20

21 **Abstract.** With high emissions of aerosols and the known world’s “Third Pole” of the Tibet Plateau (TP) in
22 East Asia, knowledge on the energy budget over this region is widely concerned. This study first attempts
23 to estimate the present-day land energy balance over East Asia by combining surface and satellite
24 observations, as well as the atmospheric reanalysis and Coupled Model Intercomparison Project phase 6
25 (CMIP6) simulations. Compared to the global land budget, a substantially larger fraction of atmospheric
26 shortwave radiation of 5.2% is reflected, highly associated with the higher aerosol loadings and more clouds
27 over East Asian land. While a slightly smaller fraction of atmospheric shortwave absorption of 0.6% is
28 unexpectedly estimated, possibly related to the lower water vapor content effects due to the thinner air over
29 the TP to overcompensate for the aerosol and cloud effects over East Asian land. The weaker greenhouse
30 effect and fewer low clouds due to the TP are very likely the causes for the smaller fraction of East Asian-
31 land surface downward longwave radiation. Hence, high aerosol loadings, clouds, and the TP over East Asia
32 play vital roles in the shortwave budgets, while the TP is responsible for the longwave budgets during this
33 regional energy budget assessment. The further obtained cloud radiative effects suggest that the presence of
34 clouds results in a larger cooling effect on the climate system over East Asian land than that over globe. This
35 study provides a perspective to understand fully the roles of potential factors in influencing the different
36 energy budget assessments over regions.

37

38 **1. Introduction**

39 Current patterns of Earth’s weather and climate are largely determined by the spatiotemporal
40 distributions of energy exchanges between the surface, atmosphere, and space. Theoretically, the outgoing
41 longwave radiation (OLR) is balanced by the incoming and reflected solar radiation at the top of the
42 atmosphere (TOA) to produce an equilibrium climate. The incoming solar radiation can be scattered by
43 clouds and aerosols or absorbed by the intermediary atmosphere, thereby contributing to the diverse energy
44 transformation at the surface (Trenberth et al., 2009; Wild et al., 2013a). The Earth’s surface energy balance
45 is of particular significance because it is the key driver of atmospheric and oceanic circulations, hydrological
46 cycles, and various surface processes (Wild et al., 2008; Mercado et al., 2009; Wild et al., 2013a; L’Ecuyer
47 et al., 2015). Anthropogenic influences on climate change are driven by the uneven distribution of the TOA
48 net radiation caused by forcings perturbed by variations of the atmospheric composition of greenhouse gases
49 and aerosols as well as aerosol-cloud interactions (Trenberth et al., 2009; Stephens et al., 2012; Wild et al.,
50 2013a; Trenberth et al., 2014; L’Ecuyer et al., 2015; Wild et al., 2019).

51 Many efforts have been made to quantify the magnitudes of different radiative components or energy
52 budgets in the climate system over a range of time-space scales, such as on global scales (Lin et al., 2008;
53 Trenberth et al., 2009; Stephens et al., 2012; Wild et al., 2013b; Wild et al., 2015; L’Ecuyer et al., 2015;
54 Wild et al., 2019; Wild, 2020), over land and ocean domains or the energy transport between them (Fasullo
55 and Trenberth, 2008a, b; Trenberth et al., 2009; Wild et al., 2015; L’Ecuyer et al., 2015), over the Arctic
56 (Previdi et al., 2015; Christensen et al., 2016), and over individual continents and ocean basins (L’Ecuyer et
57 al., 2015; Kim and Lee, 2018; Thomas et al., 2020). The energy balance at the TOA can be accurately

58 monitored by satellites from the most advanced Clouds and the Earth's Radiant Energy System (CERES)
59 Energy Balanced and Filled (EBAF) data product (Loeb et al., 2018), while considerably larger uncertainties
60 appear at the surface fluxes owing to weaker observational constraints (Raschke et al., 2016; Kato et al.,
61 2018; Huang et al., 2019). These assessments mostly build upon complementary approaches from a
62 combination of space and surface observations, climate models, and reanalyses. To date, the discrepancies
63 of independent global mean surface radiative fluxes have estimated to be within a few W m^{-2} (Wild, 2017a,
64 b), enabling the accurate quantification of global surface budgets. In addition, the surface radiative
65 components simulated by various climate models vary substantially in a range of around 10–20 W m^{-2} on
66 global scales, but exhibit greater inter-model discrepancies on regional scales (Li et al., 2013; Wild et al.,
67 2013a; Boeke and Taylor, 2016; Wild et al., 2015; Wild, 2017a, b, 2020). Existing challenges on the surface
68 energy estimates include considerable uncertainties from surface albedo and skin temperature, as well as the
69 partitioning of surface net radiation into sensible and latent heat (SH; LH) (Wild, 2017a, b).

70 Due to the large population and the largest emission source of aerosols and their precursors, East Asia,
71 especially China, has long been a hotpot in climate change research. Aerosols can interact with radiation
72 directly by scattering and absorbing solar/thermal radiation (Ghan et al., 2012) and indirectly by modifying
73 cloud microphysical properties and lifetimes (Li et al., 2011), thereby influencing Earth's radiation balance.
74 As the world's largest and highest plateau, the Tibet Plateau (TP) covers nearly one ~~third~~^{third}~~fifth~~ of the East
75 Asian land area, significantly affecting the atmospheric circulation, energy budget, and water cycles of
76 climate system through its orographic and thermal effects (Liu et al., 2007; Xu et al., 2008a, b; Wu et al.,
77 2015). Deeper insights into the energy budget differences over East Asian and global land under the
78 background of high aerosol emissions and the role of the TP in East Asia are of the meaningful and essential
79 attempts. Moreover, clouds play a key role in modulating global and regional energy budgets and
80 hydrological cycles through increasing the reflected solar radiation and also the downward thermal radiation,
81 leading to a cooling and warming of climate system (Stephens, 2005; Wild et al., 2013a; Li et al., 2015; H.
82 Wang et al., 2021). Therefore, our emphasis in this study is on the regional characterization of the East Asian
83 energy balance under both all-sky and clear-sky conditions based on a combination of surface observations,
84 satellite-derived products, reanalysis, and Coupled Model Intercomparison Project phase 6 (CMIP6) models.
85 The cloud influence on the radiative energy budgets at the TOA, within the atmosphere, and at the surface
86 is further quantified over this region. Section 2 introduces the different data sources used in this study,
87 including surface and satellite observations, climate models, and reanalysis. Sections 3 and 4 provide detailed
88 analyses of the all-sky and clear-sky estimates of the energy balance components. The inferred cloud
89 radiative effects (CREs) at the TOA, within the atmosphere, and at the surface are presented in Section 5.
90 Summary and conclusions are given in Section 6. The present-day in this study represents years of 2010–
91 2014, which corresponds to the last five years of the historical simulations in CMIP6 climate models. East
92 Asian land as considered in this study consists of five countries, including China, Japan, South and North
93 Korea, as well as Mongolia.

94

95 2. Data sources

96 2.1. Surface observations

97 Considering the efforts to diminish the inhomogeneities in the measurement of ground-based surface
98 (downward) solar radiation (SSR) (Tang et al., 2011; Wang, 2014; Wang et al., 2015; Wang and Wild, 2016;
99 He et al., 2018; Yang et al., 2018, 2019) and the large amount of observational stations over China, the
100 homogenized monthly all-sky and clear-sky SSR datasets from the China Meteorological Administration
101 (CMA) National Meteorological Information Center (NMIC) are used in this study (<http://data.cma.cn/enl>)
102 (Yang et al., 2018, 2019). In this dataset, the clear-sky condition at observational sites is defined based on
103 the measured cloud fraction per day of no more than 15% (Yang et al., 2018). Taking clear-sky data (with
104 relatively complex missing months compared to the all-sky dataset) as an example, sites with more than one
105 year of > 2 missing months were deleted to ensure ≥ 4 years of available data during the period 2010-2014,
106 then the spline interpolation was performed on the missing months of the selected sites. As a consequence,
107 99 and 76 sites are available for the all-sky and clear-sky studies, respectively. Besides, to further explore
108 the anthropogenic influence on SSR, 84 (62) urban and 15 (14) rural stations for all-sky (clear-sky)
109 conditions are defined according to the administrative divisions of China (Wang et al., 2017).

110 For the remaining East Asian sites, we use the monthly Global Energy Balance Archive (GEBA) dataset
111 (<http://www.geba.ethz.ch>) (Wild et al., 2017), which contains a worldwide widespread distribution of
112 monthly data from many sources, e.g., from the World Radiation Data Center (WRDC), the Baseline Surface
113 Radiation Network (BSRN), etc. Among these data sources, the BSRN dataset has a much higher precision
114 and temporal resolution (up to 1 min) compared to the GEBA, but its site number is very limited over East
115 Asia (only a few sites located in Japan and one site in Xianghe, China, but with no data available during this
116 study period). Moreover, the relative random error of the monthly SSR from the GEBA data evaluated by
117 Gilgen et al. (1998) is 5%.

118 In order to retain as many sites as possible during the study period, we widen the selection criterion of
119 the GEBA data, i.e., sites with data ≥ 4 years and missing months ≤ 3 . Eventually, 8, 2, 4, and 14 sites are
120 selected from GEBA in China, Mongolia, South and North Korea, and Japan, respectively. Especially,
121 among the 14 sites in Japan, five pairs of the duplicate sites are obtained from the WRDC and BSRN sources,
122 respectively, and the left 4 sites are only from the WRDC (9 sites available). For China, only one site from
123 Hongkong out of 8 GEBA sites is not repetitive from the above-mentioned CMA sites (1 site available).
124 Therefore, 16 out of 28 GEBA sites are available under all-sky conditions (including 15 sites over regions
125 outside China and 1 site over Hongkong, China) by taking the average of these duplicate sites in Japan
126 instead, while the clear-sky reference sites are obtained from the interpolated CERES EBAF clear-sky
127 estimates at the GEBA sites (also 16 sites) due to the limited numbers of observational sites over these
128 regions. Additionally, we regard four island sites in Japan as rural stations (not shown in the figures), while
129 the sites in Mongolia as well as South and North Korea are all urban sites.

