18 **Abstract**

19 Reactive halogens play a prominent role in the atmospheric chemistry of the Arctic during  
20 springtime. Field measurements and modeling studies suggest that halogens are emitted to the atmosphere  
21 from snowpack and reactions on wind-blown snow-sourced aerosols. The relative importance of  
22 snowpack and blowing snow sources is still debated, both at local scales and regionally throughout the  
23 Arctic. To understand implications of these halogen sources on a pan-Arctic scale, we simulate Arctic  
24 reactive bromine chemistry in the atmospheric chemical transport model GEOS-Chem. Two mechanisms  
25 are included: 1) a blowing snow sea salt aerosol formation mechanism and 2) a snowpack mechanism  
26 assuming uniform molecular bromine production from all snow surfaces. We compare simulations  
27 including neither mechanism, each mechanism individually, and both mechanisms to examine conditions  
28 where one process may dominate or the mechanisms may interact. We compare the models using these  
29 mechanisms to observations of bromine monoxide (BrO) derived from multiple-axis differential optical  
30 absorption spectroscopy (MAX-DOAS) instruments on O-Buoy platforms on the sea ice and at a coastal  
31 site in Utqiagvik, Alaska during spring 2015. Model estimations of hourly and monthly average BrO are  
32 improved by assuming a constant yield of 0.1% molecular bromine from all snowpack surfaces on ozone  
33 deposition. The blowing snow aerosol mechanism increases modeled BrO by providing more bromide-

34 rich aerosol surface area for reactive bromine recycling. The snowpack mechanism led to increased model  
35 BrO across the Arctic Ocean with maximum production in coastal regions, whereas the blowing snow  
36 aerosol mechanism increases BrO in specific areas due to high surface wind speeds. Our uniform  
37 snowpack source has a greater impact on BrO mixing ratios than the blowing snow source. Model results  
38 best replicate several features of BrO observations during spring 2015 when using both mechanisms in  
39 conjunction, adding evidence that these mechanisms are both active during the Arctic Spring. Extending  
40 our transport model throughout the entire year leads to predictions of enhanced fall BrO that are not  
41 supported by observations.

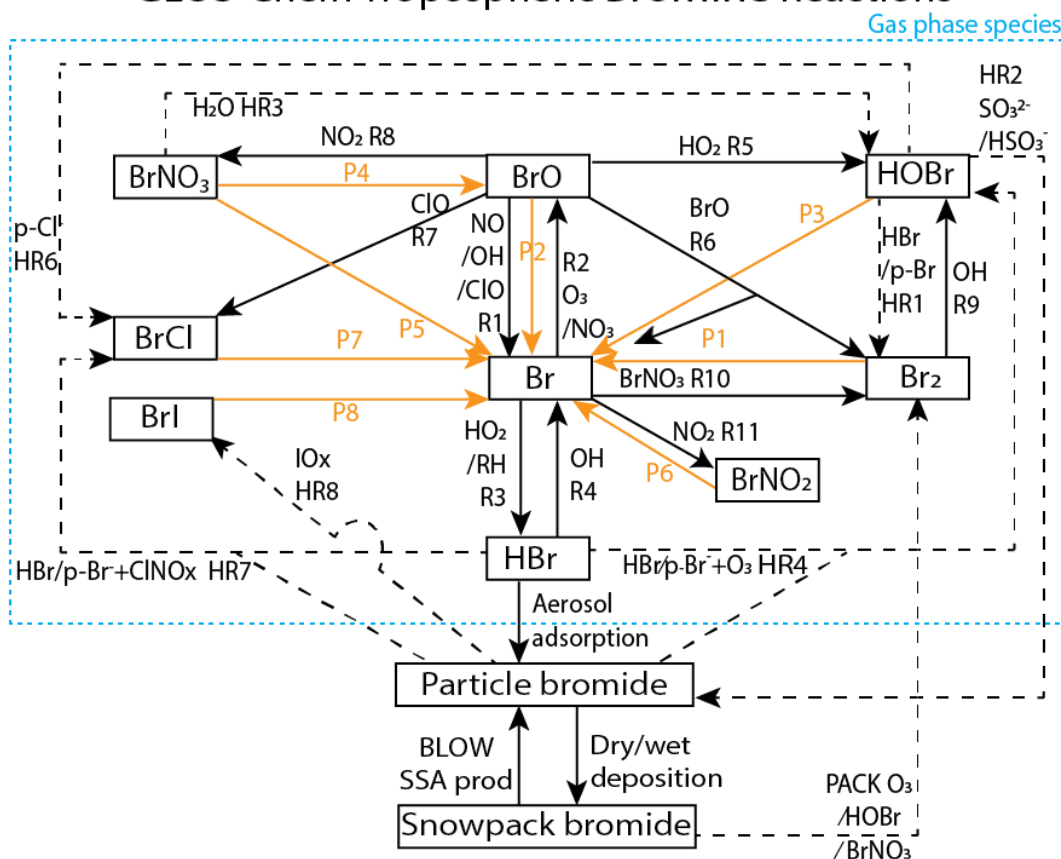

## 42 **1. Introduction**

43 Simulating Arctic halogen chemistry is a persistent problem for global models because processes  
44 appear to differ between the Arctic and middle latitudes (Parrella et al., 2012; Schmidt et al., 2016).  
45 Space-based instruments observe large column densities of reactive bromine across swaths of the Arctic  
46 Ocean during the Arctic spring (Chance, 1998; Richter et al., 1998; Wagner and Platt, 1998). Increased  
47 levels of tropospheric reactive bromine are associated with ozone depletion events (Barrie et al., 1988;  
48 Foster et al., 2001; Koo et al., 2012; Halfacre et al., 2014) as well as oxidation of gaseous elemental  
49 mercury (Schroeder et al., 1998; Nghiem, 2013; Moore et al., 2014). Bromine radicals have been  
50 observed to lead directly to ozone depletion and mercury oxidation (Wang et al., 2019a). Deposition of  
51 oxidized mercury to the snowpack can have deleterious effects on the health of Arctic humans and  
52 animals (AMAP, 2011). Arctic reactive bromine chemistry impacts tropospheric oxidative chemistry but  
53 is not typically accounted for in global models. Model studies have found that reactive halogen chemistry  
54 can explain the oxidation of gaseous elemental mercury (Holmes et al., 2010) and reduce radiative forcing  
55 from ozone (Sherwen et al., 2016c). Replicating reactive halogen chemistry in models requires inclusion  
56 of multi-phase chemical reactions as well as mechanisms affecting sea salt aerosol particle production and  
57 chemical reactions within the snowpack.

58 These increased levels of tropospheric reactive bromine radicals are a product of heterogeneous  
59 photochemical reactions at the interface between air and saline surfaces such as surface snowpack and sea  
60 salt aerosols (Saiz-Lopez and von Glasow, 2012; Simpson et al., 2015). Figure 1 depicts the gas-phase,  
61 heterogeneous, and photochemical reactions thought to control tropospheric bromine, all of which are  
62 included in the model and results presented in this manuscript. Bromine radicals (Br) are produced by  
63 photolysis of molecular bromine (P1) or by self-reaction of BrO (R6) and react with ozone to form  
64 bromine monoxide (BrO) (R2). Under sunlit conditions, BrO is most often photolyzed back to Br  
65 radicals and an oxygen atom (P2) that then most often reforms ozone, resulting in a null cycle. Due to this  
66 rapid interchange of Br and BrO, these two compounds form the BrO<sub>x</sub> family. If processes other than BrO

67 photolysis (P2) convert BrO back to Br without producing ozone, the imbalance between these other  
68 processes and P2 result in net ozone depletion. For example, ozone is depleted through R6 or R7 when  
69 BrO reacts with another halogen oxide to form either Br<sub>2</sub> or BrCl, or through other more extended  
70 processes. A reactive halogen activating cycle occurs when a BrO radical reacts with a hydroperoxy  
71 (HO<sub>2</sub>) radical in R5 to form gaseous hypobromous acid (HOBr). Heterogeneous chemistry can occur on a  
72 saline surface between HOBr and particulate bromide (p-Br<sup>-</sup>) in HR1 forming Br<sub>2</sub> or particle chloride (p-  
73 Cl<sup>-</sup>) in HR6 forming BrCl. For each cycle of reactions P1, R2, R5, and HR1, one hydroperoxy radical is  
74 removed from the atmosphere, one bromine atom is released to the atmosphere, and one ozone molecule  
75 is destroyed. This process of activation of particulate and snow bromide to Br<sub>2</sub> by consuming other  
76 radicals (e.g. HO<sub>2</sub>) is known as the "bromine explosion" (Wennberg, 1999). Ground-based instruments  
77 have observed sharp increases in reactive bromine levels over the course of a single day from below 2  
78 pmol/mol up to a maximum of 41 pmol/mol (Pöhler et al., 2010). Reactions may also sequester reactive  
79 bromine into more stable bromine reservoir species. BrO may react with nitrogen dioxide (NO<sub>2</sub>) in R8 to  
80 form bromine nitrate (BrNO<sub>3</sub>), which can also undergo hydrolysis on aqueous and ice surfaces to form  
81 HOBr as in HR3.

# GEOS-Chem Tropospheric Bromine Reactions

82  
 83 **Figure 1: GEOS-Chem tropospheric bromine reactions.** Tropospheric bromine reservoirs shown in  
 84 black boxes, with attached lines indicating reactions. Solid black lines R1-R11 indicate gas phase  
 85 chemical reactions, solid orange lines P1-P8 indicate photolysis reactions, and dashed black lines HR1-  
 86 HR8 indicate heterogeneous reactions. All gaseous species may undergo dry deposition. Additional  
 87 sources of tropospheric bromine include the production of particulate bromide by the BLOW mechanisms  
 88 and the production of Br<sub>2</sub> by the PACK mechanism, as well as the degradation of organobromines to form  
 89 Br (OR1). Table 3 enumerates the specific species involved in each equation and shows reaction rates for  
 90 each respective equation.

91 A potentially important competitor for recycling of reactive bromine through HOBr is its reaction  
 92 with sulfur (IV) species, such as the reaction between HSO<sub>3</sub><sup>-</sup> and HOBr in HR2 (Chen et al., 2017). To  
 93 the extent that this reaction competes with HR1, it can slow the release of bromide from surfaces and  
 94 reduce gas-phase reactive bromine (e.g., reduce BrO). Deposition of the HBr formed from HOBr by HR2  
 95 can remove reactive bromine from the troposphere. In general, the termination of this chemistry leads to  
 96 formation of HBr, which undergoes gas-particulate uptake to particulate bromide (p-Br<sup>-</sup>).

97 Ozone deposited to a saline surface can oxidize Br<sup>-</sup> to form HOBr (similar to p-Br<sup>-</sup> reactions  
98 HR4a and HR4b) which is then converted to Br<sub>2</sub> or another dihalogen (e.g., BrCl). Production of reactive  
99 bromine during ozone deposition does not require light and can occur at night (Oum et al., 1998; Artiglia  
100 et al., 2017). The production of Br<sub>2</sub> is increased at low pH levels (Halfacre et al., 2019).

101 We define the inorganic bromine family, Br<sub>y</sub>, in this manuscript as the sum of the bromine  
102 species: Br, BrO, HOBr, BrNO<sub>3</sub>, 2xBr<sub>2</sub>, BrCl, BrI, and HBr, excluding p-Br<sup>-</sup>. The release of bromine from  
103 sea salt aerosol particles was found to be the dominant global source of reactive bromine (Sander et al.,  
104 2003; Zhu et al., 2019). Sea salt aerosol particles (SSA) are one of the most abundant aerosol particle  
105 types present in the troposphere (De Leeuw et al., 2011). Due to their abundance, SSA particles greatly  
106 increase the particulate bromide on aerosol surfaces available for heterogeneous reactive bromine  
107 chemistry. Debromination of acidified aerosol increases reactive bromine by 30%, although global  
108 models may underestimate Arctic reactive bromine when considering only open ocean-sourced SSA  
109 (Schmidt et al., 2016). Initial literature on Arctic reactive bromine chemistry identified aerosol particles  
110 as a potential saline surface for reactive bromine photochemistry (Fan and Jacob, 1992; Vogt et al., 1996)  
111 and field studies confirmed that SSA is depleted in bromide (Ayers et al., 1999; Hara et al., 2018). If one  
112 supposes that SSA can only be produced from the open ocean source of SSA, the lack of Arctic Ocean  
113 open water during the winter/spring is at odds with observations of high SSA concentrations observed  
114 during the winter months in polar regions (Wagenbach et al., 1998; Huang et al., 2018). The formation of  
115 SSA from the sublimation of blowing snow particles over the Arctic Ocean was proposed as an alternate  
116 SSA production mechanism (Yang et al., 2008, 2010, 2019). Recent field studies have confirmed the  
117 direct production of SSA from blowing snow (Frey et al., 2020). A blowing snow SSA mechanism was  
118 implemented in the global chemical model GEOS-Chem and was able to explain wintertime SSA  
119 enhancements over the Arctic (Huang and Jaeglé, 2017) as well as CALIOP-detected aerosol particle  
120 abundance (Huang et al., 2018) and high levels of Arctic BrO detected by satellites in spring (Huang et  
121 al., 2020).

