## Abstract.

In both the Upper Green River Basin (UGRB) of Wyoming and the Uintah Basin of Utah, strong wintertime ozone (O<sub>3</sub>) formation episodes leading to O<sub>3</sub> concentrations ~~exceeding the 8-hour O<sub>3</sub> NAAQS (occasionally exceeding 70 ppb)~~ have been observed over the last two decades. Wintertime O<sub>3</sub> events in the UGRB were first observed in 2005 and since then have continued to be observed intermittently when meteorological conditions are favorable, despite significant efforts to reduce emissions. While O<sub>3</sub> formation has been successfully simulated using observed volatile organic compound (VOC) and nitrogen oxide (NO<sub>x</sub>) concentrations, successful simulation of these wintertime episodes using emission inventories in a 3-D photochemical model has remained elusive. An accurate 3-D photochemical model driven by an emission inventory is critical to understand the spatial extent of events and which emission sources have the most impact on O<sub>3</sub> formation. In the winter of 2016-2017 (December 2016 - March 2017) several high O<sub>3</sub> events were recorded with 1-hour concentrations exceeding 70 ppb. This study uses the Weather Research Forecasting model with chemistry (WRF-Chem) to simulate one of the high O<sub>3</sub> events observed in the UGRB during March of 2017. The WRF-Chem simulations were carried out using the 2014 edition of the Environmental Protection Agency National Emissions Inventory (EPA-NEI 2014v2), which, unlike previous versions, includes estimates of emissions from non-point oil and gas production sources. Simulations were carried out with two different chemical mechanisms: the Model for Ozone and Related Chemical Tracers (MOZART) and the Regional Atmospheric Chemistry Mechanism (RACM), and ~~the~~ results were compared with ~~the observed~~ data from 7 weather and air quality monitoring stations in the UGRB operated by Wyoming Department of Environmental Quality (WYDEQ). The simulated meteorology compared favorably to observations in terms of predicting temperature inversions ~~and,~~ surface temperature and wind speeds. Notably, because of snow cover present in the basin, the photolysis surface albedo ~~was modified in all simulations. Without this modification,~~ none of the simulations formed had to be modified to form O<sub>3</sub> exceeding 70 ppb, though the models were relatively insensitive to the exact photolysis albedo if it was over 0.65. ~~The MOZART simulation produced more O<sub>3</sub> in the basin than the RACM simulation and compares better with the observations. However, while O<sub>3</sub>-precursors NO<sub>x</sub> and NMHC are predicted similarly in simulations with both chemistry mechanisms, but simulated NMHC mixing ratios are a factor of six or more lower than the observations, while NO<sub>x</sub> mixing ratios are also underpredicted but are much closer to the observations within the region of oil and gas production. The results show that both the RACM and MOZART chemical mechanisms were able to produce O<sub>3</sub> even~~

~~though the NMHC mixing ratios in the model were a factor of six too low, an intriguing result for future studies. Sensitivity studies show that increasing VOC and NO<sub>x</sub> emissions to match observed mixing ratios had a relatively small effect on the ozone produced. However, further increases in NO<sub>x</sub> created much more ozone, suggesting ozone formation in the basin is very sensitive to NO<sub>x</sub> emissions.~~

## 1 Introduction

Tropospheric ozone ( $O_3$ ) is a secondary pollutant harmful to human health, plants, and other animals (Fuhrer et al., 1997; Ebi and McGregor, 2008) when at elevated levels (Fuhrer et al., 1997; Ebi and McGregor, 2008). The current 2015 US National Ambient Air Quality Standard (NAAQS) for the 8-h average  $O_3$  mixing ratio is 70 parts per billions (ppb) (EPA)<sup>1</sup>. As of August 14, 2020, the 2015 NAAQS standard for the 8-h average  $O_3$  mixing ratio has been proposed to be retained (EPA, 2020). Any hourly occurrence of  $O_3$  concentration greater or equal to the NAAQS standard is referred to as an  $O_3$  event throughout this paper. In the past decades, there has been a significant increase in wintertime as well as summertime  $O_3$  events in the western US (Cooper et al., 2012).