130 As shown in Fig. S1, there are 99 (rural/total: 15/99) and 16 (rural/total: 4/16) sites from the CMA and
131 GEBA available under all-sky conditions, respectively, whereas 76 (rural/total: 14/99) and 16 (from the
132 CERES-interpolated data at the 16 GEBA sites) sites are considered for clear-sky conditions, respectively.
133 More detailed station information is given in Table S1.

134

135 2.2. Satellite observation

136 Owing to the excellent temporal and spatial coverage of satellite instruments, CERES data products are
137 widely used to track variations of Earth's energy budgets. The newly released CERES EBAF Edition 4.1
138 with a monthly $1^\circ \times 1^\circ$ latitude-longitude resolution is used in this study (<https://ceres.larc.nasa.gov/data/>). In
139 this dataset, the TOA radiation components are adjusted within their uncertainty ranges based on the
140 independent observational ocean estimates of global heating rate (Loeb et al., 2018). Unlike the directly
141 measured TOA energy budget, the EBAF-surface energy fluxes are calculated by the cloud and aerosol
142 properties from satellite-derived products as well as the atmospheric profiles from reanalysis, with a lower
143 accuracy than their TOA counterparts (Kato et al., 2018). The uncertainty ranges in $1^\circ \times 1^\circ$ regional monthly
144 all-sky and clear-sky longwave (LW) and shortwave (SW) radiation fluxes at the TOA are also documented
145 by Loeb et al. (2018).

146

147 2.3. Climate models and reanalysis

148 Data from 40 CMIP6 climate models are used for the analyses in this study with their model
149 abbreviations, modeling groups, and resolutions in Table S2. A detailed description of the modeling groups
150 participating in CMIP6 is provided at <https://pcmdi.llnl.gov/CMIP6/>~~https://pcmdi.llnl.gov/CMIP6/~~. The
151 CMIP6 model-calculated radiation fluxes under investigation for this study include energy budgets under
152 both all-sky and clear-sky conditions from 'historical all forcings' experiments covering the period 2010-
153 2014. In these historical simulations, both natural (e.g., solar variability and volcanic aerosols) and
154 anthropogenic (e.g., greenhouse gases, aerosols, and land use) forcings are considered to reproduce the
155 climate change and evolution since preindustrial times as accurately as possible (Eyring et al., 2016). Only
156 the first ensemble member of each model is selected for the analysis and the model numbers vary slightly
157 among different available energy components.

158 In the long history of the European Center for Medium-range Weather Forecast (ECMWF), ERA5 is
159 the fifth generation product. It is a comprehensive reanalysis from 19~~579~~ ~~(soon be backdated to 1950)~~ to
160 near real time, which assimilates as many observations as possible in the upper air and near surface
161 ([https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-era5-single-levels-monthly-](https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-era5-single-levels-monthly-means?tab=form)
162 [means?tab=form](https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-era5-single-levels-monthly-means?tab=form)). Monthly means of the radiative components from ERA5 are used in this study with a
163 resolution of $0.25^\circ \times 0.25^\circ$ (regridded to $1^\circ \times 1^\circ$). Compared to previous reanalyses (such as ERA-Interim), a
164 major strength of ERA5 is the much higher temporal and spatial resolutions, as well as a [higher vertical](#)
165 [resolution with 137 levels](#)~~larger number of vertical levels~~ (Hersbach et al., 2020). Several independent

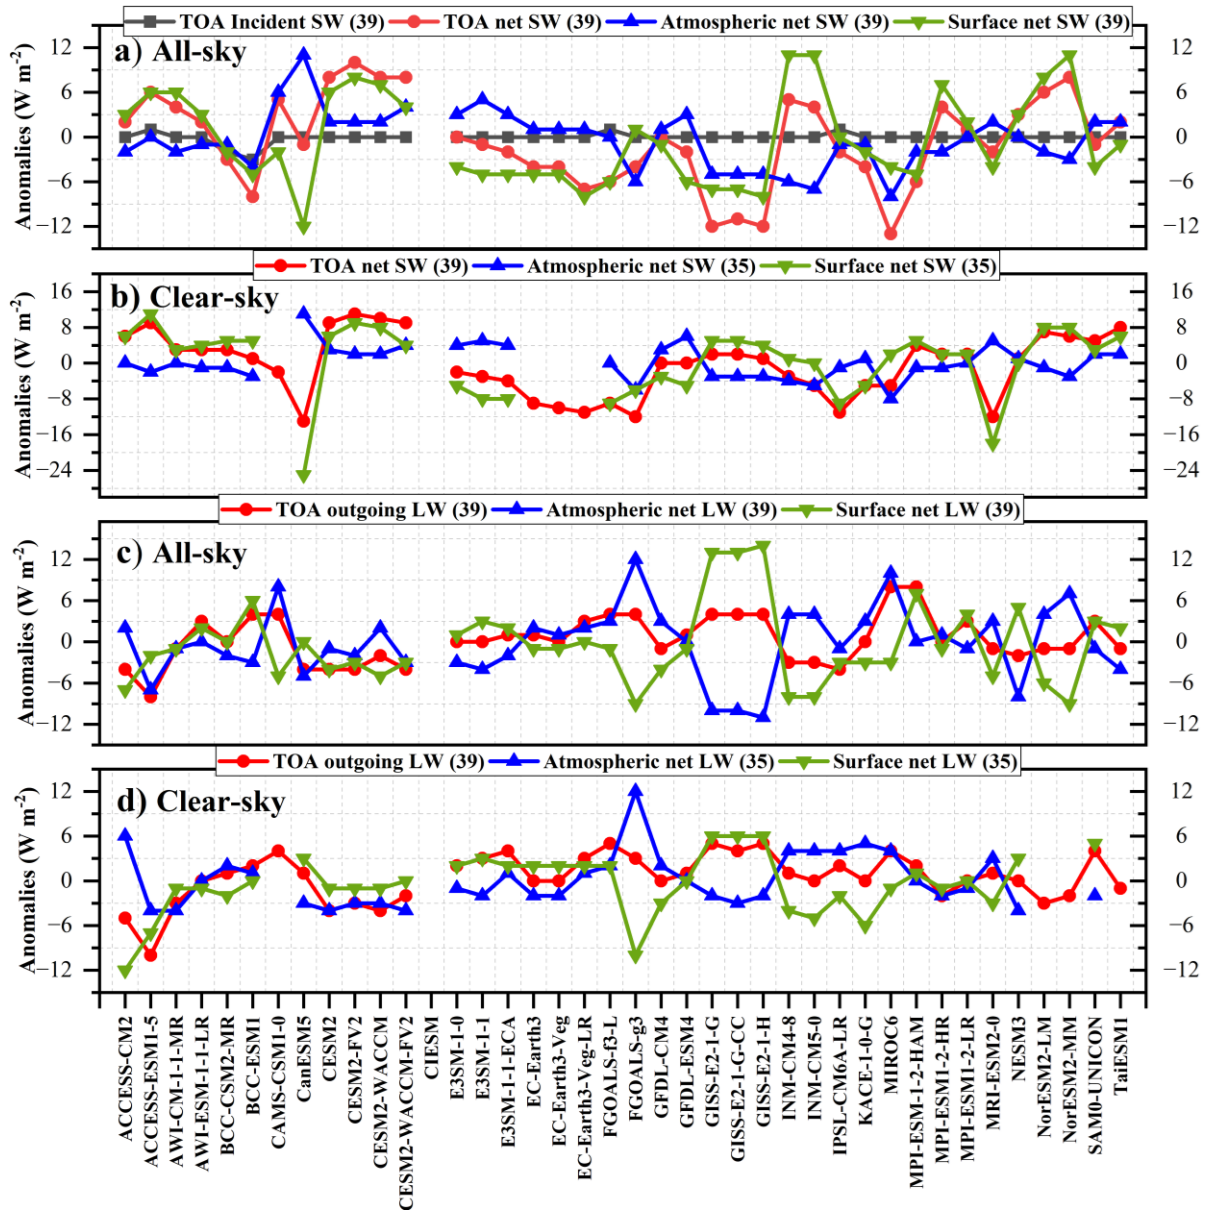

166 studies have evaluated the performance of ERA5 since its release. For example, excellent closure of the
 167 Arctic energy budget based on ERA5 atmospheric data has been assessed by Mayer et al. (2019). The
 168 representation of surface irradiance of ERA5 has been compared with other reanalyses and with ground and
 169 satellite observations (Trolliet et al., 2018; Urraca et al., 2018). Specifically, Trolliet et al. (2018) found that
 170 the surface solar irradiance over the tropical Atlantic Ocean from ERA5 exhibits fewer biases than the second
 171 version of the Modern-Era Retrospective Analysis for Research and Applications (MERRA-2). Urraca et al.
 172 (2018) reported that ERA5 can be a valid alternative for satellite-derived products in terms of surface
 173 irradiance in most inland stations compared to ERA-Interim or MERRA-2. Furthermore, based on BSRN
 174 station data, Tang et al. (2021) pointed out that the accuracy of the ERA5 over land in terms of surface
 175 downward longwave radiation is higher than CERES-derived product on average both at hourly and monthly
 176 times scales.