122 Snowpack containing bromide salts was also identified as a source of reactive bromine (Tang and  
123 McConnell, 1996). Molecular bromine was measured above the snowpack at levels up to 25 pmol/mol  
124 (Foster et al., 2001). Field experiments demonstrate that the snowpack emits Br<sub>2</sub>, Cl<sub>2</sub>, and BrCl, with  
125 emission affected by ambient ozone levels, the snowpack ratio of bromide to chloride, and exposure to  
126 sunlight (Pratt et al., 2013; Custard et al., 2017). Box modeling found that the flux of reactive bromine  
127 from the surface of the Arctic Ocean sea ice is a prerequisite for bromine activation (Lehrer et al., 2004).  
128 Box modeling found that both HOBr and BrNO<sub>3</sub> can be converted to Br<sub>2</sub> in the snowpack (Wang and  
129 Pratt, 2017). Detailed one dimensional models of the snowpack-air interface find that reactive bromine

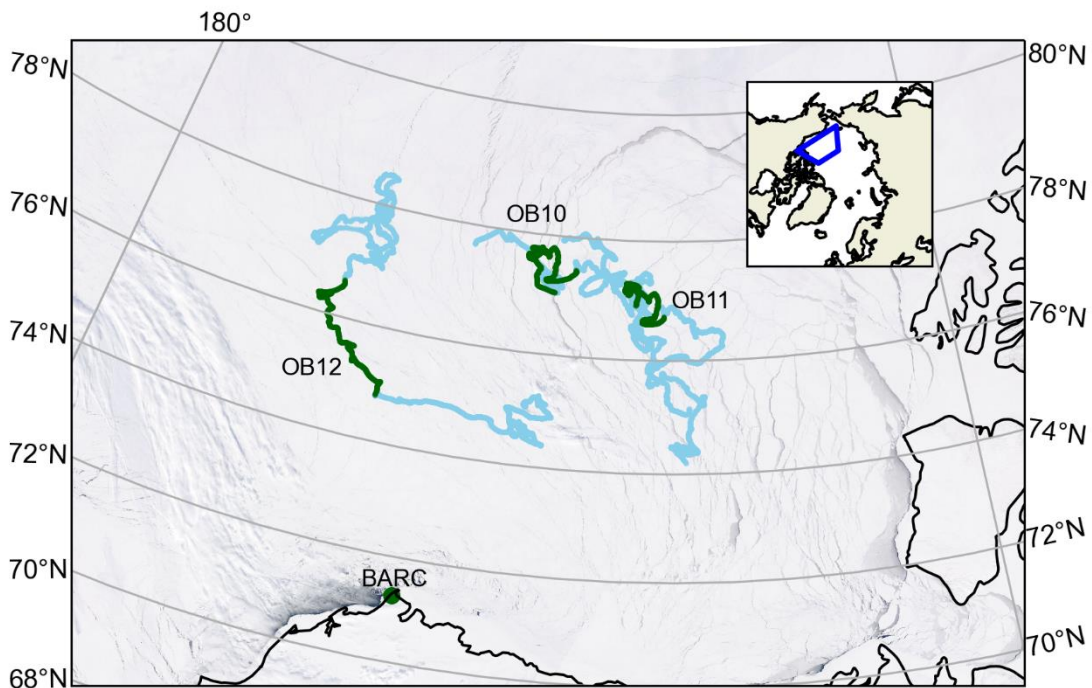

130 production can occur in the interstitial air between snowpack grains (Thomas et al., 2011; Toyota et al.,  
131 2014), with ozone depletion events arising from snowpack reactive bromine production (Thomas et al.,  
132 2011; Toyota et al., 2014; Cao et al., 2016). However, a detailed snowpack model coupled to an  
133 atmospheric model would be sensitive to important parameters such as snowpack bromide content and  
134 acidity of the air-ice interface that are highly variable across the Arctic (Toom-Sauntry and Barrie, 2002;  
135 Krnavek et al., 2012). A mechanism to parameterize the release of molecular bromine from snowpack  
136 upon deposition of ozone, HOBr, and BrNO<sub>3</sub> was implemented in the GEM-AQ model and captured  
137 many of the observed features of reactive bromine in the Arctic troposphere (Toyota et al., 2011). The  
138 mechanisms from Toyota et al. (2011) assumes a 100% yield of molecular bromine on deposition of  
139 HOBr or BrNO<sub>3</sub> (see Figure 1 PACK) and a diurnally varying yield of Br<sub>2</sub> on ozone deposition of 7.5%  
140 during the daytime (solar elevation angle > 5°) and 0.1% during the nighttime (solar elevation angle < 5°)  
141 (see Figure 1 PACK). In the Toyota et al. (2011) parameterization, the daytime yield of Br<sub>2</sub> from ozone  
142 was increased to 7.5% to match surface ozone depletion observations and is based on the assumption that  
143 photochemical reactions in the snowpack would trigger a bromine explosion and amplify the net release  
144 of Br<sub>2</sub> (Toyota et al., 2011). Herrmann et al (2021) implemented the Toyota et al. (2011) mechanism in  
145 WRF-Chem and found snowpack Br<sub>2</sub> production was capable of replicating ozone depletion events  
146 observed in multiple datasets. Marelle et al. (2021) implemented a surface snowpack mechanism based on  
147 Toyota et al. (2011) and a blowing snow SSA mechanism based on Yang et al. (2008) and Huang and  
148 Jaeglé (2017) and found improved prediction of ozone depletion events, the majority of which were  
149 triggered by the snowpack mechanism. The Toyota et al. (2011) mechanism was also implemented in the  
150 EMAC model and replicated many of the features of reactive bromine events observed by satellite-based  
151 GOME sensor (Falk and Sinnhuber, 2018).

152 Field campaigns have directly observed the production of SSA from blowing snow (Frey et al.,  
153 2020) as well as production of Br<sub>2</sub> from the snowpack (Pratt et al., 2013) in the environment. This  
154 manuscript uses both production mechanisms for the first time in the global chemical model GEOS-  
155 Chem. We devised a set of six model runs to test each mechanism individually and together as well as one  
156 control run using neither mechanism. We compare BrO simulated in each model run against extensive  
157 ground-based observations of BrO made from February to June 2015. This set of modeling scenarios  
158 allows identification of the effects of each mechanism on BrO as well as the synergistic effects of both  
159 mechanisms working together.

## 160 2. Data sources and methods

### 161 2.1 MAX-DOAS observation platforms

162 Multiple axis differential optical absorption spectroscopy (MAX-DOAS) remotely measures the  
163 vertical profile of BrO (Hönninger and Platt, 2002; Carlson et al., 2010; Frieß et al., 2011; Peterson et al.,  
164 2015; Simpson et al., 2017). BrO is commonly used as a proxy for total tropospheric reactive bromine  
165 (Chance, 1998; Richter et al., 1998; Wagner and Platt, 1998; Theys et al., 2011; Choi et al., 2012). MAX-  
166 DOAS instruments were mounted on all of the fifteen floating autonomous platforms (O-Buoys) deployed  
167 in the Arctic sea ice as a part of the National Science Foundation-funded Arctic Observing Network  
168 project (Knepp et al., 2010). Since MAX-DOAS requires sunlight to operate, measurements are not  
169 available in winter. Spring observations on the O-Buoys typically begin in April when there is enough O-  
170 Buoy solar power to defrost the MAX-DOAS viewport. Figure 2 shows the O-Buoys active during 2015.  
171 O-Buoy 10 was deployed into sea ice in fall 2013 and measured reactive halogen chemistry in spring  
172 2014 and 2015. Most O-Buoys were destroyed in the summer, crushed between fragments of melting sea  
173 ice. However, O-Buoy 10 survived summer 2014 in an intact ice floe, survived the winter of 2014-15,  
174 and re-started MAX-DOAS observations in April 2015. O-Buoys 11 and 12 were deployed in fall 2014  
175 and also re-started observing BrO in April 2015. Figure 2 shows the GPS-derived tracks of the O-Buoys  
176 for their full deployment and highlights the O-Buoy locations from April to June 2015 when the BrO  
177 observations considered in this analysis were gathered. A MAX-DOAS instrument of the same design  
178 was deployed at the Barrow Arctic Research Center (BARC) on the coast of the Arctic Ocean located at  
179 156.6679°W, 71.3249°N near Utqiagvik, AK (Simpson, 2018), also shown in Figure 2. Unlike the O-  
180 Buoy MAX-DOAS systems, which were powered by batteries and solar panels, the BARC MAX-DOAS  
181 was powered from local utilities and was able to defrost its viewport to gather BrO observations earlier in  
182 the year, including February and March 2015. The BARC MAX-DOAS data was compared with two O-  
183 Buoy style MAX-DOAS instruments deployed on Icelander platforms (deployed on top of sea ice instead  
184 of within) and measurements from the various MAX-DOAS systems were found to be comparable  
185 (Simpson et al., 2017). The reactive bromine season ends when the BrO slant column densities fall below  
186 the instrument detection limit and do not recover, which we call the seasonal end date (Burd et al., 2017).  
187 All O-Buoy and BARC (Utqiagvik) data are available at arcticdata.io (Simpson et al., 2009; Simpson,  
188 2018). More information on the time periods of spring BrO observations can be found in Swanson et al.  
189 (2020) and Burd et al. (2017). For comparison to the MAX-DOAS BrO observations, GEOS-Chem model  
190 simulations are sampled along the GPS-derived paths of O-Buoys 10, 11 and 12 as well as at BARC.

191

192 **Figure 2: Locations of MAX-DOAS BrO observations used in this work.**

193 Blue lines show the drift tracks of O-Buoys, with green showing the locations with valid BrO  
 194 measurements in spring 2015. Location of Barrow Arctic Research Center (BARC) in Utqiagvik indicated  
 195 by green dot. True color MODIS imagery on 1 April 2015 shows typical sea ice coverage (NASA 2015).  
 196 Inset map shows location of map grid within northern hemisphere.

## 197 **2.2 MAX-DOAS profile retrieval**

198 Vertical profiles of BrO were derived from MAX-DOAS observations by means of optimal  
199 estimation inversion procedures detailed in Peterson et al. (2015) with settings detailed in Simpson et al.  
200 (2017). The HeiPro optimal estimation algorithm (Frieß et al., 2006, 2019) is used to retrieve a vertical  
201 profiles of BrO between the surface and 4km from the MAX-DOAS observations. Examination of the  
202 averaging kernels from each MAX-DOAS retrieval finds the retrieved vertical profile of BrO is best  
203 represented by two quantities: the vertical column density of BrO in the lowest 200 m, and the vertical  
204 column density of BrO in the lowest 2000 m of the troposphere referred to in this manuscript as  $\text{BrO}_{\text{LTcol}}$   
205 (Peterson et al., 2015). It was shown in Peterson et al. (2015) that these two quantities were largely  
206 independent of each other, were fairly insensitive to variations in the assumed prior profile, and  
207 represented the ~2-3 degrees of freedom for signal indicated by the optimal estimation retrieval. An  
208 important consideration of this method is that when the visibility is poor, the MAX-DOAS is unable to  
209 traverse the lowest 2000m AGL and the  $\text{BrO}_{\text{LTcol}}$  cannot be measured accurately. Therefore, our quality-  
210 control algorithm eliminates  $\text{BrO}_{\text{LTcol}}$  observations when the degrees of freedom for signal in the lofted  
211 (200m - 2000m AGL) layer were below 0.5 (Simpson et al., 2017). The average fitting error ( $1\sigma$  error) of  
212  $\text{BrO}_{\text{LTcol}}$  during spring 2015 was  $5.6 \times 10^{12}$  molecules/cm<sup>2</sup>.