According to the US Energy Information Administration (EIA), in 2018, Wyoming was the 8th largest producer of oil and natural gas in the United States, with a majority of the natural gas production coming from the Upper Green River Basin (UGRB). Specifically, the UGRB accounts for 60% of the state's natural gas production and 16% of its oil production (Wyoming State Geological Survey; WSGS, 2020). As of 2017, there were 5506 total wells (5436 producing wells) in the Jonah and Pinedale fields that constitute the UGRB, a 5.7% increase in the total and 5.9% increase in the producing wells in the UGRB compared with those in 2016 (<http://pipeline.wyo.gov/FieldReportYear.cfm>). By September 2020, there had been 8.8% of increase in the total wells since 2017 and 14.6% increase in producing wells in the UGRB.

The formation of  $O_3$  has traditionally been an urban summertime phenomena because of the need for strong solar intensity and sufficient Volatile Organic Compound (VOC) (volatile organic compounds (VOCs)). Elevated concentrations of wintertime  $O_3$  in a few rural US basins have been associated with the rapid development of natural gas and oil production fields (Mansfield and Hall, 2013; Edwards et al., 2014; Ahmadov et al., 2015; Field et al., 2015a, b). Such elevated  $O_3$  events can occur in winter under specific meteorological conditions: a snow-covered ground that provides high albedo that increases solar intensity while also preventing solar heating of the ground (Carter and Seinfeld, 2012) and weak/calm winds. Combined, these conditions result in a persistent temperature inversion and little horizontal/vertical transport, which provides the conditions needed for the photochemical production and build up of  $O_3$  (Mansfield and Hall, 2018).

Several studies have been carried out to understand the meteorological and chemical processes leading to high wintertime  $O_3$  events in western US oil and gas basins. These studies have focused on observational measurements (Schnell et al., 2009; Oltmans et al., 2014b; Rappenglück et al., 2014; Field et al., 2015b; Lyman and Tran, 2015), aircraft measurements (Oltmans et al., 2014a), statistical models (Mansfield and Hall, 2013), box models (Carter and Seinfeld, 2012; Edwards et al., 2013, 2014), and 3-D photochemical models (Rodriguez et al., 2009; Ahmadov et al., 2015) (Rodriguez et al., 2009; Ahmadov et al., 2015; Matichuk et al., 2015). Most of these studies have been carried out in the UGRB and Utah's Uintah Basin (UB), and both basins have been identified as regions exceeding the NAAQS (Lyman and Tran, 2015). These studies have shown the principal role played by emissions from oil and natural gas production fields in the formation of wintertime  $O_3$ . However, the assessment of wintertime  $O_3$  formation in these regions poses serious challenges because each basin has complex topography and meteorological conditions along with poorly constrained precursor (VOC and nitrogen oxide ( $NO_x$ ) emissions) emission. One shortfall of all previous

---

<sup>1</sup><https://www.epa.gov/criteria-air-pollutants/naaqs-table>

studies is that most of them have not utilized an existing emission inventory to model O<sub>3</sub> formation. Rather, these studies have  
65 utilized observed atmospheric concentrations of precursors to model O<sub>3</sub> formation, thus making it difficult to assess how future  
expansion of production or various emission reductions will affect O<sub>3</sub> formation.

Schnell et al. (2009) summarized the confluence of three major factors for wintertime O<sub>3</sub> formation: (i) the extensive produc-  
tion of oil and natural gas that releases NO<sub>x</sub> and VOCs or hydrocarbons (HCs) into the atmosphere, (ii) calm wind conditions,  
and (iii) high albedo caused by snow accumulation at the surface that leads to a strong temperature inversion. A strong in-  
70 version traps O<sub>3</sub> and its precursors near the ground; if the inversion persists for several days, the concentrations of O<sub>3</sub> and its  
precursors increase. The high surface albedo also provides additional shortwave radiation for photochemistry compared to a  
dry landscape.