177 **3. Assessment of land energy balance budgets under all-sky conditions**

178 3.1. Shortwave components

179 Under all-sky conditions, the present-day annual land-mean anomalies of TOA incident solar radiation
 180 as well as the SW net radiation at the TOA, within the atmosphere, and at the surface regarding to their
 181 respective multi-model means as simulated by various CMIP6 models over East Asia are shown in Fig. 1a.
 182 A summary of the CMIP6 model statistics (such as available model number, model spread, and the standard
 183 deviation (SD)), along with the corresponding multi-model mean, ERA5-, and CERES-derived estimates of
 184 different energy balance components are listed in Table 1. As shown in Fig. 1a, with the exception of the
 185 BCC-CSM2-MR and BCC-CESM1 models, all models give an estimate around 334 W m^{-2} for TOA
 186 incoming solar radiation with a very small SD of 0.2, closely matching the multi-model mean as well as the
 187 CERES and ERA5 estimates (Table 1). The multi-model means of solar absorption at the TOA, within the
 188 atmosphere, and at the surface are 217, 73, and 144 W m^{-2} , respectively, all within 2 W m^{-2} of the biases
 189 against the CERES-derived estimates, while they are $3\text{--}4 \text{ W m}^{-2}$ larger for those from ERA5 at the TOA and
 190 within the atmosphere, yielding 1 W m^{-2} of bias against the CERES-based estimate at the surface (Table 1).
 191 However, the individual models vary significantly in their simulated annual East Asian land-mean solar
 192 absorption both at the TOA and surface (Fig. 1a), with SDs of around 6 W m^{-2} and inter-model spreads of
 193 more than 20 W m^{-2} (Table 1). Considering the smaller absolute amount of atmospheric and surface solar
 194 absorption compared to the TOA counterpart (73 and 144 vs. 217 W m^{-2} ; Table 1), the relative (percentage)
 195 differences relative to their respective multi-model means (relative (percentage) difference =
 196 $\frac{\text{range}}{\text{multi-model mean}} \times 100\%$) indicate that the uncertainties within the atmosphere and at the surface are larger
 197 than that at the TOA (i.e., TOA: $\frac{22}{217} \times 100\% = 10\%$; Atmosphere: $\frac{19}{73} \times 100\% = 26\%$; Surface:
 198 $\frac{23}{144} \times 100\% = 16\%$).

199

200

201 **Figure 1.** Annual land mean anomalies of (a, b) shortwave (SW) and (c, d) longwave (LW) budgets
 202 (Units: $W m^{-2}$) with regard to their respective multi-model means for present-day climate under (a, c)
 203 all-sky and (b, d) clear-sky conditions over East Asia as simulated by various CMIP6 models. The black, red,
 204 blue, and green lines represent the TOA incoming solar radiation, as well as the net SW/LW radiation at
 205 the TOA, within the atmosphere, and at the surface, respectively.

206

207 **Table 1.** Annual land mean estimates (Units: $W m^{-2}$) of the magnitudes of various energy balance
 208 components and cloud radiative effects (CREs) over East Asia under all-sky and clear-sky conditions at the
 209 TOA, within the atmosphere, and at the surface, respectively. The CMIP6 model statistics (e.g., available
 210 model number, spread, standard deviation (SD)), as well as the corresponding multi-model mean, ERA5-,
 211 and CERES-derived estimates are also given in the Table.

Component ($W m^{-2}$)	CMIP6				ERA5	CERES
	models	spread	SD	mean

LH	40	26	4.7	-43	-38	—
SH	40	21	5.2	-31	-29	—

212

213 The simulated SSR, however, shows the largest spread of more than 30 W m⁻² (ranging from 172–205
214 W m⁻²) among all the substantially differing all-sky surface radiation components, with a large SD of 7.6 W
215 m⁻² (Fig. 2a; Table 1). The multi-model mean SSR is estimated to be 186 W m⁻², suggesting positive and
216 negative deviations of 8 and 5 W m⁻² from the CERES- and ERA5- derived estimates, respectively (Table
217 1). Interestingly, although the discrepancy between them is very large (8 or 5 W m⁻²), both the resulting
218 surface solar absorption differences are very small (within 3 W m⁻²), indicating that a higher SSR goes

219 together with a higher surface albedo (Table 1), which agrees well with that on a global mean level (Wild et
 220 al., 2015).

221

222

223 **Figure 2.** Annual land mean surface downward (a) SW and (b) LW radiation (Units: $W m^{-2}$) under both
 224 all-sky (orange bars) and clear-sky (green bars) conditions over East Asia as calculated by various CMIP6
 225 models.

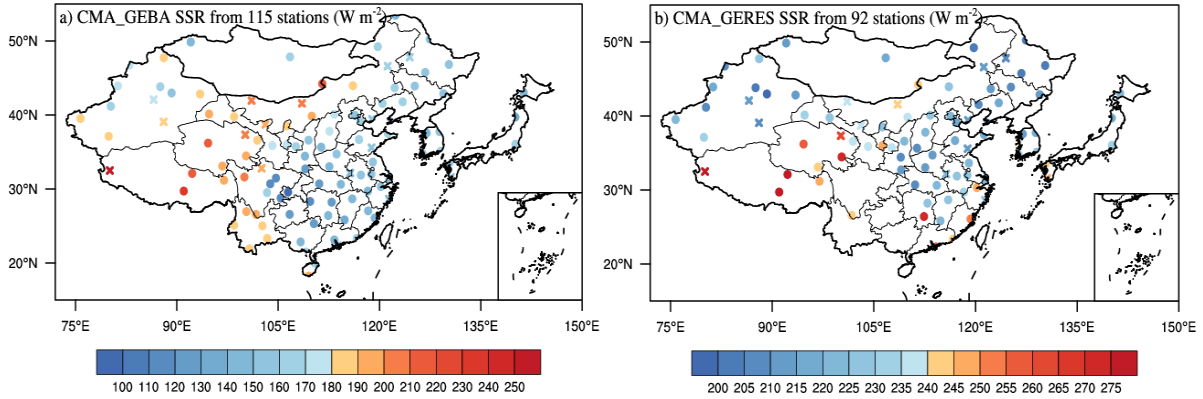

226

227 3.2. Best estimates for the surface downward SW radiation

228 As a major component of Earth's energy balance, the solar radiation reaching the Earth's surface
 229 governs a wide range of surface physical and chemical processes. The spatial distributions of the site-based
 230 annual mean SSR from the CMA and GEBA (Section 2.1) over East Asia under all-sky conditions are
 231 presented in Fig. 3a, together with the classified rural and urban sites. In short, the high values are mainly
 232 located at the high elevation stations over western China and a few island sites in Japan (e.g.,
 233 Minamitorishima, Japan; not shown in the figure), especially over the TP, with the largest value reaching
 234 $263 W m^{-2}$ (Geer, Tibet), which is associated with the high atmospheric transparency over these regions.
 235 However, the low annual mean values are primary over southwestern China, with the smallest value of 103
 236 $W m^{-2}$ (Shapingba, Chongqing), which is possibly caused by the higher aerosol loadings (Liao et al., 2015;

237 de Leeuw et al., 2018) and more clouds (Li et al., 2017; You et al., 2019; Lei et al., 2020; Zhang et al., 2020)
 238 over these regions. This distribution pattern is highly consistent with that over China documented by Q.
 239 Wang et al. (2021).