## 213 **2.3 SSA production from open ocean**

214 Seafoam from breaking waves and bursting of bubbles forms aerosol droplets suspended in the  
215 marine boundary layer (Lewis and Schwartz, 2004). We calculate emission of sea salt aerosol particles  
216 from the open ocean as a function of wind speed and sea surface temperature (SST) using the mechanism  
217 initially described in Jaeglé et al. (2011) and updated with decreased emissions over cold ( $\text{SST} < 5^\circ\text{C}$ )  
218 ocean waters (Huang and Jaeglé, 2017). Two separate SSA tracers are transported: accumulation mode  
219 SSA ( $r_{\text{dry}} = 0.01\text{--}0.5 \mu\text{m}$ ) and coarse mode SSA ( $r_{\text{dry}} = 0.5\text{--}8 \mu\text{m}$ ). Sea salt bromide is emitted assuming  
220 bromine content of  $2.11 \times 10^{-3}$  kg Br per kg of dry SSA (primarily NaCl) based on the mean ionic  
221 composition of sea water (Sander et al., 2003). Bromide content is tracked separately on accumulation  
222 mode SSA and on coarse mode SSA. Freshly emitted SSA is alkaline and can be titrated to a pH of 5 by  
223 uptake of acid gases  $\text{SO}_2$ ,  $\text{H}_2\text{SO}_4$ , and  $\text{HNO}_3$  (Alexander et al., 2005). Heterogeneous chemical reactions  
224 can convert SSA-transported bromide into gaseous reactive bromine species in the atmosphere. We run  
225 our open ocean SSA calculations at  $0.5^\circ$  latitude x  $0.625^\circ$  longitude spatial resolution using the  
226 harmonized emissions component (HEMCO) for highest possible detail (Keller et al., 2014; Lin et al.,  
227 2021) including cold water corrections used in Jaeglé et al. (2011). Production of SSA from open oceans  
228 followed by advection can lead to reactive bromine recycling over Arctic Ocean sea ice. Each of our  
229 model runs reads the dataset generated offline by HEMCO rather than spend computational time

230 replicating open ocean SSA emissions. We call our control run using only open ocean SSA emissions  
231 BASE.

## 232 **2.4 Blowing snow SSA production**

233 Snow can be lofted from the snowpack into the lowest layers of the troposphere by high wind  
234 speeds, where it can undergo saltation (bouncing leading to fragmentation) and sublimation to form SSA  
235 (Yang et al., 2008, 2010; Frey et al., 2020). This process is modeled as a function of humidity, ambient  
236 temperature, wind speed, snow particle size distribution, and the salinity of the blowing snow (Yang et  
237 al., 2008, 2010). We assume that snowpack exists on all sea ice surfaces during the Arctic Spring after  
238 snow accumulation during winter on sea ice of all ages. Three thresholds must be met for SSA production  
239 from blowing snow (Dery and Yau, 1999; Déry and Yau, 2001). A temperature threshold restricts SSA  
240 production from blowing snow to temperatures below freezing. The humidity threshold is based on  
241 relative humidity with respect to ice. Sublimation from snow crystals cannot occur if the air is saturated,  
242 and no SSA is produced if  $RH_{ice}$  is greater than 100%. The wind speed threshold requires 10-m wind  
243 speed to be greater than a threshold value defined in Equation 1 for any production of SSA (Dery and  
244 Yau, 1999; Déry and Yau, 2001).

$$245 \quad U_t = 6.975 + 0.0033(T_s + 27.27)^2 \quad (1)$$

246 The wind speed threshold ( $U_t$ ) is dependent on surface temperature ( $T_s$ ) in Celsius with a minimum  
247 threshold of 6.975 m/s at  $-27.27$  °C and a maximum threshold at  $0$  °C of 9.429 m/s. The 10-m wind speed  
248 threshold is the most stringent and often controls the production of SSA from blowing snow.

249 Production of blowing snow SSA is highly sensitive to surface wind speed. We use the highest  
250 resolution surface wind speed dataset to ensure the most accurate modeling of SSA and reactive bromine.  
251 The MERRA-2 Global Reanalysis Product has a  $0.5^\circ$  latitude x  $0.625^\circ$  longitude resolution which is  
252 typically re-gridded to a lower resolution for global chemical modeling. Previous use of the snowpack  
253 blowing snow SSA mechanism used MERRA-2 data re-gridded to either  $2^\circ \times 2.5^\circ$  or  $4^\circ \times 5^\circ$  latitude and  
254 longitude (Huang and Jaeglé, 2017; Huang et al., 2018, 2020). Re-gridding to coarser spatial resolution  
255 may smooth out the highest 10-m wind speeds by averaging them with lower wind speeds in the grid cell.  
256 The Utqiagvik MERRA-2 10-m wind speeds at different spatial resolutions are shown in Supplemental  
257 Figures S1, S2 and S3 to illustrate this effect. Average Utqiagvik 10-m wind speeds for 2015 are 5.3 m/s  
258 at  $2^\circ \times 2.5^\circ$  resolution and 5.5 m/s at  $0.5^\circ \times 0.625^\circ$  resolution. The maximum Utqiagvik 10-m wind speed at  
259 MERRA-2  $2^\circ \times 2.5^\circ$  is 16.3 m/s, while the maximum wind speed at MERRA-2  $0.5^\circ \times 0.625^\circ$  is 19.3 m/s.  
260 These extremely high wind speed events are more common at higher spatial resolution and can contribute  
261 an outsized amount of SSA to the marine boundary layer. Supplemental Figure S4 shows the measured  
262 10-m wind speed at BARC, along with daily average threshold wind speed (Equation 1). Spikes in daily

263 averaged wind speed at BARC in April can contribute to SSA formation and justify the use of high-  
264 resolution MERRA-2 wind speed data.

265 Snow salinity is influenced by snow age and the material underlying the snow (Krnavek et al.,  
266 2012). The median surface snowpack salinity near Utqiagvik was measured at 0.67 practical salinity units  
267 (PSU) for 2-3 weeks old sea ice, 0.12 PSU for thicker first year ice, and 0.01 PSU for multi-year ice  
268 (MYI) (Krnavek et al., 2012). Snow salinity is also a function of snow depth above sea ice, with blowing  
269 surface snow having much lower salinity than snow at depth that is in contact with the sea ice (Frey et al.,  
270 2020). Domine et al. (2004) measured median salinity at 0.1 PSU on snowpack over first year ice and  
271 0.02 on snowpack over multi-year ice. In this analysis we use a salinity of 0.1 PSU on first-year sea ice as  
272 in Huang et al. (2020). The production of reactive bromine from sea ice types is entirely dependent on  
273 PSU in this parameterization. Previous modeling efforts have used 0.01 PSU for MYI (Huang et al.,  
274 2018) and underestimate BrO production in high Arctic areas with increased MYI coverage. The bromide  
275 content of surface snow over MYI is enriched by deposition of SSA and trace gases, and MYI regions  
276 may play a role in springtime halogen chemistry (Peterson et al., 2019). Previous analysis of O-Buoy data  
277 found no statistically significant differences in springtime BrO between regions of the Arctic (Swanson et  
278 al., 2020). We use 0.05 PSU for snowpack on MYI as in Huang et al. (2020).

279 Another important parameter for SSA formation is the number of SSA particles formed from each  
280 blowing snowflake. A value of 5 particles per snowflake was used in Huang and Jaeglé (2017) based on  
281 wintertime observations of supermicron and sub-micron SSA at Barrow. Values of 1 and 20 particles per  
282 snowflake have been tested (Yang et al., 2019) but it was unclear which value was more realistic. We use  
283 a particle formation value of 5 particles per snow grain as in Huang et al. (2020).

284 Snowpack may be enriched or depleted in bromide compared to seawater, which is thought to be  
285 an effect of atmospheric deposition or release of bromine from snowpack (Krnavek et al., 2012).  
286 Snowpack enrichment due to atmospheric deposition is less pronounced when snowpack salinity is high,  
287 with snowpack containing 1000  $\mu\text{M Na}^+$  (approximately 0.06 PSU) or more never exceeding twice the  
288 seawater ratio of bromine to chloride (Krnavek et al., 2012). Domine et al. (2004) found an increased  
289 enrichment factor of five times seawater in snow with a salinity of 100  $\mu\text{M Cl}^-$  (approximately 0.006  
290 PSU). We use a snowpack enrichment factor of bromide five times that of seawater as in Huang et al.  
291 (2020) where this enrichment best agreed with GOME-2 observations. However, we note that a bromide  
292 enrichment factors five times seawater exceeds enrichment factors of two measured in snowpack with a  
293 salinity of 0.1 PSU (Krnavek et al., 2012).

294 Our choice of model input settings is similar to Huang et al. (2020) but we will be running the  
295 blowing snow SSA mechanism in HEMCO at a  $0.5^\circ$  latitude x  $0.625^\circ$  longitude spatial resolution. The  
296 model run using the results of our high-resolution blowing snow SSA HEMCO simulation is called  
297 BLOW.

## 298 **2.5 Snowpack emissions of molecular bromine**

299 We base our Br<sub>2</sub> emissions scheme on Toyota et al. (2011) and Marelle et al. (2021), which  
300 prescribe a yield of Br<sub>2</sub> upon snowpack deposition of ozone, BrNO<sub>3</sub> and HOBr. In other modeling studies,  
301 this simplified deposition-based mechanism captured the synoptic-scale behavior of reactive bromine  
302 production across the Arctic (Toyota et al., 2011; Falk and Sinnhuber, 2018; Herrmann et al., 2021;  
303 Marelle et al., 2021). These modeling studies used different yields of Br<sub>2</sub> upon deposition over land  
304 snowpack, multi-year ice, and first year ice, restricting the production of molecular bromine from ozone  
305 deposition to first year ice surfaces. None of these studies were coupled to a snowpack model tracking  
306 snow bromide, and effectively assume an infinite bromide reservoir with Br<sub>2</sub> production limited only by  
307 the deposition flux and Br<sub>2</sub> yield.

308 Field studies indicate that snowpack over multi-year ice, first-year ice, and land regions may  
309 contribute to reactive bromine chemistry. Krnavek et al. (2012) found snow bromide content spanning six  
310 orders of magnitude, with individual samples taken from multi-year ice, first-year ice, and land regions  
311 showing variability of up to three orders of magnitude for each region. Analysis of variance in  
312 tropospheric BrO from 2011-2016 found no statistically significant differences in tropospheric BrO  
313 between different regions of the Arctic (Swanson et al., 2020). Both coastal snowpack and multi-year ice  
314 regions may produce reactive bromine. Molecular bromine production has been observed from coastal  
315 snowpack on exposure to ozone (Pratt et al., 2013; Custard et al., 2017). Airborne sampling has observed  
316 enhanced BrO up to 200 km inland (Peterson et al., 2018). Snow above multi-year sea ice regions is  
317 depleted in bromide, indicating that it may play a role in Arctic bromine chemistry (Peterson et al., 2019).

318 Our modeling study tests the hypothesis that all snow has a uniform ability to produce molecular  
319 bromine, effectively assuming an infinite bromide reservoir with Br<sub>2</sub> production limited only by the  
320 deposition flux. We differ from previous model parameterizations in allowing uniform Br<sub>2</sub> production  
321 upon snowpack deposition of ozone, BrNO<sub>3</sub> and HOBr over all sea ice surfaces and selected coastal  
322 snowpack regions. We only allow snowpack Br<sub>2</sub> production when the surface temperature is below  
323 freezing. Surface temperatures may rise above freezing and drop back below freezing in the Arctic spring,  
324 which may allow for snowpack Br<sub>2</sub> to simulate late-season bromine production events after snowpack  
325 melt such as those observed in Burd et al. (2017). We expect higher predictions of snowpack molecular

326 bromine production than recent modeling efforts (Herrmann et al., 2021; Marelle et al., 2021) in which  
327 ozone deposition over land and multi-year ice surfaces did not produce molecular bromine.

