year, while Herrmann et al.
 658 (2021) only spans February, March, and April. Our longer timescale highlights the issue of increased
 659 daytime Br₂ yield during May and June (see Figure 4 PHOTOPACK) with increased emissions over the
 660 Arctic Ocean that are not in agreement with satellite observations of minimal Arctic tropospheric BrO in
 661 June (Richter et al., 1998).

662 **Table 2: Model root mean square error by run and location.**

663 Root mean squared model error (RMSE) shown in $\text{pmol/mol BrO}_{\text{LTcol.}}/10^{12} \text{ molec/cm}^2$ RMSE calculated
 664 as the square root of the mean of the squared errors for all observations with valid BrO_{LTcol} in Spring
 665 2015.

$\text{Units in BrO}_{\text{LTcol.}}/10^{12} \text{ molec/cm}^2$	OB10	OB11	OB12	UtqiaġvikUTQ
BASE	9.9	12.9	22.9	13.0
BLOW	9.7	12.7	22.4	12.5

PACK	9.9	10.0	18.6	15.2
BLOW+PACK	10.1	10.1	15.7	17.5
PHOTOPACK	30.0	24.8	26.2	30.1
BLOW+PHOTOPACK	30.3	24.6	26.3	31.4

666

667 **4.2 Addition of PACK mechanism increases surface ozone predictive skill**

668 The Barrow Arctic Research Center (BARC) in Utqiagvik has the most comprehensive coverage
669 of surface ozone in Spring 2015. A constant yield of 0.1% Br₂ from ozone deposition allows us to
670 approximate the average vertical extent of ozone depletion events at Utqiagvik in May 2015. The increase
671 in Br_y in the PACK and BLOW+PACK runs is confined to the lowest 1000 m of the atmosphere (see
672 Supplemental Figure S97). Ozone depletions, caused by reactive bromine chemistry, often only occur
673 within the lowest 1000 m of the troposphere (Bottenheim et al., 2002; Salawitch et al., 2010). Previous
674 studies have found evidence of lofted BrO in plumes at altitudes up to 900 m AGL (Peterson et al., 2017).
675 The monthly average Utqiagvik May surface ozone in BLOW and BLOW+PACK is 22 nmol/mol,
676 matching mean May surface ozone from 1999-2008 (Oltmans et al., 2012). The PHOTOPACK runs
677 generate mean May surface ozone depletion to approximately 5 nmol/mol, far below the May mean. The
678 PACK and BLOW+PACK runs duplicate the approximate vertical extent of elevated bromine levels and
679 the strength of typical historic May ozone depletion.

680 Figure 8 shows hourly ozone predictions alongside BARC ozone observations (McClure-Begley,
681 Petropavlovskikh, and Oltmans, 2014). The BASE model fails to replicate variance in ozone measured at
682 BARC in Utqiagvik, with a Pearson correlation coefficient to observations of 0.35. Adding PACK
683 improves Pearson correlation to 0.47, within rounding error of BLOW+PACK Pearson correlation of
684 0.47. Both PACK and BLOW+PACK significantly improve model performance in replicating ozone
685 depletions in such as the depletion below 30 nmol/mol from March 20 to March 29 but fail to track the
686 subsequent recovery of ozone to background levels on April 1. Predicted PACK ozone does not recover
687 to background levels up to the until a height of roughly 1000 m. A similar pattern where our model
688 replicates low ozone but fails to predict the recovery of ozone to background levels occurs on April 5 and
689 15. Examination of ozone profiles in GEOS-Chem found that GEOS-Chem underpredicts tropospheric
690 ozone by 10-20 ppb north of 60° latitude (Wang et al., 2021), which contributes to the low ozone
691 predictions in our runs. Previous modeling of Utqiagvik spring 2012 ozone in WRF-Chem found a similar
692 linear correlation coefficient of 0.5 to BROMEX observations (Simpson et al., 2017) when using both
693 blowing snow and snowpack mechanisms (Marelle et al., 2021). We are biased low compared to
694 observations, with a root mean square error of 17.0 nmol/mol in BLOW+PACK compared to a root mean
695 square error of 12.9 nmol/mol in Marelle et al. (2021). This may be partially due to limited vertical
696 resolution in GEOS-Chem that may be inadequate to describe shallow surface-based temperature

697 inversions and subsequent recovery. The high bias in ozone deposition velocity over sea ice surfaces may
698 also contribute to low ozone mixing ratios near the surface.