240

241

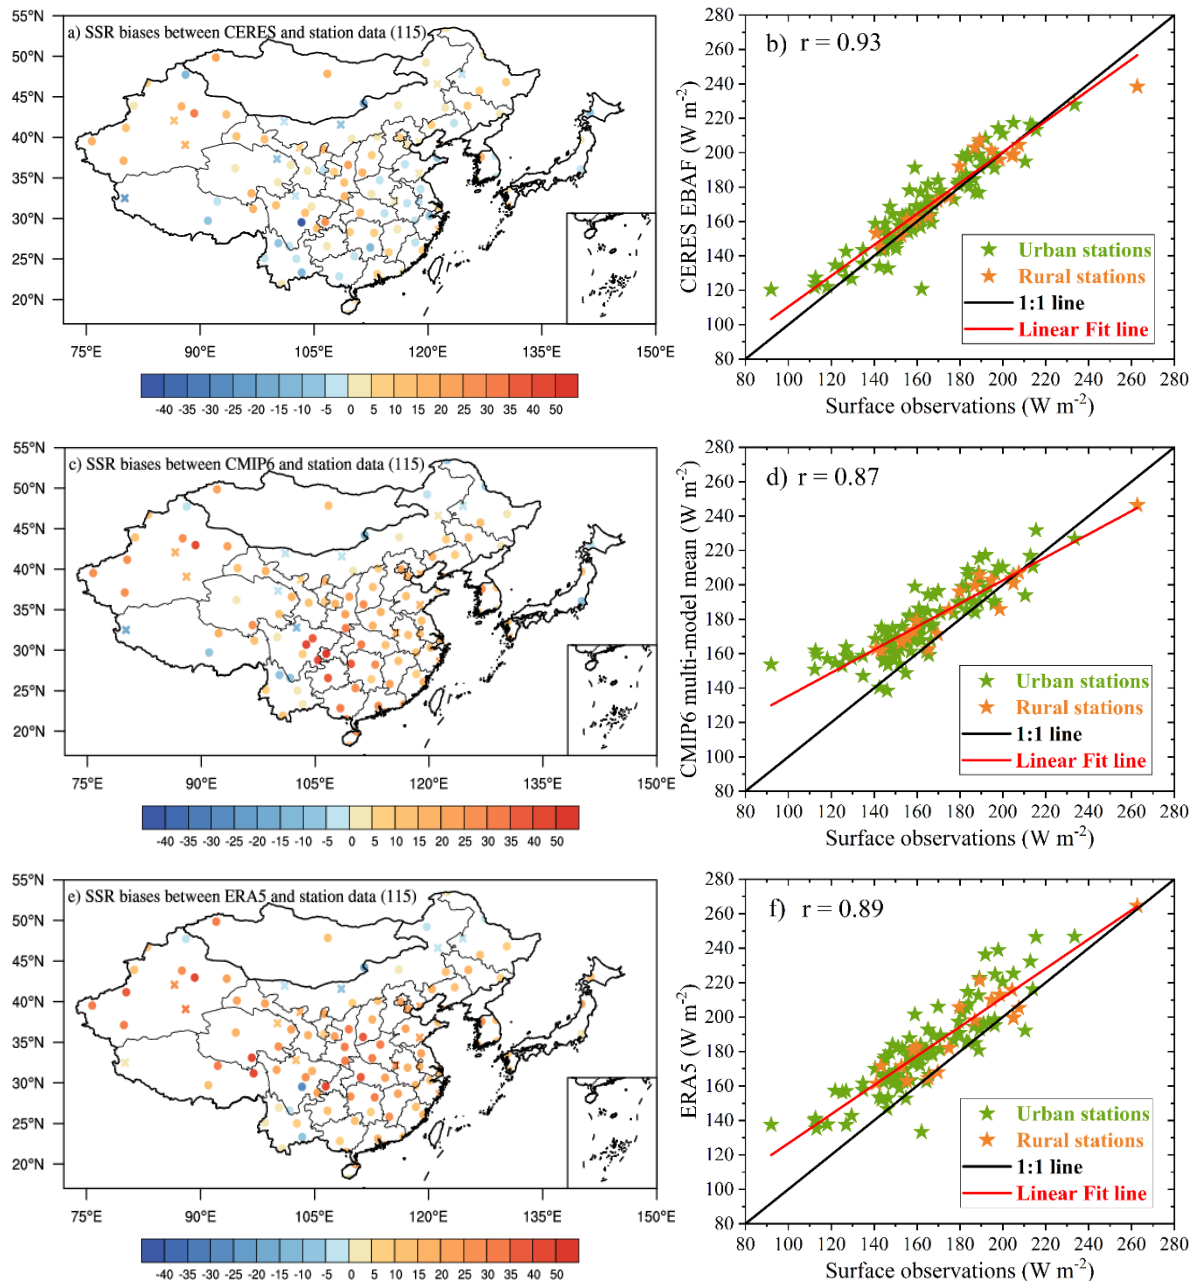

242 **Figure 3.** Spatial distributions of annual mean surface downward solar radiation (SSR) (Units: $W m^{-2}$) under
 243 (a) all-sky and (b) clear-sky conditions over East Asia. The all-sky sites are available from 99 CMA (China)
 244 and 16 GEBA (remaining regions outside China and one site in Hongkong, China) stations, while there are
 245 76 CMA and 16 CERES-interpolated sites for clear-sky conditions. The cross and circle symbols indicate
 246 rural (19 vs. 18 for all-sky and clear-sky conditions) and urban stations (96 vs. 74), respectively.

247

248 Figure 4 shows the distributions of annual mean SSR biases derived from the CERES, CMIP6 multi-
 249 model mean, and ERA5 against the surface observations, as well as the comparisons of their respective
 250 annual land means at the surface sites with their observed counterparts. The corresponding quantifications
 251 of the magnitudes of station-mean biases are also given in Table 2. According to the comparisons, they all
 252 correlate well with the ground-based observations, with their respective high correlation coefficients of 0.93,
 253 0.87, and 0.89, indicative of the highest accuracy in the CERES-derived estimate (Figs. 4b, d, and f). To
 254 quantify their SSR mean biases against the corresponding observed counterparts, the CERES-based bias at
 255 all sites is the smallest, with a station-mean bias of $3.8 W m^{-2}$, followed by the CMIP6 multi-model mean
 256 and the ERA5 reanalysis (with respective station-mean biases of 13.8 and $16.5 W m^{-2}$) (Table 2).
 257 Additionally, among all the aforementioned SSR estimates, the East Asian urban sites are in general more
 258 significantly overestimated than the rural sites on average compared to the surface observations (Figs. 4b, d,
 259 and f; Table 2). This further supports the argument that rural stations might be more representative for larger
 260 scale comparisons (e.g., the general circulation model grid scales) than the urban stations (which are
 261 vulnerable to local pollution) (Wang et al., 2018). The overestimations are mainly located in the high-latitude
 262 regions over East Asia for CERES-derived estimates (among them the underestimations mostly from rural
 263 sites), while the underestimates are primarily located in lower-latitude and eastern coastal regions (Figs. 4a
 264 and b). The CMIP6 multi-model mean and ERA5-derived SSR generally greatly overestimate the surface-
 265 based observations both at urban and rural sites, except for the regions over northern and northeastern Inner
 266 Mongolia, northwestern Heilongjiang (located in the northeastern China), and some individual sites over
 267 southwestern China (Figs. 4c-f). The annual land-mean area-weighted average SSR over East Asia derived

268 from CERES is estimated to be 178 W m^{-2} , which is closest to the surface observational estimate of 174 W m^{-2}
 269 m^{-2} , compared to the much higher overestimations of both the CMIP6 multi-model mean and ERA5 (186
 270 and 191 W m^{-2}) against the surface observations (Table 3), which shows a high consistency with their bias
 271 distributions and the collocated quantifications (Fig. 4; Table 2).

272

273

274 **Figure 4.** Spatial distributions of annual mean SSR biases (Units: W m^{-2}) derived from (a) CERES-EBAF,
 275 (c) CMIP6 multi-model mean, and (e) ERA5 reanalysis at a combination of the CMA and GEBA sites under
 276 all-sky conditions over East Asia. The corresponding comparisons of their respective annual means at the
 277 surface sites with their observed counterparts are displayed in (b), (d), and (f), respectively. The cross and
 278 circle symbols in Figs. a, c, e as well as the orange and green stars in Figs. b, d, f indicate rural and urban
 279 stations, respectively.

280

281 **Table 2.** Annual station-mean SSR biases (Units: $W m^{-2}$) derived from CERES-EBAF, CMIP6 multi-model
 282 mean, and ERA5 compared to the surface observational sites under all-sky and clear-sky conditions during
 283 2010-2014 over East Asian land, together with the separate station averages of biases at urban and rural sites.
 284 The values in parentheses represent the percentages of SSR biases relative to their respective station-mean
 285 averages with – (The largest percentages of SSR biases relative to their respective station-mean averages are
 286 estimated to be around 10% and 4% for all-sky and clear-sky conditions.

Station-mean SSR biases against surface sites (Units: $W m^{-2}$)	All-sky			Clear-sky		
	all	urban	rural	all	urban	rural
CERES-EBAF—surface sites	3.8	4.2	1.6	0.4	0.5	-0.3
CMIP6—surface sites	13.8	15.0	7.4	9.1	9.7	6.4
ERA5—surface sites	16.5	17.2	12.7	5.7	6.2	3.6

Station-mean SSR biases (Unit: $W m^{-2}$)	All-sky			Clear-sky		
	all	urban	rural	all	urban	rural
CERES-EBAF	3.8 (2.3%)	4.2 (2.6%)	1.7 (0.9%)	0.4 (0.2%)	0.5 (0.2%)	-0.3 (-0.1%)
CMIP6	13.8 (8.3%)	15 (9.2%)	7.4 (4.1%)	9.1 (4%)	9.7 (4.3%)	6.4 (2.8%)
ERA5	16.5 (10%)	17.2 (10.5%)	12.7 (7%)	5.7 (2.5%)	6.2 (2.7%)	3.6 (1.5%)

287

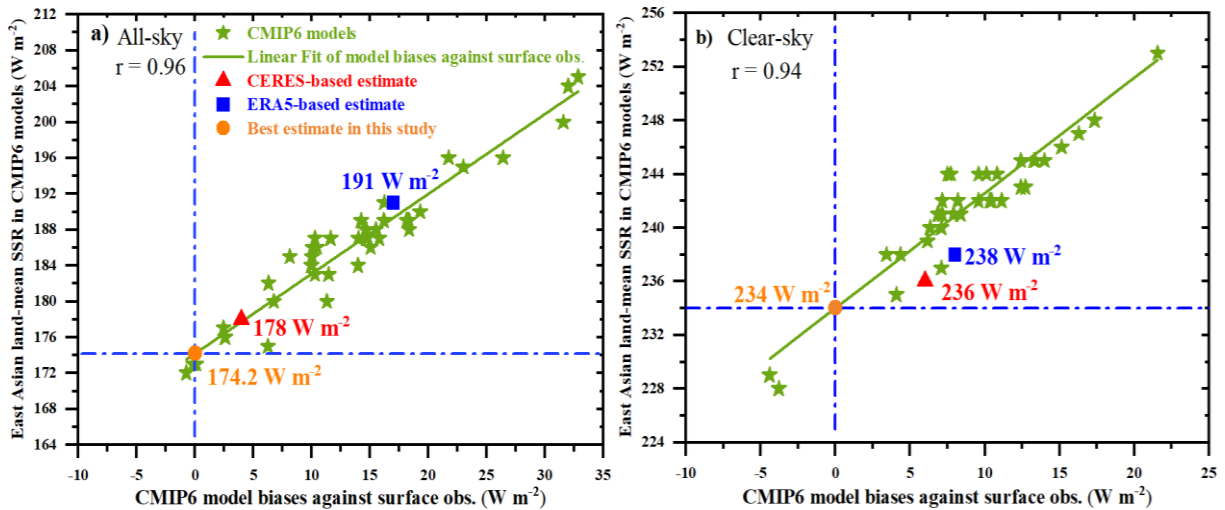

288 **Table 3.** Annual land mean area-weighted average SSR (Units: $W m^{-2}$) from a combination of the CMA and
 289 GEBA (CERES-interpolated) site observations under all-sky (clear-sky) conditions during the period 2010-
 290 2014 over East Asia, together with the corresponding estimates from the CERES-EBAF, CMIP6 multi-
 291 model means, and ERA5, respectively.