### 328 **2.5.1 Snowpack Br<sub>2</sub> production over sea ice**

329 We assume a uniform production of Br<sub>2</sub> on deposition to snowpack over oceanic ice whether the  
330 ice is first-year sea or multi-year sea ice. We use MERRA-2 fractional ocean ice coverage fields, which  
331 introduces some artifacts. MERRA-2 classifies the freshwater Great Lakes as ocean, but sea ice and  
332 snowpack on those frozen lakes is unlikely to have sufficient bromide to support large Br<sub>2</sub> fluxes due to  
333 its distance from the ocean. Therefore, we specifically prohibit snowpack Br<sub>2</sub> emissions in the Great  
334 Lakes region (between 41° N and 49° N latitude and 75° W and 93° W longitude). This choice is in  
335 agreement with McNamara et al. (2020), who found road salt derived aerosol particles are responsible for  
336 80-100% of atmospheric ClNO<sub>2</sub> in Michigan with no strong indication for a source of reactive halogens  
337 from nearby Great Lakes.

### 338 **2.5.2 Snowpack Br<sub>2</sub> production over land**

339 We wish to only enable production of Br<sub>2</sub> over land if the snowpack is sufficiently enriched in  
340 bromide. Snowpack over land surfaces and glaciers may be enriched in bromide by oceanic SSA sources  
341 (Jacobi et al., 2012, 2019). The distance that SSA may be transported inland from the coast is limited by  
342 geographical features such as mountains. Based on direct observations of reactive bromine chemistry up  
343 to 200 km from the Alaskan coastline (Peterson et al., 2018), we include unlimited production of Br<sub>2</sub> from  
344 specific land grid cells within 200 km of the coast upon deposition of ozone, HOBr, and BrNO<sub>3</sub>. We only  
345 allow the fraction of each grid cell that is within 200 km of the coastline (Group and Stumpf, 2021) to  
346 produce molecular bromine. We further restrict snowpack Br<sub>2</sub> emissions to locations that are less than 500  
347 m above sea level, because higher elevation locations are unlikely to be enriched by sea spray. This  
348 altitude screen eliminates Br<sub>2</sub> emissions from coastal mountains such as the Alaskan Rockies, the Brooks  
349 Range in Alaska, and the Scandinavian Mountains as well as from the Greenland Plateau. Halogen  
350 chemistry may occur over the Greenland ice sheet (Stutz et al., 2011) contrary to this screen, but this will  
351 have minimal impact on the regions of interest in this manuscript.

352 Our final screen is based on the average snow depth in each land grid cell. Both modeling studies  
353 (Thomas et al., 2011; Toyota et al., 2014) and field studies (Domine et al., 2004; Pratt et al., 2013;  
354 Custard et al., 2017; Frey et al., 2020) agree that bromine chemistry can occur in the better ventilated and  
355 illuminated top of the snowpack. Regions with less than 10 cm of snowpack may not have sufficient  
356 snow for reactive bromine chemistry, thus we only produce snowpack Br<sub>2</sub> when the average snow depth  
357 in a land grid cell is 10 cm or greater. This filter prevents molecular bromine production in the lower  
358 latitude regions with minimal snow coverage and is necessary because ozone deposition to plants in

359 snow-free grid cells often exceeds the slow deposition of ozone to snowpack and would not be expected  
360 to produce Br<sub>2</sub>.

### 361 **2.5.3 Diurnal yield of Br<sub>2</sub> on ozone deposition**

362 We choose two alternate assumptions for the yield of Br<sub>2</sub> during the day. Toyota et al. (2011)  
363 initially assumed a constant yield of Br<sub>2</sub> from ozone deposition of 0.1% based on laboratory observations  
364 of nighttime bromine activation on ozone deposition (Oum et al., 1998; Wren et al., 2010, 2013) and then  
365 adjusted the daytime yield of Br<sub>2</sub> on ozone deposition to 7.5% to better match surface ozone mixing ratios  
366 measured at coastal stations. This increased daytime yield value was chosen based on the assumption that  
367 photochemistry may trigger an autocatalytic cycle leading to a 75-fold increase in Br<sub>2</sub> yield. The  
368 PHOTOPACK runs uses the increased daytime Br<sub>2</sub> yield of 7.5% when the solar elevation angle is 5° or  
369 greater. Previous implementations of the snowpack mechanism (Toyota et al., 2011; Herrmann et al.,  
370 2021; Marelle et al., 2021) predict ozone deposition velocities over Arctic sea ice on the order of 0.01  
371 cm/s. Their findings agree with a modeling sensitivity study finding best agreement with observations  
372 using ozone deposition rates between 0.00-0.01 cm/s (Helmig et al., 2007). Our model predicts similar  
373 polar open ocean ozone deposition rates of 0.009 cm/s (Pound et al., 2020) but predicts higher modeled  
374 deposition velocity of ozone over Arctic sea ice between 0.02 cm/s and 0.1 cm/s based on the month (see  
375 Supplemental Figure S5), with higher values influenced by proximity to the coast as observed along non-  
376 Arctic coastlines in Bariteau et al. (2010). Thus, our PHOTOPACK run may predict much higher Br  
377 emissions than previous snowpack predictions despite the same yield values due to differences in  
378 deposition. To match our magnitude of Br<sub>2</sub> production with previous implementations of the snowpack  
379 mechanism (Toyota et al., 2011; Herrmann et al., 2021; Marelle et al., 2021) we add two PACK runs with  
380 a constant Br<sub>2</sub> yield on ozone deposition of 0.1% based on yield values in Toyota et al. (2011). Both  
381 PACK and PHOTOPACK runs assume 100% conversion of deposited HOBr and BrNO<sub>3</sub> to Br<sub>2</sub>. Table 1  
382 shows further model run yield details.

### 383 **Table 1 Model run settings**

384 Sea salt aerosol particles are produced from blowing snow as detailed in Section 2.5. Daytime is defined  
385 as when the solar elevation angle is greater than 5°, nighttime is defined as when the solar elevation angle  
386 is less than 5°.

Model Run	Blowing snow SSA produced	Millimoles Br yielded per mole O3 deposited (daytime)	Millimoles Br yielded per mole O3 deposited (nighttime)
BASE	FALSE	0	0
BLOW	TRUE	0	0
PACK	FALSE	1	1
BLOW+PACK	TRUE	1	1

PHOTOPACK	FALSE	75	1
BLOW+PHOTOPACK	TRUE	75	1

387

## 388 **2.6 GEOS-Chem chemistry and transport model**

389 The GEOS-Chem global atmospheric chemistry and transport model (Bey et al., 2001) simulates  
390 emissions, transport, and chemistry of atmospheric trace gases and aerosols, including halogens. The  
391 chemical mechanism in GEOS-Chem 12.9.3 (<http://www.geos-chem.org>, last access 29 October 2019,  
392 DOI:10.5281/zenodo.3974569) includes HO<sub>x</sub>-NO<sub>x</sub>-VOC-O<sub>3</sub>-halogen-aerosol tropospheric chemistry  
393 (Mao et al., 2013; Fischer et al., 2014; Fisher et al., 2016; Travis et al., 2016; Wang et al., 2021). The  
394 model has been regularly and consistently updated to reflect current understanding of heterogeneous and  
395 gas-phase halogen chemistry.

396 Halogens in the troposphere may be sourced from photooxidation of halocarbons, emissions of  
397 iodine from the ocean surface, downward transport of halogens from the stratosphere, and release of  
398 halogens through heterogeneous chemistry on SSA. Figure 1 shows a simplified version of the GEOS-  
399 Chem reaction scheme focusing on tropospheric bromine reactions and reservoirs. Heterogeneous  
400 reactions for release of reactive bromine from aerosol surfaces were added to GEOS-Chem (Parrella et  
401 al., 2012) and have been updated to include multiphase reactions involving cloud aerosols, cloud droplets,  
402 and ice aerosols as well as inter-halogen reactions between bromine, chlorine and iodine species (Schmidt  
403 et al., 2016; Sherwen et al., 2016a; Wang et al., 2019b) and input from the stratosphere (Eastham et al.,  
404 2014). Recent updates also include reactions between sulfur (IV) species and HOBr, which lead to a 50%  
405 decrease in Br<sub>y</sub> due to the scavenging of HOBr on aerosol surfaces containing sulfur (Chen et al., 2017).  
406 These HOBr-sulfur(IV) reactions are critical in moderating tropospheric BrO in the mid latitudes (Zhu et  
407 al., 2019). In GEOS-Chem 12.9 the halogen chemical mechanism was modified extensively to include  
408 chlorine chemistry as detailed in Wang et al. (2019b) with updated halogen-sulfur (IV) rates (Liu et al.,  
409 2021), reaction of S(IV) + HOCl, and improved cloud pH calculation from Shah et al. (2020). For the  
410 simulations here, GEOS-Chem uses the Modern-Era Retrospective Analysis for Research and  
411 Applications, version 2 (MERRA-2) assimilated meteorological fields (Gelaro et al., 2017) re-gridded  
412 from native resolution of 0.5°x0.625° latitude and longitude to 2°x2.5° using a reduced vertical grid of 47  
413 layers.

414 We initialize our model in October 2014 from a full-chemistry benchmark file, allowing for 6  
415 months of spin up before our period of interest spanning from March to November 2015. We run six  
416 different model simulations with settings detailed in Table 1. The base model (BASE) includes the  
417 halogen sources described above but no Arctic-specific halogen sources. The BLOW simulation adds

418 SSA production from blowing snow following Huang et al (2020) but using a more recent version of  
419 GEOS-Chem. The PACK simulation adds snowpack Br<sub>2</sub> emissions using a constant yield from O<sub>3</sub>  
420 deposition. The PHOTOPACK simulation also emits Br<sub>2</sub> from snowpack but increases the Br<sub>2</sub> yield from  
421 O<sub>3</sub> deposition under sunlight. These blowing snow SSA and snowpack sources are combined in the  
422 BLOW+PACK and BLOW+PHOTOPACK simulations.

## 423 **2.7 Comparing GEOS-Chem results to MAX-DOAS vertical column densities**

424 GEOS-Chem simulates BrO mixing ratios for each of its 47 atmospheric layers. Reducing the  
425 vertical resolution of the more-resolved GEOS-Chem predictions to be comparable to the coarser MAX-  
426 DOAS data is necessary for appropriate comparison (Rodgers and Connor, 2003). To compare the  
427 GEOS-Chem profiles with these two grid-coarsened quantities, we grid-coarsen the averaging kernels  
428 produced by the HeiPro retrieval algorithm using Supplemental Equation S1 from Payne et al. (2009) to  
429 the partial column averaging kernels shown in Figure 3. We use the average of all April averaging kernels  
430 that pass our quality criteria (>0.5 DOFS in the lofted layer), which generally represents non-cloudy  
431 conditions. We calculate modeled BrO<sub>LTcol</sub> by applying the partial column averaging kernels shown in  
432 Figure 3 to the GEOS-Chem modeled vertical BrO profiles.

433 Figure 3 shows the average partial column averaging kernel for the surface layer (0-200m AGL)  
434 has near unit sensitivity to BrO at the ground, decaying to about 0.5 at 200m AGL then to zero at about  
435 400m AGL, as desired. The sensitivity of the BrO<sub>LTcol</sub> is near unity from about the surface to 600m AGL,  
436 then slowly decays with 0.5 sensitivity at 2000m AGL. The resulting sensitivity to mid-tropospheric BrO  
437 means that free-tropospheric BrO produced by the GEOS-Chem model contributes to modeled BrO<sub>LTcol</sub>,  
438 albeit at 50% or lower sensitivity, even if the GEOS-Chem-predicted free-tropospheric BrO is above the  
439 nominal 2000m top of the integration window. The residual sensitivity of the BrO<sub>LTcol</sub> averaging kernel  
440 above 2000m is caused by the limited ability of ground-based MAX-DOAS to distinguish the true altitude  
441 of BrO at non-tangent geometries (higher viewing elevation angles) that are required to view BrO at these  
442 higher altitudes. Figure 3 shows that BrO above 4 km makes only a small contribution to the modeled  
443 BrO<sub>LTcol</sub>, which was not included in the BrO<sub>LTcol</sub>.