699

700 **Figure 8: Hourly Utqiagvik ozone timeseries**

701 Hourly timeseries of BLOW+PACK, PACK, and BASE ozone at Utqiagvik in the 2015 Arctic Spring.
702 Ozone observations at BARC in black (McClure-Begley, Petropavlovskikh and Oltmans, 2014), BASE
703 ozone in brown, PACK ozone in purple, and BLOW+PACK ozone in orange. Gaps indicate missing
704 observational data.

705

706 A similar improvement in ozone predictions on the addition of PACK is seen on the O-Buoys, but
707 is harder to quantify due to observational gaps in ozone data. Supplemental Figure S10 shows hourly
708 ozone predictions graphed over O-Buoy 11 observations and Supplemental Figure S11 shows hourly
709 ozone predictions graphed over O-Buoy 12. O-Buoy 10 was not able to gather an observations of ozone in
710 2015. The clearest impact of PACK in Figures S10 and S11 is seen in early April, with observed ozone
711 dropping near zero nmol/mol and PACK and BLOW+PACK runs dropping to five nmol/mol while the
712 BASE run remains near 20 nmol/mol. Figure S10 shows that ozone predictions on O-Buoy 10 in May are
713 less accurate, failing to fall below 10 nmol/mol ozone while observations show ozone dropping near the
714 detection limit. The O-Buoys appear to experience more late-season ozone depletion events that GEOS-

715 Chem fails to replicate, possibly due to warming temperatures increasing vertical mixing and replenishing
 716 ozone near the surface.

717
 718 **Table 3: Arctic Tropospheric Reactions Rates by Model Run**

719 Rates for each of the reactions listed in Figure 1 organized by GEOS-Chem run. All units are listed as
 720 millions of moles per hour across the region shown in Supplemental Figure S14. R in equation R2 refers
 721 to any organic molecule. Y in equation 1 represents NO, Cl, or H. X in equation HR6a represents either
 722 Br or Cl. PHOTOPACK and BLOW+PHOTOPACK are excluded as they severely overpredict BrO as
 723 seen in Figures 4 and 5.

	BASE	BLOW	PACK	BLOW+PACK	Reaction Equation
R1	17.57	17.77	27.7	28.4	<u>BrO + YO -> Br+ O₂</u>

P8	0	0	0	0	<u>BrI +hv-> Br +I</u>

724

725 5. Examining reactive bromine in the Arctic in September and October

726 O-Buoys deployed during fall 2015 measured BrO slant column densities characterized by noise
727 around zero (see Supplemental Figures S128 and S139). We do not retrieve vertical column density from
728 these fall slant column densities, because the resulting retrievals would be biased positive due to an
729 algorithm requirement that only positive BrO column densities are allowed in the optimal estimation
730 inversion. These differential slant column densities (dSCDs) can be used qualitatively to determine the
731 presence or absence of BrO above the detection limit. If the dSCDs display noise around zero at all
732 viewing angles, the BrO in the troposphere is below the detection limit of the spectrometer. ~~The A~~ pattern
733 of larger BrO dSCDs at near-horizon viewing elevation angles indicating the presence of tropospheric
734 BrO above the detection limit is only observed at Utqiagvik during Arctic Spring (see in 2015
735 Supplemental Figure S127); ~~indicate the presence of tropospheric BrO above the detection limit, which~~
736 ~~only occur during Arctic spring~~. Any BrO present in the Arctic troposphere in September and October
737 falls below detection limits at Utqiagvik (see Supplemental Figure S128) and on each O-Buoy (see
738 Supplemental Figure S139). The average Arctic Spring 2015 MAX-DOAS BrO_{LTcol} detection limits are 5
739 x 10¹² molecules/cm² (Peterson et al., 2015; Simpson et al., 2017; Swanson et al., 2020). Both BLOW and
740 PACK mechanisms lead to prediction of increased fall BrO because the weather and sea ice conditions
741 specified in the emission algorithms occur in fall as well as spring.