Average annual mean SSR during 2010-2014 over East Asia (Units: $W m^{-2}$)	Surface observations	CERES-EBAF	CMIP6	ERA5
All-sky	174	178	186	191
Clear-sky	230	236	242	238

292

293 However, the ground-based observations are spatially limited with sparse stations in some remote
 294 regions and are thus inadequate for many applications, as they may be not representative for real situations.
 295 To better constrain the large spread in the model-based SSR outlined above, we combine the ground-based
 296 observations to obtain the best estimate referring to the approach introduced in (Wild et al., 2013a). Figure
 297 5a gives various CMIP6 model biases of all-sky SSR at all the surface sites and their respective East Asian
 298 land means. The higher overestimations relative to surface observations generally correspond to higher
 299 model-based East Asian land means, with a much higher correlation coefficient of 0.96 than that of 0.88 on
 300 the global scale (Wild et al., 2015). Thus, the best estimate of the annual East Asian land-mean SSR is
 301 deduced to be $174.2 \pm 1.3 W m^{-2}$ (2σ uncertainty) in light of the linear regression analysis. The corresponding
 302 estimates from CERES and ERA5 are also labeled in the figure, at 178 and 191 $W m^{-2}$, respectively, implying
 303 a slight and substantial overestimation for CERES and ERA5 estimates. There is an overall tendency that
 304 most models overestimate the surface downward SW fluxes (36 out of 39 sites) compared to the ground-
 305 based observations, with a multi-model mean overestimation relative to site observations of $13.8 W m^{-2}$,
 306 which is also a longstanding issue in climate modelling (Wild et al., 1995; Wild et al., 2015).

307

308

309 **Figure 5.** Annual land mean SSR (Units: $W m^{-2}$) of various CMIP6 models as well as their respective model
 310 biases relative to an average over surface sites (99 CMA and 16 GEBA for all-sky; 76 CMA and 16 CERES-
 311 interpolated sites for clear-sky) under (a) all-sky and (b) clear-sky conditions during 2010-2014 over East
 312 Asia. Green stars represent various CMIP6 models. Best estimate here (orange circle) can be inferred from
 313 the intersection between the linear regression line (green solid lines) and the zero-bias line (blue dotted lines).
 314 Furthermore, the corresponding estimates from CERES-EBAF and ERA5 are also given by red triangle and
 315 blue square, respectively.

316

317 3.3. Longwave components

318 Similar to the all-sky SW counterparts, obvious discrepancies can still be noted in the annual land-mean
 319 LW radiation over East Asia among models, especially for those within the atmosphere and at the surface
 320 (Fig. 1c). Correspondingly, the simulated TOA OLR varies in a range of $12 W m^{-2}$, which is almost $10 W$
 321 m^{-2} lower than that within the atmosphere ($22 W m^{-2}$) and at the surface ($23 W m^{-2}$) (Table 1). The estimated
 322 annual East Asian land-mean TOA OLR from the CMIP6 multi-model mean is $-224 W m^{-2}$, within $2 W m^{-2}$
 323 of the deviations from the CERES- and ERA5-inferred estimates. The model spread of the simulated annual
 324 land-mean net LW radiation becomes larger from the TOA to the surface, with SDs of 3.5, 5.1, and $5.7 W$
 325 m^{-2} , respectively, which shows the same tendency as the relative (percentages) differences with respect to
 326 their multi-model means (5.4%, 14.5%, and 32.4%).

327 These large discrepancies in surface net LW radiation between models are particularly evident in the
 328 surface downward LW radiation (Fig. 2b; Table 1), with a range up to $27 W m^{-2}$ (from 267 to $294 W m^{-2}$)
 329 and a SD of $7.9 W m^{-2}$, which is also the largest deviation among all components under all-sky conditions.
 330 Compared to the CERES estimates, the slightly lower surface upward LW radiation (-352 vs. $-354 W m^{-2}$)
 331 and much lower surface downward LW radiation (280 vs. $285 W m^{-2}$) from the multi-model means are the
 332 major reason for the small deviation (within $2 W m^{-2}$) of the surface net LW radiation between them (Table
 333 1). It's interesting to note that the annual East Asian land-mean surface upward LW radiation estimated from
 334 the ERA5 is the lowest among all these estimates, at $-347 W m^{-2}$, suggesting the lowest surface skin
 335 temperature of the ERA5 product according to the Stefan-Boltzmann law, followed by the estimates from
 336 the multi-model mean and CERES (Table 1). In addition, the annual land-mean surface downward LW
 337 radiation estimated by ERA5 is $273 W m^{-2}$, approximately 7 and $12 W m^{-2}$ lower than the estimates by the

338 CMIP6 multi-model mean and CERES, respectively (Table 1). Therefore, both the lower surface upward
339 and downward LW radiation fluxes result in the small deviation in the estimated surface net LW radiation
340 from ERA5 compared to those from the multi-model mean and CERES (Table 1). Since the reanalysis
341 products take as many observed atmospheric parameters with global coverage as possible into consideration
342 during the radiative transfer calculations, they are widely used to obtain more accurate surface LW radiation
343 (Simmons et al., 2004; Wild et al., 2015). We also examined the corresponding surface LW fluxes from
344 another reanalysis, namely MERRA-2, and found much lower annual land means than those from ERA5, in
345 particular for the surface downward LW radiation (not shown), which arrives at the similar conclusions with
346 that documented by Urraca et al. (2018). Thus, considering the limited observational surface LW radiation
347 data over East Asia, ERA5 might be the best reference for the estimates of the annual land-mean surface
348 upward and downward LW radiation, at -347 and 273 W m^{-2} , respectively (Table 1).

349

350 3.4. Discussion of land energy balance over East Asia under all-sky conditions

351 3.4.1. Radiative components

352 Figure 6a displays the schematic diagram of the all-sky land mean energy balance over East Asia,
353 including the above-mentioned SW and LW radiation budgets and other radiative components discussed in
354 the following. The estimated annual East Asian land-mean incoming, reflected, and net SW radiation as well
355 as the OLR at the TOA are therefore 334 , -118 , 216 , and -226 W m^{-2} (Table 1), respectively, based on the
356 CERES EBAF dataset. The corresponding uncertainties are obtained from the uncertainty of 2.5 (1σ)
357 uncertainty) W m^{-2} for both SW and LW fluxes given by (Loeb et al., 2018). The annual East Asian land-
358 mean TOA OLR in CERES-EBAF is estimated to be 10 W m^{-2} larger than the TOA absorbed SW radiation,
359 implying an energy loss of 10 W m^{-2} at the TOA under all-sky conditions, which should be compensated by
360 the LH and SH transported from regions outside East Asia (Fig. 6a).

361

362

363

364 **Figure 6.** Diagrams of the annual land mean energy balance (Units: $W m^{-2}$) over East Asia under (a) all-
 365 sky and (b) clear-sky conditions for present-day climate. The uncertainty ranges are also given in
 366 parentheses.

367

368 For the SSR, the annual East Asian land-mean best estimate based on the CMIP6 multi-model
369 simulations and surface observations is 174.2 W m^{-2} (Fig. 5a and Fig. 6a). Considering the abnormally high
370 overestimation by ERA5 compared to surface observation, the high value of the uncertainty range is given
371 by the estimate from CERES EBAF (178 W m^{-2}), while its low value is from the lowest model estimate (172
372 W m^{-2} ; Fig. 2a) (Fig. 6a). The all-sky surface albedo information is derived from the ratio between the
373 CERES-derived surface upward and downward solar radiation, with a radiation weighted average of around
374 0.2 ($36.4/178.3$) over East Asian land. However, the corresponding surface albedos estimated by the CMIP6
375 multi-model mean and ERA5 are substantially higher than that from the CERES, with respective averages
376 of around 0.23 ($42.7/186.4$) and 0.26 ($49.6/191$). Considering the large spatial coverage of remote sensing
377 measurement to map albedo globally, the CERES-derived annual East Asian land-mean surface albedo is
378 adopted as the best estimate in this study. Therefore, considering the rounded best SSR estimate of 174 W
379 m^{-2} , the calculated surface reflected and absorbed SW radiation fluxes are around -35 and 139 W m^{-2} ,
380 respectively. As shown in Table 1, the uncertainty range of the surface absorbed SW radiation is 132 – 144
381 W m^{-2} according to the lowest value of CMIP6 models and the highest estimate among the aforementioned
382 estimates, which gives rise to an uncertainty range of the surface reflected solar radiation of 34 – 40 W m^{-2} .
383 Together with the annual East Asian land-mean SW absorption at the TOA and surface of 216 and 139 W
384 m^{-2} , the best estimate for the atmospheric SW absorption is therefore to be 77 W m^{-2} , which is within 4 W
385 m^{-2} of the differences between those estimated from the CMIP6 multi-model mean and CERES and closes
386 to the ERA5-derived estimate of 78 W m^{-2} (Table 1). The uncertainty range of the atmospheric SW
387 absorption is also determined by the estimates from different data sources as shown in Fig. 6a.