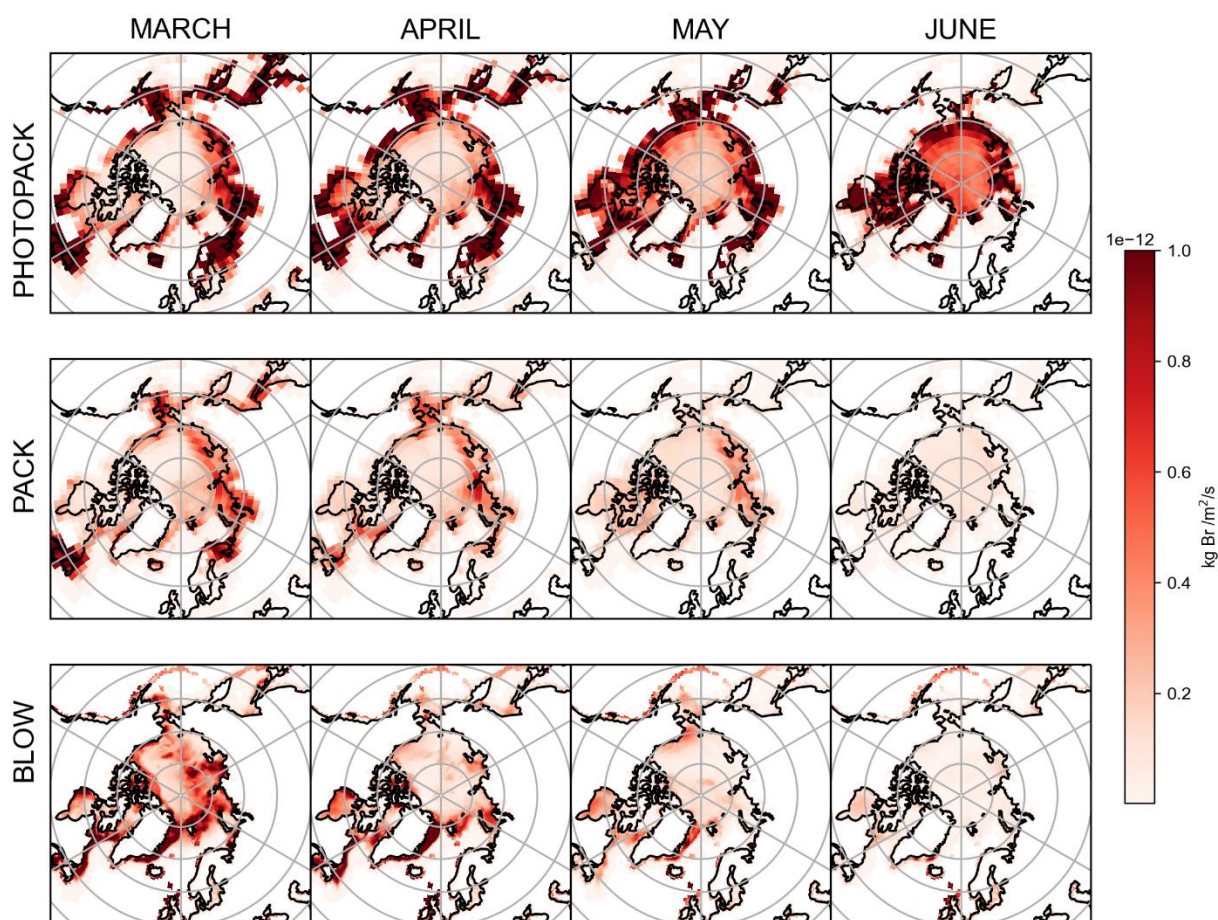

444

445 **Figure 3: Averaging kernels showing the sensitivity of retrieved  $\text{BrO}_{\text{LTcol}}$  and retrieved  $\text{BrO}_{\text{surf}}$  to**  
 446  **$\text{BrO}$  at a range of altitudes.**

447 Each line represents a row of the averaging kernel matrix.  $\text{BrO}_{\text{surf}}$  is the column from the surface to 200 m  
 448 and  $\text{BrO}_{\text{LTcol}}$  is the column up to 2000 m.

449 Although it has been suggested in the literature (von Clarmann and Glatthor, 2019) that averaged  
 450 averaging kernels can cause problems, we do not report data when there are clouds and thus are only  
 451 using the more consistent averaging kernels that occur under clear sky conditions. We use other criteria  
 452 related to vertical visibility to identify clear skies. As described in Peterson et al. (2015), the information  
 453 content (DOFS) in the lofted layer is nearly linearly related to the aerosol optical depth. We find that the

454 slant column density of the O<sub>2</sub>-O<sub>2</sub> collisional dimer (aka O<sub>4</sub>) observed at 20° elevation angle is correlated  
 455 with the lofted DOFS (Supplemental Figure S6). From this correlation we find that observations of clear  
 456 sky conditions have 20° elevation angle O<sub>4</sub> dSCD > 10<sup>43</sup> molecule<sup>2</sup>cm<sup>-5</sup> and use this cut to distinguish  
 457 clear sky versus clouds. To assure that GEOS-Chem results are only compared to the clear-sky  
 458 observational data, we apply this clear sky screen to the measured BrO<sub>LTcol</sub> timeseries. The use of this  
 459 screen also assists in minimizing variability in the averaging kernels and thus allowing the April averaged  
 460 partial column averaging kernels (Figure 3) to be applied for clear skies at any time of the year.

461

462 **Figure 4: Mean snowpack Br<sub>2</sub> and p-Br emissions by month, as simulated by GEOS-Chem.**

463 The top row shows emissions of Br<sub>2</sub> in the PHOTOPACK run, the middle row shows the emissions of  
 464 Br<sub>2</sub> in the PACK run, and the bottom row shows emissions of p-Br from adding the BLOW mechanism.

### 465 3. Examining reactive bromine in the Arctic spring

#### 466 3.1 Snowpack Br<sub>2</sub> emissions

467 The top two rows of Figure 4 shows PHOTOPACK and PACK average snowpack Br<sub>2</sub> emissions  
 468 for each spring month. The emission of Br<sub>2</sub> in PHOTOPACK increases over the Arctic Ocean in May and

469 June, when the sun is above the horizon for up to 24 hours per day and ozone deposition yield is almost  
470 always at the photo-enhanced level of 7.5%. Notably, Br<sub>2</sub> emissions over the Arctic Ocean in the  
471 PHOTOPACK and BLOW+PHOTOPACK runs are highest in June when the sun is nearly always five  
472 degrees above the horizon and surface temperatures may drop below freezing. The PACK emissions are  
473 lower than the PHOTOPACK Br<sub>2</sub> emissions by an order of magnitude and shows a seasonal cycle with a  
474 high BrO<sub>LTcol</sub> in April and May with a decrease in May and June. While our ozone deposition velocities  
475 (see Supplemental Figure S5) over Arctic sea ice are much higher than previous estimates of an  
476 approximate magnitude of 0.01 cm/s (Toyota et al., 2011), the PHOTOPACK run highlights that a 75-  
477 fold increase in daytime Br<sub>2</sub> yield can lead to predictions of increased Br<sub>2</sub> production over the North Pole  
478 in June. Monthly satellite observations show that BrO reaches a minimum over the Arctic Ocean in June  
479 (Richter et al., 1998).

480 Coastal land regions within 200 km of the coastline have some of the highest modeled snowpack  
481 Br<sub>2</sub> emissions (see Figure 4 rows 1 and 2). Within GEOS-Chem, deposition rates are greatest over land,  
482 less rapid over ice-covered ocean, and lowest over open ocean (see Supplemental Figure S5). Lower dry  
483 deposition velocities over the ice-covered Arctic Ocean lead to decreased deposition and conversion to  
484 Br<sub>2</sub>. In GEOS-Chem, ozone mixing ratios and deposition are over three orders of magnitude larger than  
485 BrNO<sub>3</sub> and HOBr mixing ratios and deposition over the Arctic Ocean, and ozone deposition contributes  
486 more than half of total Br<sub>2</sub> emitted in the PACK and BLOW+PACK runs. Our snowpack mechanism  
487 assumes that all ozone deposited to the surface of a grid cell reacts with the snowpack cover, with those  
488 reactions yielding a set percentage of Br<sub>2</sub>. This assumption is more appropriate in the barren snow-  
489 covered coastal tundra but may be less accurate in areas where deposition to vegetation dominates. This  
490 nonconservative approach may lead to overestimation of Br<sub>2</sub> emissions from snowy vegetated surfaces.  
491 Our screens for snowpack emissions described in section 1.3.5 tried to minimize these effects but may not  
492 work perfectly due to finite grid cell resolution and other challenges. Increased Br<sub>2</sub> emissions observed in  
493 Figure 4 in northern Europe may also be partially driven by increased local mixing ratios of ozone and  
494 NO<sub>x</sub> over industrialized regions such as the Kola Peninsula.

### 495 **3.2 Blowing snow aerosol bromide emissions**

496 The bottom row of Figure 4 shows the total quantity of particulate bromide released by the  
497 blowing snow SSA mechanism in the BLOW runs. Emissions over the Arctic Ocean decline each month  
498 after the March maximum as rising temperatures increase the wind speed threshold for blowing snow  
499 SSA production. Some icy coastal regions with frequently high wind speeds such as the Aleutian Islands  
500 south of Alaska and the eastern coast of Greenland continue to emit SSA p-Br<sup>-</sup> in April, and the extremely  
501 high winds in the Aleutians enable SSA production into May. The location of specific high-wind storm

502 systems in spring 2015 may be evident in the darker red spots over the Arctic Ocean, which are  
 503 particularly noticeable over the Eurasian and Central Arctic in March. These monthly averages are only  
 504 accurate for the months in spring 2015 and may not be spatially representative of blowing snow SSA  
 505 production in other years.

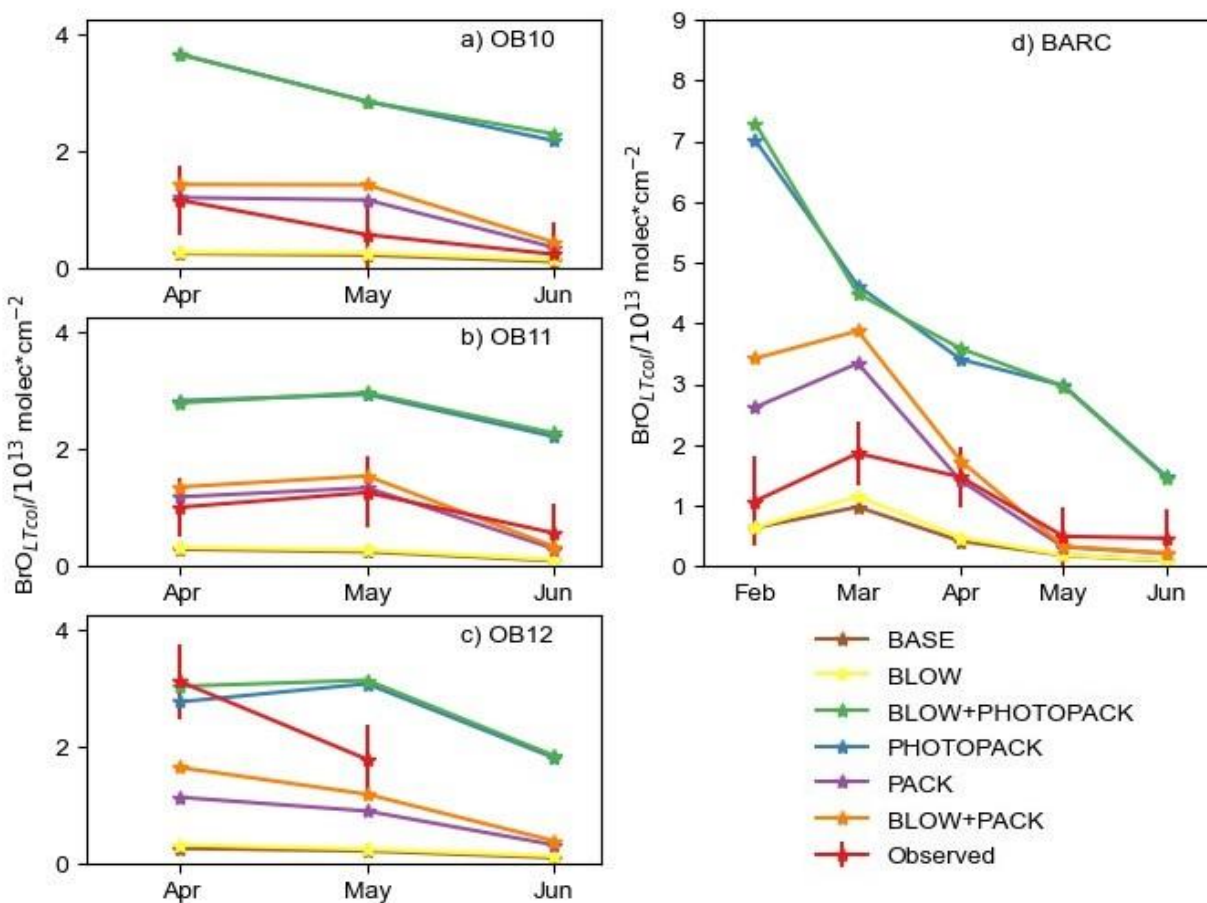

506 The impact of the blowing snow SSA emissions on measured BrO is minimal on O-Buoys in the  
 507 Beaufort Gyre, possibly due to the spatial and seasonal variations in SSA p-Br<sup>-</sup> emissions. Figure 4 shows  
 508 that 2015 SSA production was highest in March and April on the Eurasian and Central sector of the  
 509 Arctic, and thus the O-Buoys deployed as shown in Figure 2 are less exposed to the effects of SSA  
 510 production than the Arctic as a whole. Particulate bromide must be activated from SSA by heterogeneous  
 511 reactions as in Figure 1 and Table 3, leading to photochemical cycles that sustain further activation of  
 512 bromide from SSA. The dearth of sunlight over the Arctic Ocean in early March coincides with the  
 513 greatest SSA p-Br<sup>-</sup> production and means that the increased February SSA p-Br<sup>-</sup> emissions may not lead to  
 514 a direct increase in BrO.