742 Figure 9 shows fall predictions of BrO_{LTcol} filtered for times when solar elevation angle was
743 greater than 5°. BASE and ~~SNOW-PACK~~ BrO_{LTcol} remain near zero in September but rise above the
744 MAX-DOAS detection limit of 5 x 10¹² molecules/cm² BrO_{LTcol} in October. The addition of the blowing
745 snow SSA mechanism propels BLOW BrO_{LTcol} up to 6 x 10¹³ molecules/cm² in October. O-Buoys 13 and
746 14 have the highest modeled fall BrO_{LTcol} but even Utqiagvik has several days of BrO_{LTcol} above 5 x 10¹²
747 molecules/cm² in late October. There is no clear evidence of any BrO above MAX-DOAS detection limits
748 at Utqiagvik or on any O-Buoy in October, as seen by the dSCDs scattered around zero in Supplemental
749 Figures S128 and S139.

750

751

752 **Figure 9: Fall GEOS-Chem Predicted $\text{BrO}_{\text{LTcol}}$**

753 Hourly timeseries of BLOW+PACK, PACK, and BASE $\text{BrO}_{\text{LTcol}}$ on a) O-Buoy 10, b) O-Buoy 11, c) O-
 754 Buoy 12 and d) BARC at Utqiagvik during September and October 2015. BASE $\text{BrO}_{\text{LTcol}}$ in brown,
 755 BLOW $\text{BrO}_{\text{LTcol}}$ in yellow, PACK $\text{BrO}_{\text{LTcol}}$ in purple, and BLOW+PACK $\text{BrO}_{\text{LTcol}}$ in orange. All $\text{BrO}_{\text{LTcol}}$
 756 plotted continuously except for gaps where solar elevation angle was less than 5° .

757 Both mechanisms assume that snowpack and SSA are just as capable of recycling reactive
 758 bromine as in the springtime. High fall and winter SSA agrees with observations of peak SSA during
 759 polar winter in both Antarctica (Wagenbach et al., 1998) and in the Arctic (Jacobi et al., 2012). The
 760 deposition of Arctic haze (Douglas and Sturm, 2004) and SSA (Jacobi et al., 2019) increases snowpack
 761 salinity and sulfate content over the course of winter and spring. This seasonal change in snowpack
 762 salinity and acidity may enable reactive bromine recycling in the Arctic Spring, but there may not
 763 sufficient haze and SSA deposition in fall to decrease snowpack pH and increase snowpack bromide
 764 content. Additional observations of fall snowpack over sea ice including ion content could show different
 765 snowpack composition in spring and fall. Thus the GEOS-Chem model overestimates fall BrO by
 766 assuming the fall snowpack is equally capable of reactive bromine recycling as spring snowpack, possibly
 767 due to the assumption of an infinite reservoir of snowpack bromide in all seasons. Most other modeling
 768 exercises have focused on spring with unknown predictions in fall, possibly indicating problems in

769 mechanisms or parameterizations being employed, so we suggest that modeling should be done for a full
770 year to improve underlying chemistry and physics. We also suggest a fall snow sampling campaign to
771 validate modeled fall BrO.