388 The downward LW radiation emitted by the atmosphere is mainly sensitive to the near-surface
389 temperature, water vapor, and cloud properties, while the surface emission is in proportion to the skin
390 temperature according to the Stefan-Boltzmann law. As analyzed in section 3.3, the best estimates of the
391 East Asian annual land-mean surface upward and downward LW radiation amount to -347 and 273 W m^{-2} ,
392 respectively, with uncertainty ranges coming also from the above-discussed different data sources (Fig. 6a).
393 The surface net LW radiation is then estimated to be -74 W m^{-2} based on the surface upward and downward
394 LW radiation outlined above. Combined with TOA outgoing thermal radiation of -226 W m^{-2} , the estimated
395 atmospheric net LW radiation is -152 W m^{-2} , which is close to the collocated estimates from the multi-model
396 mean (-152 W m^{-2}) and ERA5 (-150 W m^{-2}) but deviates substantially from the CERES-derived estimate of
397 -157 W m^{-2} (Table 1). Considering the surface absorbed SW radiation of 139 W m^{-2} , a best estimate for
398 surface net radiation is 65 W m^{-2} , suggesting that around 65 W m^{-2} of energy is available for the non-radiative
399 SH and LH. Besides, the ERA5 estimate of 67 W m^{-2} is very close to the best estimate of 65 W m^{-2} , while
400 much higher estimates of 72 and 73 W m^{-2} are obtained from the multi-model mean and CERES (Table 1),
401 respectively.

402

403 3.4.2. Nonradiative components

404 The surface net radiation is mainly balanced by the non-radiative components of SH and LH in addition
405 to a very small proportion of ground heat flux and melt (less than 1%) (Ohmura, 2004). However, due to the
406 lack of constraints from in-situ and space observations, this partitioning of the surface net radiation into SH
407 and LH is still subject to considerable uncertainties. As shown in Fig. S2, the simulated annual East Asian
408 land-mean LH and SH vary greatly between different models, with a range of 26 and 21 W m^{-2} , respectively,
409 as well as the relative discrepancies relative to their respective multi-model means of 60% ($\frac{26}{43} \times 100\%$) and
410 68% ($\frac{21}{31} \times 100\%$), respectively, showing larger discrepancies between models with larger uncertainties in SH
411 (Table 1). The best SH estimate can therefore be obtained from the residual of the LH. To obtain a more
412 accurate surface LH from available datasets of the multi-model mean and ERA5, we take an average of them
413 as the best estimate, namely -40 W m^{-2} , the uncertainty ranges of which are also given according to these
414 estimates (Fig. 6a). Note that all the values in this study are calculated on the basis of one decimal point,
415 which may result in 1 W m^{-2} of bias during the rounding process. Combined with the surface net radiation
416 and LH of 65 and -40 W m^{-2} , respectively, the surface SH is estimated to be -25 W m^{-2} , the uncertainty range
417 of which is also given by the existing estimates from various CMIP6 models and ERA5 (Fig. 6a). In addition,
418 although the annual land-mean SH estimated from the MERRA-2 is much higher than the estimates from
419 multi-model mean and ERA5 (not shown), the estimated LH is around -39 W m^{-2} (not shown), very close to
420 the best estimate of -40 W m^{-2} , which increases our confidence in the estimation of this quantity.

421

422 3.4.3. Comparisons with global annual land-mean estimates

423 Notable discrepancies exist in the global land-mean energy budgets reported by Wild et al. (2015) and
424 the regional land-mean estimates over East Asia in this study (Fig. S3; Table 4). For the SW budgets, the
425 estimated annual land-mean TOA incident solar radiation over East Asia is 9 W m^{-2} higher than that over
426 global land ($334 \text{ vs. } 325 \text{ W m}^{-2}$), implying a slightly lower land-mean solar zenith angle over East Asia.
427 Comparisons also show a slightly higher relative percentage of TOA reflected solar radiation of 0.8% despite
428 of the much lower surface reflected SW radiation of 4.3% over East Asian land compared to global land with
429 respect to their respective TOA incident solar radiation (thereafter call ‘relative percentage’ for short). This
430 suggests much more relative atmospheric SW reflection of 5.2% over East Asian land, which agrees fairly
431 well with more aerosols (Wei et al., 2019) and clouds (King et al., 2013; Fan et al., 2018; also see Fig. S4)
432 over this region compared to global land. However, the annual land-mean solar radiation reaching the East
433 Asian surface is around 10 W m^{-2} lower than that over global land ($174 \text{ vs. } 184 \text{ W m}^{-2}$), approximately
434 accounting for 52.1% and 56.6% of their respective incident solar radiation at the TOA, respectively,
435 indicating lower fraction of solar energy arriving at the East Asian surface compared to global land. Together
436 with the lower annual land-mean surface albedo over East Asian land compared to global land (20% vs.
437 26%), this leads to the similar relative percentages of surface absorptions (41.6% vs. 41.9%). Although the
438 magnitude of the atmospheric SW absorptions over East Asian and global land are nearly the same (both
439 around 77 W m^{-2}), the corresponding relative percentage over East Asian land is a little bit lower than that

440 over global land (around 0.6%). This is somewhat unexpected due to the fact of more clouds and aerosol
 441 loadings over East Asian land, which is possibly offset by the lower water vapor contents caused by the
 442 higher altitudes and thinner air over the TP.

443

444 **Table 4.** Comparisons of the annual mean SW/LW energy balance components (Units: $W m^{-2}$) over East
 445 Asian land (this study) and global land (Wild et al., 2015) as well as the corresponding relative percentages
 446 with regard to their respective TOA incident solar radiation/surface LW emissions, along with the relative
 447 percentage differences between them.

Component	East Asian land		Global land		Percentage difference
	Annual mean	Relative percentage	Annual mean	Relative percentage	
SW budget					
TOA solar down	334	1	325	1	—
TOA solar up	-118	35.3%	-112	34.5%	0.8%
Atmospheric SW absorption	77	23.1%	77	23.7%	-0.6%
Atmospheric SW reflection	-83	24.9%	-64	19.7%	5.2%
Surface solar down	174	52.1%	184	56.6%	-4.5%
Surface solar up	-35	10.5%	-48	14.8%	-4.3%
Surface solar absorption	139	41.6%	136	41.9%	-0.3%
LW budget					
TOA LW up	-226	65.1%	-232	62.4%	2.7%
Atmospheric LW absorption	-152	43.8%	-166	44.6%	-0.8%
surface LW down	273	78.7%	306	82.3%	-3.6%
Surface LW up	-347	1	-372	1	—

448

449 For the LW budgets, the regional surface LW emission over East Asia is estimated to be much lower
 450 than the global land-mean estimates in Wild et al. (2015) (Fig. S3), which mainly results from the lower
 451 temperature over the TP induced by high altitudes. The relative percentage of land mean surface downward
 452 LW radiation with respect to the surface emission over East Asia is about 78.7 %, which is lower than the
 453 global estimate of 82.3%, corresponding well to a reduction in greenhouse effect and fewer low clouds due
 454 to the TP (Fig. S4) considering its coverage over East Asian land. Ultimately, a higher percentage of LW
 455 radiation is emitted to space over East Asian land compared to global land (65.1% vs. 62.4%). Our estimates
 456 also indicate approximately similar amounts of LH (40 vs. 38 $W m^{-2}$) and much lower SH (25 vs. 32 $W m^{-2}$)
 457 over East Asia compared to the global land-mean estimates (Fig. S3), which is possibly related to the
 458 lower East Asian-land surface temperature.

459 In general, as can be concluded from Table 4, although much less surface SW radiation of 4.3% is
 460 reflected over East Asian land compared to global land, a slightly more SW reflection of 0.8% is estimated
 461 at the TOA, indicating much larger atmospheric SW reflection of 5.2% due to the stronger scattering from
 462 aerosols and clouds over East Asian land than global land. However, the SW absorption within the
 463 atmosphere over East Asian land is 0.6% lower than that over global land despite of the more absorption
 464 from clouds and aerosols, which is possibly offset by the lower water vapor contents caused by the thinner
 465 air over the TP. The lower surface temperature, weaker greenhouse effect and fewer low clouds due to the
 466 high altitudes and the thinner air over the TP in East Asian land are the major reasons for the relative lower