515 **Table 2: Model root mean square error by run and location.**

516 Root mean squared model error (RMSE) shown in BrO<sub>LTcol</sub>/10<sup>12</sup> molec/cm<sup>2</sup> RMSE calculated as the  
 517 square root of the mean of the squared errors for all times with valid observed BrO<sub>LTcol</sub> in Spring 2015.

Units in BrO <sub>LTcol</sub> /10 <sup>12</sup> molec/cm <sup>2</sup>	OB10	OB11	OB12	Utqiagvik
BASE	9.9	12.9	22.9	13.0
BLOW	9.7	12.7	22.4	12.5

521 **Figure 5: Monthly average BrO<sub>LTcol</sub> in observations and model**

522 Monthly averages of BrO at a) O-Buoy 10, b) O-Buoy 11, c) O-Buoy 12, and d) BARC at Utqiaġvik only  
 523 using predictions and observations when dSCDO<sub>4</sub> > 1\*10<sup>43</sup> molecules<sup>2</sup>cm<sup>-5</sup>. Observations with average 1σ  
 524 error shown in red. All units in 10<sup>13</sup> molecules/cm<sup>2</sup>.

525

526 **3.3 Snowpack Br<sub>2</sub> emissions have more impact than blowing snow SSA on monthly BrO abundance**

527 Increased levels of bromine have been historically seen at Utqiaġvik during February, March,  
 528 April and May (Berg et al., 1983). Previous O-Buoy data analysis noted BrO dropping to zero in June  
 529 (Burd et al., 2017). Figure 5 shows monthly averaged modeled BrO<sub>LTcol</sub> at Utqiaġvik and on the O-Buoys  
 530 for each model configuration. The difference in GEOS-Chem modeled monthly averaged BrO<sub>LTcol</sub> for O-  
 531 Buoys is minimal between the BASE and BLOW runs, the PHOTOPACK and BLOW+PHOTOPACK  
 532 runs, and the PACK and BLOW+PACK runs. Both BASE and BLOW runs predict near-zero BrO<sub>LTcol</sub> on  
 533 all O-Buoys and during most months at Utqiaġvik. The exception to this is the slight increases in monthly  
 534 modeled BrO<sub>LTcol</sub> to 1\*10<sup>13</sup> molecules/cm<sup>2</sup> in March and April. This BASE increase in BrO<sub>LTcol</sub> indicates  
 535 that oceanic SSA rather than blowing snow SSA can affect modeled BrO at Utqiaġvik due to its closer

536 proximity to open ocean regions than the O-Buoys. The increases in BrO from the BASE model due to  
537 the addition of BLOW, most evident at Utqiaġvik in March 2015, are a result of increased particulate  
538 bromide available for activation on aerosol surfaces. The PACK and BLOW+PACK runs show the  
539 highest skill in reproducing observations, falling within the monthly average of hourly measured  $\text{BrO}_{\text{LTcol}}$   
540 error for 9 of the 13 months plotted in Figure 5. Both PACK and BLOW+PACK replicate the observed  
541 monthly pattern especially well on O-Buoy 11 and at Utqiaġvik. Both runs replicate the seasonal pattern  
542 of maximum modeled  $\text{BrO}_{\text{LTcol}}$  at Utqiaġvik in March followed by a decrease to near-zero modeled  
543  $\text{BrO}_{\text{LTcol}}$  in May despite model overprediction of  $\text{BrO}_{\text{LTcol}}$  in February and March. The BLOW+PACK  
544 monthly  $\text{BrO}_{\text{LTcol}}$  is between  $1 \times 10^{12}$  molecules/cm<sup>2</sup> and  $1 \times 10^{13}$  molecules/cm<sup>2</sup> higher than PACK monthly  
545  $\text{BrO}_{\text{LTcol}}$  due to the addition of blowing snow SSA. This increase is most pronounced in February and  
546 March at Utqiaġvik when lower temperatures lead to lower threshold wind speeds and increased SSA  
547 production (see Supplemental Figure S4).

548 The inclusion of increased daytime yield of snowpack  $\text{Br}_2$  drives monthly average  $\text{BrO}_{\text{LTcol}}$  above  
549  $3 \times 10^{13}$  molecules/cm<sup>2</sup> in the PHOTOPACK and BLOW+PHOTOPACK runs from February until June,  
550 far above peak observed monthly  $\text{BrO}_{\text{LTcol}}$  of  $2 \times 10^{13}$  molecules/cm<sup>2</sup>. The PHOTOPACK and  
551 BLOW+PHOTOPACK runs show steady decline in  $\text{BrO}_{\text{LTcol}}$  from February to June at Utqiaġvik.  
552 Predictions of PHOTOPACK and BLOW+PHOTOPACK monthly June  $\text{BrO}_{\text{LTcol}}$  above  $2 \times 10^{13}$   
553 molecules/cm<sup>2</sup> on the O-Buoys is due to increasing photo-assisted local snowpack  $\text{Br}_2$  emissions over the  
554 Arctic Ocean (see Figure 5). The PHOTOPACK mechanism predicts monthly average  $\text{BrO}_{\text{LTcol}}$  within  
555 observational error only on O-Buoy 12 in April. Aside from this replication of the sparsely sampled O-  
556 Buoy 12 April  $\text{BrO}_{\text{LTcol}}$ , the PHOTOPACK mechanism overestimates  $\text{BrO}_{\text{LTcol}}$ .

557 Table 2 shows the root mean squared error (RMSE) of each model run as compared to  $\text{BrO}_{\text{LTcol}}$   
558 observations in at each different location in Spring 2015. The PACK and BLOW+PACK runs have the  
559 lowest RMSE on O-Buoys 11 and 12, and among the lowest RMSE on O-Buoy 10. Utqiaġvik shows the  
560 lowest RMSE of  $1.25 \times 10^{13}$  molec/cm<sup>2</sup> for the BLOW run, although the PACK run is not too far off at  
561  $1.57 \times 10^{13}$  molec/cm<sup>2</sup>. Despite the fact that BLOW+PACK has a higher RMSE of  $1.75 \times 10^{13}$  molec/cm<sup>2</sup> at  
562 Utqiaġvik, the BLOW+PACK run performs the best or near the best of all runs on the O-Buoys and  
563 includes both known processes for Arctic reactive bromine production. The PHOTOPACK and  
564 BLOW+PHOTOPACK runs with increased daytime yield have a consistently high RMSE of  $2.46 \times 10^{13}$   
565 molec/cm<sup>2</sup> or higher, often double the RMSE of other model runs.

566

568

### 569 **Figure 6: May Hourly BrO<sub>LTcol</sub> timeseries**

570 Hourly timeseries of BLOW+PACK, PACK, and BASE BrO<sub>LTcol</sub> on a) O-Buoy 10, b) O-Buoy 11, c) O-  
 571 Buoy 12 and d) BARC at Utqiaġvik in the 2015 Arctic Spring. Observations and error bars in red, BASE  
 572 BrO<sub>LTcol</sub> in brown, PACK BrO<sub>LTcol</sub> in purple, and BLOW+PACK BrO<sub>LTcol</sub> in orange. All BrO<sub>LTcol</sub> plotted  
 573 continuously except for gaps where dSCDO<sub>4</sub> > 1 \* 10<sup>43</sup> molecules<sup>2</sup>cm<sup>-5</sup>.

### 574 **3.4 BLOW+PACK run best replicates hourly BrO events in mid and late May**

575 The model's hourly predictions of BrO<sub>LTcol</sub> in May 2015 are shown in Figure 6 for the BASE,  
 576 PACK, and BLOW+PACK runs. Figure 6 screens modeled BrO<sub>LTcol</sub> for times when dSCD O<sub>4</sub> > 1 \* 10<sup>43</sup>  
 577 molecules<sup>2</sup>cm<sup>-5</sup>, while Supplemental Figures S7 and S8 make direct comparisons between observations of  
 578 BrO<sub>LTcol</sub> for O-Buoys (S7) and at Utqiaġvik (S8) throughout all of Spring 2015. The O-Buoys show  
 579 fluctuations in observed BrO<sub>LTcol</sub> during May and show consistent increased columns of BrO<sub>LTcol</sub> from  
 580 May 10 to May 20. The BASE run never rises above 10<sup>13</sup> molecules/cm<sup>2</sup> and underpredicts most May  
 581 hourly BrO<sub>LTcol</sub>, although it predicts monthly BrO<sub>LTcol</sub> on OB10 within observational errors in May and  
 582 June. Both PACK and BLOW+PACK runs show better skill in replicating BrO<sub>LTcol</sub>. The addition of the  
 583 snowpack mechanism allows us to predict increased BrO<sub>LTcol</sub> in late May on O-Buoys 10 and 11. This

584 points to the role of surface snowpack in late-season events in agreement with the findings of Burd et al.  
585 (2017).

586 We can identify the role of blowing snow SSA by comparing the PACK and BLOW+PACK runs.  
587 Both PACK and BLOW+PACK runs underestimate  $\text{BrO}_{\text{LTcol}}$  during the first ten days of May. BrO  
588 predictions and show higher variability and peaks starting on May 10. The blowing snow SSA  
589 mechanism increases BLOW+PACK  $\text{BrO}_{\text{LTcol}}$  on May 12 and 13. PACK is skilled at replicating observed  
590 O-Buoy 11  $\text{BrO}_{\text{LTcol}}$  on both days, and both PACK and BLOW+PACK are within observational  $\text{BrO}_{\text{LTcol}}$   
591 error on May 13.

592 A BrO event also occurs on May 13 on O-Buoy 10. While the strength of the O-Buoy 10 BrO  
593 event is overestimated by PACK and BLOW+PACK, the shape of that event is reproduced in both runs.  
594 Observed  $\text{BrO}_{\text{LTcol}}$  decreases rapidly on all O-Buoys after May 14, and the model is unable to track this  
595 sharp decrease. Rapid changes in  $\text{BrO}_{\text{LTcol}}$  may be caused by sharp edges in BrO-enriched airmasses such  
596 as those seen by Simpson et al. (2017). GEOS-Chem run at this resolution cannot replicate abrupt  
597 changes in BrO, but it does slowly decrease  $\text{BrO}_{\text{LTcol}}$  to reach  $\text{BrO}_{\text{LTcol}}$  to less than  $10^{13}$  molecules/cm<sup>2</sup> on  
598 May 16. The BLOW+PACK mechanism is skilled in replicating the magnitude and features of a mid-  
599 May BrO event on O-Buoys 10 and 11.