772 6. Conclusions

773 We add snowpack Br₂ production to GEOS-Chem based on multiple field observations
774 demonstrating molecular bromine production in snowpack interstitial air. We use a mechanistic
775 parameterization of snowpack Br₂ production based on Toyota et al. (2011) in which Br₂ is emitted from
776 all snowpack of sufficient salinity and depth over land and sea ice upon deposition of the precursor
777 species HOBr, BrNO₃, and ozone. Prior work has also added a blowing snow SSA production mechanism
778 that increases aerosol particulate bromide and thus facilitates heterogeneous recycling of reactive bromine
779 on these aerosol particle surfaces. We update the halogen scheme to GEOS-Chem 12.9.3 and performed
780 six model simulations including a BASE run with neither blowing snow SSA nor snowpack emissions, a
781 PACK run assuming constant yield of Br₂ on ozone deposition over all snow surfaces, a PHOTOPACK
782 run assuming increased daytime yield of Br₂ on ozone deposition (similar in Toyota et al., 2011), a
783 BLOW run using only blowing snow SSA formation and two additional runs combining BLOW and each
784 respective PACK mechanism. The increased daytime yield of Br₂ in PHOTOPACK leads to
785 overprediction of BrO in these simulations, but the PACK run (with constant Br₂ yield day and night)
786 matches monthly averaged BrO vertical column densities within measurement error for 9 of 13 cases at
787 O-Buoy and Utqiagvik in springtime months. The PACK and BLOW+PACK runs were successful in
788 replicating observed ~~mid-May~~ BrO events on O-Buoys in May as well as recurrence events at the end of
789 May. The BLOW mechanism effectively increases aerosol surface available for turnover of reactive
790 bromine. The snowpack mechanism has more impact on modeled BrO mixing ratios than the blowing
791 snow SSA mechanism, but both contribute to tropospheric reactive bromine. We extend our model run to
792 the full year and find that enhanced daytime Br₂ yield can lead to increased Arctic Ocean Br₂ production
793 in the summer. Examining modeled BrO in fall 2015 reveals prediction of BrO when using these
794 mechanisms that are at odds with observations.

795 The inclusion of two Arctic reactive bromine production mechanisms based on literature
796 observations of snowpack Br₂ emission and blowing snow SSA formation improves model skill in
797 replicating Arctic tropospheric BrO in spring 2015. The snowpack is an important source of reactive
798 bromine, and SSA particles provide an abundant surface for sustained reactive bromine recycling in the
799 troposphere. We find that using both snowpack and blowing snow SSA bromine production mechanisms
800 is necessary for modeling BrO in the Arctic.

801 *Competing interests:* The authors declare that they have no conflict of interest.

802 Author contributions. WFS, WRS and CH designed the study. WRS collected and curated MAX-DOAS
803 data. KC, LM, JT, LJ, JH and contributed code for reactive bromine mechanisms. CH, KC, LJ, JH, BA,
804 SZ, QC, XW, and TS contributed model updates. WFS carried out modeling and analysis. WFS wrote the
805 paper with input from all authors.

806 7. Acknowledgements

807 We acknowledge support from the National Science Foundation for providing funding under grants ARC-
808 1602716, AGS-1702266, AGS-2109323, and ARC-1602883. This work also supported by the CNRS
809 INSU LEFE-CHAT program under the grant Brom-Arc, and NASA grant 80NSSC19K1273. This
810 research has received funding from the European Union's Horizon 2020 research and innovation program
811 under grant agreement no. 689443 via project iCUPE (Integrative and Comprehensive Understanding on
812 Polar Environments). The O-Buoy and Utqiagvik ground-based BrO datasets are available in the
813 arcticdata.io repository (doi:10.18739/A2WD4W). We recognize the work of Jiayue Huang in adding the
814 blowing snow SSA mechanism to GEOS-Chem. We would like to thank the National Oceanic and
815 Atmospheric Administration (NOAA) Global Monitoring Division for the provision of ozone and
816 temperature data near Utqiagvik available online at doi:10.7289/V57P8WBF. We acknowledge use of the
817 coastline distance dataset from the Pacific Islands Ocean Observing System. We acknowledge the use of
818 imagery from the Land Atmosphere Near Real-Time Capability for EOS (LANCE) system and services
819 from the Global Imagery Browse Services (GIBS), both operated by the NASA/GSFC/Earth Science Data
820 and Information System (ESDIS, <https://earthdata.nasa.gov>) with funding provided by NASA/HQ. We
821 owe a debt of gratitude to all members of the Atmospheric Chemistry and Global Change group at Florida
822 State University for their support for working with GEOS-Chem and Python. We thank the global GEOS-
823 Chem community for their tireless work to improve the model. We also thank all involved in the O-Buoy
824 project for data collection and analysis.