Some studies have specifically pointed out the importance of deep snow cover or high surface albedo in the formation of  
wintertime O<sub>3</sub>. Oltmans et al. (2014b) and Rappenglück et al. (2014) noted that in March 2011, the UGRB experienced high  
75 hourly O<sub>3</sub> concentrations exceeding 150 ppb, which was associated with the deepest snow cover of the season. In addition,  
Oltmans et al. (2014b) also pointed out that for the period with snow coverage on the ground, the sum of incoming and  
reflected ultraviolet levels ~~were~~was almost 80% higher than the period with no snow cover, addressing the impact of fresh snow  
accumulation during high O<sub>3</sub> events. Rappenglück et al. (2014) noted a significant increase in the background O<sub>3</sub> concentration  
from around 40 ppb in January to 60 ppb in March 2011, owing to the changes in the meteorological and chemical processes  
80 each month that change the pollutant concentration.

Numerous measurement studies have pointed out the important roles played by topography and both meteorological and  
chemical processes in the ~~basin~~UGRB, leading to different O<sub>3</sub> and precursor concentrations within each basin and from year to  
year. Field et al. (2015b) carried out air quality measurements in the UGRB for two consecutive winters (2011 and 2012) at a  
site located 5 km southeast of a Wyoming Department of Environmental Quality (WYDEQ) air quality and weather monitoring  
85 station (Boulder). They measured O<sub>3</sub>, reactive nitrogen compounds, methane (CH<sub>4</sub>), total non-methane hydrocarbon (NMHC),  
carbon monoxide (CO), and other standard meteorological parameters. The lower concentration of observed O<sub>3</sub> in 2012 were  
associated with lower NMHC concentrations, which was lower compared to 2011. Furthermore, Lyman and Tran (2015)  
measured O<sub>3</sub> and meteorological parameters at different location in the UB and observed a negative correlation between the  
O<sub>3</sub> concentration and station elevation. The stations at higher elevations showed very few O<sub>3</sub> exceedance events compared to  
90 those at lower elevation. As mentioned by Schnell et al. (2009),the prolonged inversion period traps O<sub>3</sub> near the basin floor  
due to low wind speeds and limited vertical transport, hence reducing O<sub>3</sub> concentrations at the higher elevations. Oltmans et al.  
(2014a) conducted 7 aircraft flights in the UB and found that the high O<sub>3</sub> concentrations were confined in the shallow inversion  
layer, namely 300-400 m above the ground.

Mansfield and Hall (2013) used a statistical model to accurately predict O<sub>3</sub> formation, but they ~~note~~noted challenges in ex-  
95 tending the findings from one basin to another, as factors such as the thermal inversion and snow cover that play an important  
role in wintertime O<sub>3</sub> formation vary among basins. They used quadratic regression models to predict the daily O<sub>3</sub> concentra-  
tions in the UB and UGRB ~~-They and~~ found that the high O<sub>3</sub> events in the UB and UGRB occurred in February and March,

respectively. However, the most intense inversion periods in both basins occurred in January. For both the UB and UGRB, they concluded that these high O<sub>3</sub> events were highly sensitive to the solar radiation, which intensifies as the year progresses.

100 Carter and Seinfeld (2012) used a box model to study NO<sub>x</sub>-limited and VOC-limited regimes in the UGRB. They found that the concentrations of NO, NO<sub>2</sub> and NMHC, and VOC/NO<sub>x</sub> ratios varied both spatially and temporally within the basin. Hence, they suggested that equal attention needs to be given to the geographical distribution of O<sub>3</sub> precursors and the local meteorology. Edwards et al. (2013) utilized the Dynamically Simple Model of Atmospheric Chemical Complexity (DSMACC), a photochemical box model with a very thorough chemical mechanism, to assess the sensitivity of NO<sub>x</sub> and VOC along with  
105 radical precursors<sup>1</sup> for O<sub>3</sub> production in the UB. Using this model, with input of observed O<sub>3</sub> precursors, they were able to accurately simulate relatively small amounts of O<sub>3</sub> formation in the absence of snow cover in 2013. Furthermore, Edwards et al. (2014) demonstrated that the same model could simulate large amounts of O<sub>3</sub> production in the UB when snow cover was present, and they emphasized the importance of carbonyl photolysis in the radical chemistry.