600 Figure 7 shows all Spring 2015  $\text{BrO}_{\text{LTcol}}$  observations on O-Buoys 10, 11, 12, and BARC plotted  
601 against PACK  $\text{BrO}_{\text{LTcol}}$  and BLOW+PACK  $\text{BrO}_{\text{LTcol}}$ . The increase in  $\text{BrO}_{\text{LTcol}}$  on adding BLOW leads to  
602 fewer underpredictions of observations (see bottom right section of Figure 7b). The Pearson correlation  
603 coefficient ( $r$ ) between PACK  $\text{BrO}_{\text{LTcol}}$  and observed  $\text{BrO}_{\text{LTcol}}$  is 0.33, improving to 0.39 on addition of  
604 BLOW in the BLOW+PACK run. Other runs show less skill in replicating observations, with a BASE  
605  $\text{BrO}_{\text{LTcol}}$  Pearson correlation to observations of 0.19 and a BLOW  $\text{BrO}_{\text{LTcol}}$  Pearson correlation to  
606 observations of 0.23. We also performed a simple linear regression to determine the relationship between  
607 predictions and observations for each run. The slope of the line of best fit improves drastically on addition  
608 of PACK, changing from 0.06 for BASE and 0.07 for BLOW to 0.33 for PACK and 0.44 for  
609 BLOW+PACK. There is a positive synergistic effect on the slope of the line of best fit when using both  
610 BLOW and PACK in combination rather than individually. The use of both BLOW and PACK  
611 mechanisms corroborates literature findings on the processes influencing Arctic reactive bromine and  
612 increases correlation between GEOS-Chem predictions and observations.

613

614 **Figure 7: Hourly modeled BrO<sub>LTcol</sub> versus BrO<sub>LTcol</sub> observations**

615 Two dimensional histograms showing density of GEOS-Chem predicted BrO<sub>LTcol</sub> versus all observed  
 616 Spring 2015 hourly Br<sub>LTcol</sub>, with a) PACK BrO<sub>LTcol</sub> shown at left sorted into square bins of 0.2 with an  
 617 Pearson *r* correlation to observations of 0.33 and b) BLOW+PACK BrO<sub>LTcol</sub> on the bottom sorted into  
 618 square bins of 0.2 with Pearson *r* correlation to observations to 0.39. All units are in molecules/cm<sup>2</sup>. 1:1  
 619 line drawn in the center in black, with a margin of the average observational error plotted in dashed black  
 620 lines around the central 1:1 line.

621 **4. Arctic Spring reactive bromine modeling discussion**

622 **4.1 Use of both mechanisms in conjunction leads to best prediction of tropospheric BrO results**

623 Initial implementation of this snowpack mechanism in Toyota et al. (2011) increased the daytime  
 624 yield of Br<sub>2</sub> from ozone deposition to 7.5% to improve agreement between observed and modeled surface  
 625 ozone mixing ratios. Toyota et al. (2011) also increased the surface resistance of ozone to 10<sup>4</sup> s/m, which  
 626 decreased deposition velocities on Arctic snowpack to approximately 0.01 cm/s. Our model using a  
 627 constant yield of Br<sub>2</sub> from ozone deposition at 0.1% performs best despite observations that sunlight has  
 628 an effect on reactive bromine recycling in the snowpack (Pratt et al., 2013; Custard et al., 2017). GEOS-  
 629 Chem does not explicitly model heterogeneous photochemistry within the snowpack interstitial space but  
 630 does include heterogeneous bromine chemistry on aerosol particle surfaces after the Br<sub>2</sub> is emitted from  
 631 the snowpack into the lowest model layer. The updates to GEOS-Chem halogen chemistry (Schmidt et  
 632 al., 2016; Sherwen et al., 2016b; Chen et al., 2017; Wang et al., 2019b) should be mechanistically  
 633 sufficient to model daytime heterogeneous chemistry of reactive bromine on aerosol surfaces. We note  
 634 that improvements to GEOS-Chem have increased the explicit modeling of these photochemical recycling  
 635 and amplification processes, possibly reducing the need for empirical increases to daytime yields.

636 Our findings differ from recent implementations of the snowpack mechanism in Herrmann et al.  
 637 (2021) and Marelle et al. (2021). While all snowpack mechanisms are based on Toyota et al. (2011),  
 638 several large differences in model configuration and mechanism implementation explain these

639 differences. We allow Br<sub>2</sub> production from ozone deposition over all snow surfaces, leading to much  
640 higher Br<sub>2</sub> production over MYI and coastal regions. Land snowpack can produce Br<sub>2</sub> on exposure to  
641 ozone and sunlight (Pratt et al., 2013; Custard et al., 2017) and Figure 4 shows our coastal snowpack  
642 producing large quantities of Br<sub>2</sub>. Tropospheric reactive bromine chemistry has been observed up to 200  
643 km inland from the coast (Peterson et al., 2018). Marelle et al. (2021) underestimates BrO in late March  
644 and overestimates Utqiagvik BrO in early April. This seasonal pattern may be due to increased daytime  
645 ozone yield on first year ice near Utqiagvik in April. Herrmann et al. (2021) found that HOBr and BrNO<sub>3</sub>  
646 deposition was more important in driving snowpack Br<sub>2</sub> production and that the daytime yield of 7.5%  
647 Br<sub>2</sub> on ozone deposition underpredicted BrO. We find that ozone contributes slightly more than HOBr  
648 and BrNO<sub>3</sub> because we allow for Br<sub>2</sub> production on ozone deposition over multi-year ice and coastal  
649 snowpack regions. The temporal coverage of this study spans the entire year, while Herrmann et al.  
650 (2021) only spans February, March, and April. Our longer timescale highlights the issue of increased  
651 daytime Br<sub>2</sub> yield during May and June (see Figure 4 PHOTOPACK) with increased emissions over the  
652 Arctic Ocean that are not in agreement with satellite observations of minimal Arctic tropospheric BrO in  
653 June (Richter et al., 1998).

#### 654 **4.2 Addition of PACK mechanism increases surface ozone predictive skill**

655 The Barrow Arctic Research Center (BARC) in Utqiagvik has the most comprehensive coverage  
656 of surface ozone in Spring 2015. A constant yield of 0.1% Br<sub>2</sub> from ozone deposition allows us to  
657 approximate the average vertical extent of ozone depletion events at Utqiagvik in May 2015. The increase  
658 in Br<sub>y</sub> in the PACK and BLOW+PACK runs is confined to the lowest 1000 m of the atmosphere (see  
659 Supplemental Figure S9). Ozone depletions, caused by reactive bromine chemistry, often only occur  
660 within the lowest 1000 m of the troposphere (Bottenheim et al., 2002; Salawitch et al., 2010). Previous  
661 studies have found evidence of lofted BrO in plumes at altitudes up to 900 m AGL (Peterson et al., 2017).  
662 The monthly average Utqiagvik May surface ozone in BLOW and BLOW+PACK is 22 nmol/mol,  
663 matching mean May surface ozone from 1999-2008 (Oltmans et al., 2012). The PHOTOPACK runs  
664 generate mean May surface ozone depletion to approximately 5 nmol/mol, far below the May mean. The  
665 PACK and BLOW+PACK runs duplicate the approximate vertical extent of elevated bromine levels and  
666 the strength of typical May ozone depletion.

667 Figure 8 shows hourly ozone predictions alongside BARC ozone observations (McClure-Begley,  
668 Petropavlovskikh, and Oltmans, 2014). The BASE model fails to replicate variance in ozone measured at  
669 BARC in Utqiagvik, with a Pearson correlation coefficient to observations of 0.35. Adding PACK  
670 improves Pearson correlation to 0.47, within rounding error of BLOW+PACK Pearson correlation of  
671 0.47. Both PACK and BLOW+PACK significantly improve model performance in replicating ozone

672 depletions such as those below 30 nmol/mol from March 20 to March 29 but fail to track the subsequent  
673 recovery of ozone to background levels on April 1. Predicted PACK ozone does not recover to  
674 background levels up to the height of roughly 1000 m. A similar pattern where our model replicates low  
675 ozone but fails to predict the recovery of ozone to background levels occurs on April 5 and 15.  
676 Examination of ozone profiles in GEOS-Chem found that GEOS-Chem underpredicts tropospheric ozone  
677 by 10-20 ppb north of 60° latitude (Wang et al., 2021), which contributes to the low ozone predictions in  
678 our runs. Previous modeling of Utqiagvik spring 2012 ozone in WRF-Chem found a similar linear  
679 correlation coefficient of 0.5 to BROMEX observations (Simpson et al., 2017) when using both blowing  
680 snow and snowpack mechanisms (Marelle et al., 2021). We are biased low compared to observations,  
681 with a root mean square error of 17.0 nmol/mol in BLOW+PACK compared to a root mean square error  
682 of 12.9 nmol/mol in Marelle et al. (2021). This may be partially due to limited vertical resolution in  
683 GEOS-Chem that may be inadequate to describe shallow surface-based temperature inversions and  
684 subsequent recovery. The high bias in ozone deposition velocity over sea ice surfaces may also contribute  
685 to low ozone mixing ratios near the surface (Helmig et al., 2007).

687

### 688 **Figure 8: Hourly Utqiagvik ozone timeseries**

689 Hourly timeseries of BLOW+PACK, PACK, and BASE ozone at Utqiagvik in the 2015 Arctic Spring.  
 690 Ozone observations at BARC in black (McClure-Begley, Petropavlovskikh and Oltmans, 2014), BASE  
 691 ozone in brown, PACK ozone in purple, and BLOW+PACK ozone in orange. Gaps indicate missing  
 692 observational data.

693

694 A similar improvement in ozone predictions on the addition of PACK is seen on the O-Buoys, but  
 695 is harder to quantify due to observational gaps in ozone data. Supplemental Figure S10 shows hourly  
 696 ozone predictions graphed over O-Buoy 11 observations and Supplemental Figure S11 shows hourly  
 697 ozone predictions graphed over O-Buoy 12. O-Buoy 10 was not able to gather an observations of ozone in  
 698 2015. The clearest impact of PACK in Figures S10 and S11 is seen in early April, with observed ozone  
 699 dropping near zero nmol/mol and PACK and BLOW+PACK runs dropping to five nmol/mol while the  
 700 BASE run remains near 20 nmol/mol. Figure S10 shows that ozone predictions on O-Buoy 10 in May are  
 701 less accurate, failing to fall below 10 nmol/mol ozone while observations show ozone dropping near the  
 702 detection limit. The O-Buoys appear to experience more late-season ozone depletion events that GEOS-  
 703 Chem fails to replicate, possibly due to warming temperatures increasing vertical mixing and replenishing  
 704 ozone near the surface.

705

706 **Table 3: Arctic Tropospheric Reactions Rates by Model Run**  
 707 Rates for each of the simulated reactions listed in Figure 1 grouped by GEOS-Chem run. All units are  
 708 listed as millions of moles per hour across the region shown in Supplemental Figure S14. R in equation  
 709 R2 refers to any organic molecule. Y in equation 1 represents NO, Cl, or H. X in equation HR6a  
 710 represents either Br or Cl. PHOTOPACK and BLOW+PHOTOPACK are excluded as they severely  
 711 overpredict BrO as seen in Figures 4 and 5.