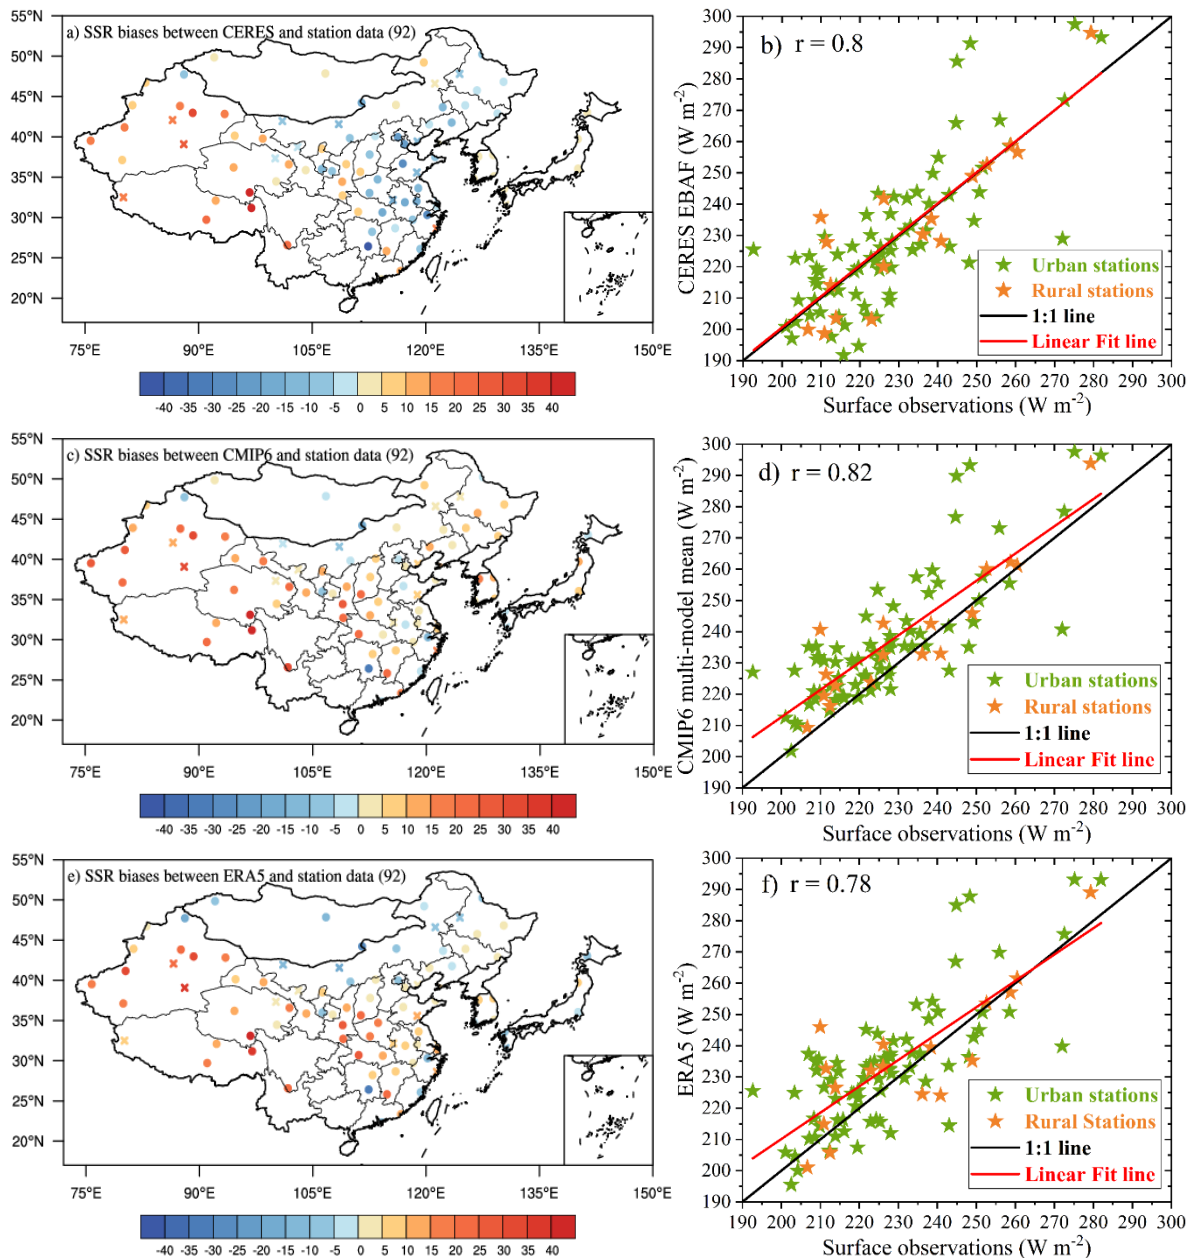

467 surface LW emission, less and more fractions of surface downward LW radiation of 3.6% and the OLR of
468 2.7% over East Asian land compared to global land, respectively.

469

470 **4. Assessment of land energy balance budgets under clear-sky conditions**

471 The clear-sky land energy balance budgets over East Asia are similarly evaluated as all-sky conditions.
472 Detailed analyses are given in Supplemental material if interested. The annual land-mean SW clear-sky
473 absorptions at the TOA and surface over East Asia show larger variations among different models than that
474 under all-sky conditions (Fig. 1a and b; Table 1), which is consistent with that reported by Wild et al. (2019)
475 but is amazingly in contrast to the recognition that the representation of clouds is the largest uncertainties in
476 climate models (Dolinar et al., 2015). Specially, the surface SW clear-sky absorptions simulated by various
477 models still exhibit a larger uncertainty than the TOA counterparts despite of the lower absolute values (Fig.
478 1b; Table 1). Contrary to the all-sky counterparts, the simulated clear-sky SSR among different models,
479 shows notably smaller inter-model spread and SD than the surface SW absorptions (Table 1), with much
480 smaller model discrepancy compared to the all-sky conditions (Fig. 2a; Table 1).

481 To further constrain the outlined inter-model discrepancy of the simulated clear-sky SSR, surface
482 observations from the CMA and CERES-interpolated estimates at the GEBA sites are utilized in this study.
483 The high values of the station-based clear-sky SSR are mainly located in the TP, but with an abnormally
484 high value located at the southern China (Fig. 3b). All the East Asian land-mean clear-sky SSR estimates
485 from CERES, CMIP6 multi-model mean, and ERA5 agree reasonably well with the surface observations,
486 but with smaller correlation coefficients ranging from 0.78 to 0.82 compared to the all-sky conditions (Figs.
487 7 b, d, and f). The CERES-derived clear-sky SSR is mainly overestimated in central and western China, but
488 with slight underestimations mainly located in northeastern, eastern, and southern China (Fig. 7a). Similar
489 bias patterns can also be found in the clear-sky SSR from the CMIP6 multi-model mean and ERA5 compared
490 to the surface observations, except for some individual sites over northeastern Inner Mongolia, eastern China,
491 western Mongolia, and Japan (Figs. 7c and e), but with relatively smaller overestimations than the all-sky
492 counterparts (Figs. 4c and e; Table 2). Specifically, the smallest station mean bias in CERES-derived SSR
493 compared to the multi-model mean and ERA5 (Table 2) can be attributed to its even distributed surface sites
494 of overestimations and underestimations (Figs. 7b, d, f). Again, among all the aforementioned clear-sky SSR
495 biases, more overestimations exist in urban stations than the rural stations (b, d, f in Figs. 4 and 7; Table 2).
496 Consequently, all East Asian land-mean area-weighted averages of clear-sky SSR from CERES, CMIP6
497 multi-model mean, and ERA5 show higher overestimations of around 6, 12, and 8 W m^{-2} , respectively,
498 compared to the surface observed counterpart of 230 W m^{-2} (Table 3). Based on the similar method
499 introduced in Wild et al. (2015), the best estimate for the East Asian land-mean clear-sky SSR is determined
500 to be $234 \pm 1.1 \text{ W m}^{-2}$ (2σ uncertainty), with a slightly smaller correlation coefficient of 0.94 and smaller
501 deviations from the CERES and ERA5 estimates compared to the all-sky counterparts (Fig. 5b; Table 3).
502 Besides, the overestimations still exist in the observed land-mean clear-sky SSR for most climate models
503 over East Asia, with a smaller multi-model mean overestimation of 9.1 W m^{-2} than the all-sky counterparts.

505

506 **Figure 7.** Spatial distributions of annual mean SSR biases derived from (a) CERES-EBAF, (b) CMIP6
 507 multi-model mean, and (c) ERA5 reanalysis against surface observations from a combination of the CMA
 508 and CERES-interpolated sites under clear-sky conditions over East Asia. The corresponding comparisons of
 509 their respective annual land means at the surface sites with their observed counterparts are displayed in (b),
 510 (d), and (f), respectively. The cross and circle symbols in Figs. a, c, e as well as the orange and green stars
 511 in Figs. b, d, f indicate rural and urban stations, respectively.

512

513 This clear-sky energy budget only represents the removal of cloud but maintains the same atmospheric
 514 conditions as the all-sky conditions, which is not balanced because it is not the equilibrium state the Earth
 515 would achieve when no clouds could form. Ultimately, the clear-sky East Asian land-mean energy budget is
 516 not closed and with no quantifications of SH and LH as displayed in Fig. 6b. In addition to the analyses
 517 above, the clear-sky TOA energy budgets are derived from CERES-derived product, with uncertainty ranges

518 referred to Loeb et al. (2018), while the surface LW budgets are again from ERA5 reanalysis. Also,
 519 additional clear-sky radiation weighted surface albedo of 0.19 from CERES is obtained to estimate the
 520 surface reflected and absorbed SW radiation. Apart from the TOA budget, all the rest uncertainty ranges
 521 are given by different data sources from various CMIP6 models, as well as the multi-model mean, CERES-,
 522 and ERA5-derived estimates, ~~except for their TOA counterparts.~~

523 We doublecheck the energy balance components evaluated in this study by referring to the uncertainty
 524 ranges from CERES-derived product given by Kato et al. (2018) (Table 5), which indicates that all estimated
 525 energy components fall within these uncertainty ranges, except for the all-sky surface downward LW
 526 radiation, with about 3 W m⁻² lower than the corresponding lowest CERES range. This is in line with its
 527 much higher CERES-derived estimate compared to that of the ERA5 (285 vs. 273 W m⁻²) (Table 1).

528

529 **Table 5.** Uncertainties (Units: W m⁻²) in 1°×1° regional monthly surface SW, LW, and net (SW + LW)
 530 fluxes under all-sky and clear-sky conditions for the CERES-EBAF Edition 4.1 product (referring to Kato
 531 et al. (2018)), as well as its corresponding estimates of various surface fluxes.

Uncertainties(1 σ)	All-sky	Clear-sky
SW down	178±14	236±6
SW up	36±11	45±11
SW net	142±13	191±13
LW down	285±9	256±8
LW up	354±15	353±15
LW net	69±17	97±17
SW + LW net	73±20	95±20

532

533 Overall, around 21.6% and 56.9% of the TOA incoming solar radiation are absorbed by the atmosphere
 534 and surface, respectively, for clear-sky conditions, while these absorptions are 23.1% and 41.6% for all-sky
 535 conditions. This implies that the existence of clouds results in more atmospheric SW absorption of around
 536 1.5% and much less surface solar absorption of around 15.3% with respect to the TOA incoming solar
 537 radiation.