There have been a few studies that have utilized 3-D photochemical models to simulate high O<sub>3</sub> events in western US  
110 oil and gas basins, though to date there has not been a successful 3-D photochemical ~~modelling~~-modeling study that has simulated high wintertime O<sub>3</sub> in the UGRB. Rodriguez et al. (2009) applied the Comprehensive Air Quality Model with Extensions (CAMx) to assess the impacts of the development of oil and gas fields in the western US on the air quality of various parks and national wilderness areas in the inter-mountain west of the US for 2002. They concluded that the model captured the general trend in O<sub>3</sub> on a monthly scale; however, the model did not capture wintertime O<sub>3</sub> formation events occurring  
115 during strong inversions. Ahmadov et al. (2015) used the Weather Research Forecasting model coupled with Chemistry (WRF-Chem, version 3.5.1) to study wintertime O<sub>3</sub> pollution in the UB. To account for the emissions from the oil and gas sector, they employed two different emission scenarios. The first emission dataset was the US EPA National Emission Inventory 2011 version 1 (NEI2011; bottom-up) and the second emission dataset was derived from in situ aircraft and ground-based measurements (top-down). They reported an underestimation of hydrocarbons (CH<sub>4</sub> and other VOCs) and an overestimation  
120 of NO<sub>x</sub> emissions in the NEI2011 inventory compared to the top-down emission scenario. Ahmadov et al. (2015) found that the model simulation using the bottom-up NEI2011 inventory underestimated the high O<sub>3</sub> concentrations observed in the UB and that it was necessary to utilize observed concentrations of VOCs and NO<sub>x</sub> to successfully simulate observed O<sub>3</sub> mixing ratios. Additionally, Matichuk et al. (2017) used WRF and Community Multiscale Air Quality (CMAQ) model to study a 10-day high-ozone episode in 2013 in the UB. Similar to Ahmadov et al. (2015), they also used the NEI2011 emission dataset, but they found that the CMAQ model did not reproduce the observed O<sub>3</sub>, NO<sub>x</sub>, and VOC levels in the UB. Matichuk et al. (2017) identified a positive temperature bias and overestimation of the daytime planetary boundary layer height in the WRF simulations, which was hypothesized to be the reason for underestimation of O<sub>3</sub>, NO<sub>x</sub>, and VOCs from the CMAQ model.

As outlined above, wintertime O<sub>3</sub> production requires a thermal inversion as well as sufficiently deep snow (i.e., deep enough  
130 to cover most of the vegetation) over a larger area; hence, not all winters experience high O<sub>3</sub> concentrations. Additionally, reported emissions from oil and gas have been significantly reduced over the last decade WYDEQ (2018). In the winter of 2005

---

<sup>1</sup> Formaldehyde, nitrous acid and nitryl chloride

and 2006, the newly installed WYDEQ monitoring stations at Boulder, Daniel South, and Jonah observed multiple occurrences of high O<sub>3</sub> concentrations that exceeded the existing 1997 8-hour O<sub>3</sub> standard (84 ppb, WYDEQ, 2018). Since 2005, WYDEQ has operated regular annual O<sub>3</sub> monitoring in the UGRB, and several air quality and weather monitoring stations have been added in the basin. In recent years (most notably 2008, 2011, 2017, 2019, and 2020), elevated wintertime O<sub>3</sub> events have been observed in the UGRB, with hourly O<sub>3</sub> concentrations exceeding 70 ppb for several days in each year. The formation and occurrence of elevated wintertime O<sub>3</sub> concentrations is an unusual event compared to its urban summertime formation. In July 2012, the UGRB was declared as a marginal non-attainment area for O<sub>3</sub> by the US EPA (Rappenglück et al., 2014). In the winter of 2012, there were only 3 days in which the 8-hour averaged O<sub>3</sub> mixing ratios exceeded 75 ppb (NAAQS 2008), while in the winter of 2011, there were 7 days of exceedance (Field et al., 2015b) at a site located near the Boulder station. In March 2017, the Boulder station observed several hours of an hourly averaged O<sub>3</sub> concentration exceeding 70 ppb (NAAQS 2015).