	BASE	BLOW	PACK	BLOW+PACK	Reaction Equation
R1	17.57	17.77	27.7	28.4	BrO + YO -> Br + O <sub>2</sub>
R2	236.28	261.75	435.74	472.14	Br + O <sub>3</sub> -> BrO + O <sub>2</sub>
R3	0.7	0.84	1.38	1.54	Br + RH -> HBr, Br + HO <sub>2</sub> -> HBr
R4	0.01	0.01	0.02	0.02	HBr + OH -> Br + H <sub>2</sub> O
R5	9.41	9.47	14.41	14.01	BrO + HO <sub>2</sub> -> HOBr
R6	1.63	2.4	12.78	16.16	BrO + BrO -> Br <sub>2</sub> + O <sub>2</sub>
R7	0.03	0.06	0.04	0.06	BrO + ClO -> BrCl + O <sub>2</sub>
R8	2.8	2.94	5.69	5.86	BrO + NO <sub>2</sub> -> BrNO <sub>3</sub>
R9	0	0	0	0	Br <sub>2</sub> + OH -> Br + HOBr
R10	0.15	0.17	1.39	1.64	Br + BrNO <sub>3</sub> -> Br <sub>2</sub> + NO <sub>3</sub>
R11	0.18	0.18	0.55	0.7	Br + NO <sub>2</sub> -> BrNO <sub>2</sub>
HR1a	0.04	0.03	0.15	0.1	HOBr + HBr -> Br <sub>2</sub> + H <sub>2</sub> O
HR1b	0.79	0.95	1.47	1.68	HOBr + p-Br <sup>-</sup> -> Br <sub>2</sub> + OH <sup>-</sup>
HR2	0.17	0.21	0.38	0.38	HOBr + H <sub>2</sub> O + HSO <sub>3</sub> <sup>-</sup> -> H <sub>2</sub> SO <sub>4</sub> + HBr + OH <sup>-</sup>
HR3	0.25	0.29	0.43	0.44	BrNO <sub>3</sub> + H <sub>2</sub> O -> HNO <sub>3</sub> + HOBr
HR4a	0	0	0	0	HBr + O <sub>3</sub> -> HOBr + O <sub>2</sub>
HR4b	0.07	0.09	0.14	0.15	p-Br <sup>-</sup> + O <sub>3</sub> + H <sub>2</sub> O -> HOBr + O <sub>2</sub> + OH <sup>-</sup>
HR5	0	0	0	0	BrNO <sub>3</sub> + HCl -> BrCl + HNO <sub>3</sub>
HR6a	0	0	0	0	HOX + HX -> BrCl + H <sub>2</sub> O
HR6b	0.29	0.54	0.37	0.68	HOBr + p-Cl <sup>-</sup> -> BrCl + OH <sup>-</sup>
HR7a	0	0	0	0	HBr + ClNO <sub>x</sub> -> BrCl + HNO <sub>x</sub>
HR7b	0	0	0	0	p-Br <sup>-</sup> + ClNO <sub>x</sub> + H <sub>2</sub> O -> BrCl + HNO <sub>x</sub> + OH <sup>-</sup>
HR8	0	0	0	0	p-Br <sup>-</sup> + IO <sub>x</sub> -> IBr + O <sub>x</sub>
P1	1.38	1.76	6.04	7.24	Br <sub>2</sub> + hv -> 2Br
P2	203.54	227.07	362.89	392.04	BrO + hv -> Br + O
P3	8.45	8.11	12.6	11.75	HOBr + hv -> OH + Br
P4	0.36	0.37	0.57	0.56	BrNO <sub>3</sub> + hv -> BrO + NO <sub>2</sub>
P5	2.04	2.1	3.24	3.17	BrNO <sub>3</sub> + hv -> Br + NO <sub>3</sub>
P6	0.18	0.18	0.55	0.7	BrNO <sub>2</sub> + hv -> Br + NO <sub>2</sub>
P7	0.35	0.63	0.45	0.76	BrCl + hv -> Br + Cl
P8	0	0	0	0	BrI + hv -> Br + I

712

## 713 5. Examining reactive bromine in the Arctic in September and October

714 O-Buoys deployed during fall 2015 measured BrO slant column densities characterized by noise  
715 around zero (see Supplemental Figures S12 and S13). We do not retrieve vertical column density from  
716 these fall slant column densities, because the resulting retrievals would be biased positive due to an  
717 algorithm requirement that only positive BrO column densities are allowed in the optimal estimation  
718 inversion. These differential slant column densities (dSCDs) can be used qualitatively to determine the  
719 presence or absence of BrO above the detection limit. If the dSCDs display noise around zero at all  
720 viewing angles, the BrO in the troposphere is below the detection limit of the spectrometer. A pattern of  
721 larger BrO dSCDs at near-horizon viewing elevation angles indicating the presence of tropospheric BrO  
722 above the detection limit is only observed at Utqiagvik during Arctic Spring (see Supplemental Figure  
723 S12) . Any BrO present in the Arctic troposphere in September and October falls below detection limits at  
724 Utqiagvik (see Supplemental Figure S12) and on each O-Buoy (see Supplemental Figure S13). The  
725 average Arctic Spring 2015 MAX-DOAS  $\text{BrO}_{\text{LTcol}}$  detection limits are  $5 \times 10^{12}$  molecules/cm<sup>2</sup> (Peterson  
726 et al., 2015; Simpson et al., 2017; Swanson et al., 2020). Both BLOW and PACK mechanisms lead to  
727 prediction of increased fall BrO because the weather and sea ice conditions specified in the emission  
728 algorithms occur in fall as well as spring.

729 Figure 9 shows fall predictions of  $\text{BrO}_{\text{LTcol}}$  filtered for times when solar elevation angle was  
730 greater than 5°. BASE and PACK  $\text{BrO}_{\text{LTcol}}$  remain near zero in September but rise above the MAX-DOAS  
731 detection limit of  $5 \times 10^{12}$  molecules/cm<sup>2</sup>  $\text{BrO}_{\text{LTcol}}$  in October. The addition of the blowing snow SSA  
732 mechanism propels BLOW  $\text{BrO}_{\text{LTcol}}$  up to  $6 \times 10^{13}$  molecules/cm<sup>2</sup> in October. O-Buoys 13 and 14 have  
733 the highest modeled fall  $\text{BrO}_{\text{LTcol}}$  but even Utqiagvik has several days of  $\text{BrO}_{\text{LTcol}}$  above  $5 \times 10^{12}$   
734 molecules/cm<sup>2</sup> in late October. There is no clear evidence of any BrO above MAX-DOAS detection limits  
735 at Utqiagvik or on any O-Buoy in October, as seen by the dSCDs scattered around zero in Supplemental  
736 Figures S12 and S13.

737

738

739 **Figure 9: Fall GEOS-Chem Predicted  $\text{BrO}_{\text{LTcol}}$**

740 Hourly timeseries of BLOW+PACK, PACK, and BASE  $\text{BrO}_{\text{LTcol}}$  on a) O-Buoy 10, b) O-Buoy 11, c) O-  
 741 Buoy 12 and d) BARC at Utqiagvik during September and October 2015 BASE  $\text{BrO}_{\text{LTcol}}$  in brown,  
 742 BLOW  $\text{BrO}_{\text{LTcol}}$  in yellow, PACK  $\text{BrO}_{\text{LTcol}}$  in purple, and BLOW+PACK  $\text{BrO}_{\text{LTcol}}$  in orange. All  $\text{BrO}_{\text{LTcol}}$   
 743 plotted continuously except for gaps where solar elevation angle was less than  $5^\circ$ .

744

745 Both mechanisms assume that snowpack and SSA are just as capable of recycling reactive  
 746 bromine as in the springtime. High fall and winter SSA agrees with observations of peak SSA during  
 747 polar winter in both Antarctica (Wagenbach et al., 1998) and in the Arctic (Jacobi et al., 2012). The  
 748 deposition of Arctic haze (Douglas and Sturm, 2004) and SSA (Jacobi et al., 2019) increases snowpack  
 749 salinity and sulfate content over the course of winter and spring. This seasonal change in snowpack  
 750 salinity and acidity may enable reactive bromine recycling in the Arctic Spring, but there may not be  
 751 sufficient haze and SSA deposition in fall to decrease snowpack pH and increase snowpack bromide  
 752 content. Additional observations of fall snowpack over sea ice including ion content could show different  
 753 snowpack composition in spring and fall. Thus, the GEOS-Chem model overestimates fall BrO by  
 754 assuming the fall snowpack is equally capable of reactive bromine recycling as spring snowpack and  
 755 providing an infinite reservoir of snowpack bromide in all seasons. Most other modeling exercises have

756 focused on spring with unknown predictions in fall, possibly indicating problems in mechanisms or  
757 parameterizations being employed, so we suggest that modeling should be done for a full year to improve  
758 underlying chemistry and physics. We also suggest a fall snow sampling campaign to validate modeled  
759 fall BrO.

## 760 **6. Conclusions**

761 We add snowpack Br<sub>2</sub> production to GEOS-Chem based on multiple field observations  
762 demonstrating molecular bromine production in snowpack interstitial air. We use a mechanistic  
763 parameterization of snowpack Br<sub>2</sub> production based on Toyota et al. (2011) in which Br<sub>2</sub> is emitted from  
764 all snowpack of sufficient salinity and depth over land and sea ice upon deposition of the precursor  
765 species HOBr, BrNO<sub>3</sub>, and ozone. Prior work has also added a blowing snow SSA production mechanism  
766 that increases aerosol particulate bromide and thus facilitates heterogeneous recycling of reactive bromine  
767 on these aerosol particle surfaces. We update the halogen scheme to GEOS-Chem 12.9.3 and performed  
768 six model simulations including a BASE run with neither blowing snow SSA nor snowpack emissions, a  
769 PACK run assuming constant yield of Br<sub>2</sub> on ozone deposition over all snow surfaces, a PHOTOPACK  
770 run assuming increased daytime yield of Br<sub>2</sub> on ozone deposition (similar in Toyota et al., 2011), a  
771 BLOW run using only blowing snow SSA formation and two additional runs combining BLOW and each  
772 respective PACK mechanism. The increased daytime yield of Br<sub>2</sub> in PHOTOPACK leads to  
773 overprediction of BrO in these simulations, but the PACK run (with constant Br<sub>2</sub> yield day and night)  
774 matches monthly averaged BrO vertical column densities within measurement error for 9 of 13 cases at  
775 O-Buoy and Utqiagvik in springtime months. The PACK and BLOW+PACK runs were successful in  
776 replicating observed BrO events on O-Buoys in May. The BLOW mechanism effectively increases  
777 aerosol surface available for turnover of reactive bromine. The snowpack mechanism has more impact on  
778 modeled BrO mixing ratios than the blowing snow SSA mechanism, but both contribute to tropospheric  
779 reactive bromine. We extend our model run to the full year and find that enhanced daytime Br<sub>2</sub> yield can  
780 lead to increased Arctic Ocean Br<sub>2</sub> production in the summer. Examining modeled BrO in fall 2015  
781 reveals prediction of BrO when using these mechanisms that are at odds with observations.

782 The inclusion of two Arctic reactive bromine production mechanisms based on literature  
783 observations of snowpack Br<sub>2</sub> emission and blowing snow SSA formation improves model skill in  
784 replicating Arctic tropospheric BrO in spring 2015. The snowpack is an important source of reactive  
785 bromine, and SSA particles provide an abundant surface for sustained reactive bromine recycling in the  
786 troposphere. We find that using both snowpack and blowing snow SSA bromine production mechanisms  
787 is necessary for modeling BrO in the Arctic.

788

789 *Competing interests:* The authors declare that they have no conflict of interest.

790 Author contributions. WFS, WRS and CH designed the study. WRS collected and curated MAX-DOAS  
791 data. KC, LM, JT, LJ, JH and contributed code for reactive bromine mechanisms. CH, KC, LJ, JH, BA,  
792 SZ, QC, XW, and TS contributed model updates. WFS carried out modeling and analysis. WFS wrote the  
793 paper with input from all authors.

## 794 **7. Acknowledgements**

795 We acknowledge support from the National Science Foundation for providing funding under grants ARC-  
796 1602716, AGS-1702266, AGS-2109323, and ARC-1602883. This work also supported by the CNRS  
797 INSU LEFE-CHAT program under the grant Brom-Arc, and NASA grant 80NSSC19K1273. This  
798 research has received funding from the European Union's Horizon 2020 research and innovation program  
799 under grant agreement no. 689443 via project iCUPE (Integrative and Comprehensive Understanding on  
800 Polar Environments). The O-Buoy and Utqiagvik ground-based BrO datasets are available in the  
801 arcticdata.io repository (doi:10.18739/A2WD4W). We recognize the work of Jiayue Huang in adding the  
802 blowing snow SSA mechanism to GEOS-Chem. We would like to thank the National Oceanic and  
803 Atmospheric Administration (NOAA) Global Monitoring Division for the provision of ozone and  
804 temperature data near Utqiagvik available online at doi:10.7289/V57P8WBF. We acknowledge use of the  
805 coastline distance dataset from the Pacific Islands Ocean Observing System. We acknowledge the use of  
806 imagery from the Land Atmosphere Near Real-Time Capability for EOS (LANCE) system and services  
807 from the Global Imagery Browse Services (GIBS), both operated by the NASA/GSFC/Earth Science Data  
808 and Information System (ESDIS, <https://earthdata.nasa.gov>) with funding provided by NASA/HQ. We  
809 owe a debt of gratitude to all members of the Atmospheric Chemistry and Global Change group at Florida  
810 State University for their support for working with GEOS-Chem and Python. We thank the global GEOS-  
811 Chem community for their tireless work to improve the model. We also thank all involved in the O-Buoy  
812 project for data collection and analysis.