538

539 5. The cloud radiative effects (CREs)

540 According to the annual land-mean best estimates of radiative components over East Asia under all-sky
 541 and clear-sky conditions obtained in previous sections, the present-day CREs can be inferred quantitatively
 542 over this region. The calculated SW, LW, and net CREs at the TOA, within the atmosphere, and at the
 543 surface are therefore presented in Fig. 8. Moreover, the corresponding calculation formulas are also given in
 544 the followings:

545

$$546 \text{ TOA SW CRE} = \text{TOA outgoing SW}_{\text{all-sky}} - \text{TOA outgoing SW}_{\text{clear-sky}}$$

547
$$\text{TOA LW CRE} = \text{TOA outgoing LW}_{\text{all-sky}} - \text{TOA outgoing LW}_{\text{clear-sky}}$$

548
$$\text{TOA Net CRE} = \text{TOA SW CRE} + \text{TOA LW CRE}$$

549

550
$$\text{Surface Net SW CRE} = \text{Surface Net SW}_{\text{all-sky}} - \text{Surface Net SW}_{\text{clear-sky}}$$

551
$$\text{Surface Net LW CRE} = \text{Surface Net LW}_{\text{all-sky}} - \text{Surface Net LW}_{\text{clear-sky}}$$

552
$$\text{Surface Net total CRE} = \text{Surface Net SW CRE} + \text{Surface Net LW CRE}$$

553

554
$$\text{Atmospheric SW CRE} = \text{TOA SW CRE} - \text{Surface Net SW CRE}$$

555
$$\text{Atmospheric LW CRE} = \text{TOA LW CRE} - \text{Surface Net LW CRE}$$

556

557

558 **Figure 8.** Diagram of the annual land mean SW, LW, and net (SW + LW) cloud radiative effects (CREs)
 559 (Units: W m^{-2}) at the TOA, within the atmosphere, and at the surface over East Asia, calculated by the
 560 differences between all-sky and clear-sky radiation budgets as given in Fig. 7.

561

562 Best estimates for the annual East Asian land-mean reflected solar radiation at the TOA under all-sky
 563 and clear-sky conditions are -118 and -72 W m^{-2} , respectively, differing by -46 W m^{-2} , indicating that the
 564 clouds give rise to an extra 46 W m^{-2} solar reflection at the TOA, thus cooling the Earth-atmosphere system.

565 Similarly, the TOA LW CRE, obtained as the difference between the TOA thermal radiation under all-sky
566 and clear-sky conditions, is 24 W m^{-2} , suggesting a warming effect of clouds on the system. Thus, the
567 estimated TOA net CRE is -22 W m^{-2} , pointing out that the overall effects of clouds result in an energy loss
568 and net cooling to the system, not only in the global mean, but also over East Asian land.

569 At the Earth's surface, the shading effects of clouds are estimated to reduce the surface solar radiation
570 by 60 W m^{-2} , from 234 to 174 W m^{-2} , while the surface solar absorption differs by 51 W m^{-2} , from 190 to
571 139 W m^{-2} , namely the surface net SW CRE is -51 W m^{-2} . On cloudy skies, the estimated surface downward
572 LW radiation increases from 253 to 273 W m^{-2} , with an increase of 20 W m^{-2} , illustrating that the surface
573 net LW CRE is 20 W m^{-2} and therefore leads to a surface warming. Thus, the surface net CRE, i.e., the sum
574 of the surface net SW and LW CRE, is then -31 W m^{-2} , indicating that clouds contribute more to the SW
575 energy budgets. Eventually, the clouds lead to the enhancement of the SW and LW absorption within the
576 atmosphere of around 5 and 4 W m^{-2} , respectively, thus resulting in an atmospheric net CRE of 9 W m^{-2} over
577 East Asian land.

578 The above CRE best estimates are compared ~~with~~ the corresponding estimates from different data
579 sources (Fig. 9; Table 1). Generally, compared to the LW CREs (Fig. 9b), the simulated SW CREs show
580 larger spreads and SDs amongst models (Fig. 9a; Table 1). For the SW CREs at the TOA, within the
581 atmosphere, and at the surface, the CERES-derived estimates match perfectly with the best estimates
582 mentioned above, within 2 W m^{-2} of the biases, followed by the estimates from the multi-model means and
583 ERA5 (Table 1). For the LW CREs, the calculated TOA LW CREs from the CMIP6 multi-model mean and
584 CERES differ by no more than 1 W m^{-2} compared to the best estimate, while large differences are noted at
585 the surface LW CREs, thereby leading to their opposite signs in the atmospheric LW CREs (Fig. 9b; Table
586 1). Specifically, since the ERA5-based TOA LW CRE deviates by no more than 3 W m^{-2} with the best
587 estimate of 24 W m^{-2} with nearly the same surface LW CRE, the estimated atmospheric LW CRE is therefore
588 the closest to the best estimate (Table 1). This is owing to the fact that we make use of the ERA5 data as the
589 reference to estimate the surface LW radiation. Thus, the major reason for the large discrepancies in the
590 atmospheric and surface LW CREs estimated from different data sources with respect to the best estimates
591 in this study is the determination of the surface downward and upward LW radiation, which is also the reason
592 for the large deviations in their net CREs (Fig. 9c).

593

594

595 **Figure 9.** Annual land mean anomalies of (a) SW, (b) LW, and (c) net (SW + LW) CRE_s (Units: W m⁻²) at
 596 the TOA (red line), within the atmosphere (blue line), and at the surface (green line) with regard to their
 597 respective multi-model means over East Asia, respectively, as represented by various CMIP6 models. The
 598 numbers in the parentheses indicate the available CMIP6 climate models for the corresponding radiation
 599 components.

600

601 A better comparison with the global annual mean best estimates of CREs by Wild et al. (2019) is given
 602 in Fig. S5. At the TOA, a slightly lower and much lower East Asian land-mean SW and LW CREs of 1 W
 603 m⁻² and 4 W m⁻² result in 3 W m⁻² more energy loss at the TOA compared to the globe. At the surface, much
 604 lower annual East Asian land-mean SW and LW CREs by 3 W m⁻² and 8 W m⁻² are estimated compared to
 605 the values over the globe, leading to a net CRE deviation of 5 W m⁻², indicative of 5 W m⁻² more energy loss
 606 at the surface. However, lower and higher annual East Asian land-mean SW and LW CREs of 2 and 4 W m⁻²
 607 within the atmosphere contribute to the nearly close net CRE with a deviation of no more than 2 W m⁻²
 608 compared to the global mean estimates. On the whole, lower annual East Asian land-mean best estimates in
 609 the absolute values of surface SW and LW CREs as well as the TOA LW CRE compared to their global
 610 mean counterparts give rise to the CRE differences between them.

611 **6. Summary and conclusions**

612 This study aims to explore how the energy budgets are interrupted by the complex orographic and
613 thermal effects of the TP, as well as the high anthropogenic aerosol emissions over East Asian land compared
614 to global land, based on complementary data sources from space and surface observations, as well as the
615 CMIP6 climate models and ERA5 reanalysis. A further quantitative investigation of CREs at the TOA,
616 within the atmosphere, and at the surface is also conducted.

617 Comparisons between all-sky and clear-sky energy budgets indicate that the overall effects of clouds
618 greatly reduce the surface solar absorption by about 15.3% and enhance that within the atmosphere by 1.5%.
619 Compared to the global land energy budget estimates from Wild et al. (2015), for the SW budgets, notably
620 more atmospheric SW reflection of 5.2% but with a slightly less atmospheric SW absorption of 0.6% with
621 respect to their respective TOA incident solar radiation are estimated over East Asian land, possibly
622 indicating that the lower water vapor content effects due to TP overcompensate for the aerosol and cloud
623 effects over East Asian land. For the LW budgets, a substantially lower surface LW emission of around 25
624 W m^{-2} and smaller relative surface downward LW radiation of around 3.6% with respect to their respective
625 surface emissions can be noticed over East Asian land compared to global land, which possibly result from
626 the lower regional surface skin temperature, as well as the weaker greenhouse effect and fewer low clouds
627 mainly induced by the high altitude and thinner air over TP, thus leading to a higher percentage of regional
628 OLR of 2.7%.

629 The CREs over East Asian land are inferred through the energy budget differences between all-sky and
630 clear-sky conditions. The clouds reduce the solar absorption at the TOA by 46 W m^{-2} and enhance the TOA
631 thermal radiation by 24 W m^{-2} , respectively, leading to a TOA net CRE of -22 W m^{-2} , a more cooling effect
632 on the regional climate system than that over globe (-19 W m^{-2}). At the surface, the net CRE is estimated to
633 be -31 W m^{-2} according to less solar absorption of 51 W m^{-2} and more downward thermal radiation of 20 W
634 m^{-2} , indicative of larger cloud impacts on SW radiation. Within the atmosphere, the estimated net CRE is 9
635 W m^{-2} due to an increase of 5 W m^{-2} of solar absorption and 4 W m^{-2} of the net thermal radiation, respectively.
636 Compared to the global mean best estimates of CREs as introduced by Wild et al. (2019), relatively lower
637 East Asian land-mean best estimates of surface SW and LW CREs as well as the TOA LW CRE contribute
638 to the CRE differences between them.

639 On the whole, all the estimated land-mean energy balance components over East Asia in this study fall
640 within the uncertainty ranges of the CERES-derived assessments, except for the all-sky surface downward
641 LW radiation. More accurate and reliable datasets should be utilized to reduce the substantial uncertainties
642 in the regional energy balance estimates, particularly in the surface budgets, and more widespread temporal
643 and spatial representations of energy budget research are recommended for more comprehensive
644 comparisons in future. For example, newly published surface radiation products with high resolutions based
645 on satellite datasets (e.g., Letu et al., 2022; Xu et al., 2022) are expected to make sense in improving the
646 accuracy of the regional/global surface radiation budget studies.