Given the continued occurrence of high O<sub>3</sub> events in the UGRB, the lack of modeling studies aimed at understanding the formation of O<sub>3</sub>, and plans to continue development of the basin, it is important to develop a photochemical model capable of reproducing high O<sub>3</sub> events of the recent past in order to understand how events can be prevented in the future. The main goal in this study is to assess if a photochemical model (particularly WRF-Chem) operating with NEI emissions can simulate wintertime O<sub>3</sub> formation in the UGRB. Successful simulation of O<sub>3</sub> events would mean the model could then be utilized to assess effective emission control in preventing future O<sub>3</sub> events as well as the impact of future development on O<sub>3</sub> formation. This study primarily focuses on one of the elevated wintertime O<sub>3</sub> events in the winter of 2017; a 4-day period from Mar 3 to Mar 7, 2017, because 2017 was an active year for elevated O<sub>3</sub> in the UGRB (WYDEQ, 2018). The observed hourly O<sub>3</sub> mixing ratios during the period exceeded 70 ppb (NAAQS 2015) for several hours at several air quality monitoring stations in the UGRB. For our O<sub>3</sub> simulations, we have chosen to simulate the 2017 season because this was the most recent year with sustained periods of high O<sub>3</sub> when this project began in 2019. It is most useful to simulate O<sub>3</sub> events from recent years (versus modeling events in 2011) because basin-wide emission estimates from the State DEQ have decreased significantly over the last decade. ~~Successful simulation of an O<sub>3</sub> event in 2011 would not be terribly meaningful for assessment of the model's ability to simulate O<sub>3</sub> formation under current emission levels given emission levels with potential impacts on both ozone precursor concentrations and VOC:NOx ratios are estimated to have been significantly different in 2011, the only year in which vertical data are available (see below).~~ Also, we do not have emissions for oil and gas from 2011. In this paper, the results from WRF-Chem simulations for the given period are analyzed, aimed at understanding the production of O<sub>3</sub> in the UGRB.

## 2 Methods

This section describes the study area, model setup, datasets, methods, and preprocessing tools utilized in the WRF-Chem simulations and to validate the model results.

## 2.1 Study Region

The focus area of this study is the UGRB. The UGRB is a valley located in Sublette County in western Wyoming, with the Wyoming Range to its west, the Gros Ventre Range to its north, and the Wind River Range to its east. There are 7 weather and air quality monitoring stations operated by the WYDEQ in or near the UGRB: BP - Big Piney, B - Boulder, DS - Daniel South, JS - Juel Spring, M - Moxa Arch, P - Pinedale and SP - South Pass, whose exact locations are shown in the upper panel of Figure 1. In addition, the geographical information related to these stations is provided in Table 1. Five of the stations (BP, B, DS, JS, and P) are in close proximity to each other and lie in the basin where wind and pollutant transport can be affected by the mountains to the east, west, and north. Stations B and P lie in close proximity to the Pinedale Anticline and Jonah Field Developments (PAJF). The natural gas and oil development fields are located southwest of stations B and P, as shown in the bottom panel of Figure 1 (Toner et al., 2019). The other two stations (M and SP) lie further away from the basin. Station SP is located in the foothills of the Wind River Range and has the highest elevation, and station M is the southernmost and lowest in elevation and is located in close proximity to an interstate highway (I-80).

## 2.2 Model Setup

Simulations of O<sub>3</sub> formation in the UGRB were conducted using WRF-Chem (Skamarock et al., 2008) version 3.9.1. WRF-Chem is a fully coupled model, in which its atmospheric chemistry component is directly coupled to the meteorological component of the model (Grell et al., 2005). The meteorological and air quality components of the model use the same transport and physics schemes as well as the same vertical and horizontal grid structure. ~~The baseline~~ This is beneficial over models such as CAMx and CMAQ where the meteorological and the atmospheric chemistry components are run separately. Ahmadov et al. (2015) also pointed out the benefit of WRF-Chem, which helped in the proper simulation of pollutant accumulation in shallow inversion layers.. The model configuration with the physical and chemical parameterizations used for the study is shown in Table 2. Figure 1 shows the model domain and terrain height, which is centered on the UGRB. The model domain is represented by a grid of 200 x 200 x 60 points with a horizontal grid spacing of 4 km; vertical grids extend up to 100 hPa, with 60-m grid spacing near the surface and 250-m grid spacing at the top of the model.

## 2.3 Datasets

The National Centers for Environmental Prediction (NCEP) North American Regional Reanalysis (NARR) (Mesinger et al., 2006) was used for the initial and boundary meteorological conditions for the simulations in this study. The data are available on a Lambert conformal conical grid with a grid spacing of approximately 0.3 degrees (32 km). The 3-hourly fields with 29 vertical pressure levels from 1000 to 100 hPa were used in this study to initialize and provide the lateral boundary conditions for the WRF-Chem simulations to study O<sub>3</sub> formation.

The NEI data were used for emissions in the the WRF-Chem simulations. The data for natural gas and oil sources were obtained from the US EPA NEI-2014 dataset (version 2, hereafter; NEI2014v2) released in February 2018 (US-EPA, 2018). The NEI2014v2 data were the latest emission inventory available at the time of the initiation of this study and is available

at a 12-km horizontal resolution. This particular version of the emission dataset incorporates the processes associated with the exploration, drilling, and production of oil, gas, and coal-bed CH<sub>4</sub> wells in the UGRB. The EPA emission estimates are the most widely used and easily available estimate that include most potential emission sources that could impact air quality. However, previous comparisons by Alvarez et al. (2018); Robertson et al. (2020) have pointed out underestimations of CH<sub>4</sub> emissions for the oil and gas extraction basins in EPA estimates compared to their observations. To account for the transport of chemical species into the model domain, data from the Community Atmosphere Model with Chemistry (CAM-CHEM; Emmons et al. (2020)) were used in the simulations.

The observed meteorological and air quality data from the aforementioned 7 weather and air quality monitoring stations were obtained from the WYDEQ website. The data are available in 5-minute and hourly formats. The hourly data were used for this study for a direct comparison of meteorological parameters, such as temperature and wind speed, and chemical species, such as O<sub>3</sub>, NO<sub>x</sub>, CH<sub>4</sub>, and NMHC, with the simulated results. The NHMC data were only available at the Boulder station as this was the only station equipped to report these results.

## 2.4 Preprocessing

~~The EPA anthro\_emiss tool provided by the Atmospheric Chemistry Observations & Modeling (ACOM) division at the National Center for Atmospheric Research (NCAR) was used for preprocessing the emissions in this study. This tool creates anthropogenic emission files from the NEI datasets for lat/lon grids that can be ingested into the WRF model. The MOZART and RACM chemistry mechanisms use different species grouping; hence, the emission inventory files were processed separately for each mechanism. Mozbe, which is also provided by ACOM, was also used in this study. The mozbe tool maps the species from the Community Atmosphere Model with Chemistry (CAM-Chem) global dataset to WRF fields that can easily be ingested into WRF-Chem as initial and boundary conditions.~~

~~For MOZ17, two other WRF-Chem utilities were also used: exo\_coldens and wesely. The exo\_coldens utility helps read O<sub>3</sub> and O<sub>2</sub> climatological atmospheric column values rather than using fixed values, and this is coupled to an updated photolysis option (photo\_opt=4). For dry deposition in MOZART, an additional file is required that allows for seasonal changes in dry deposition. The additional information is provided using the wesely utility. Both the exo\_coldens and wesely utilities read the WRF input files as well as emission files for the MOZART chemistry mechanism to produce additional data files that can be read by the WRF-Chem model.~~

~~The NEI2014v2 dataset provides emissions covering the model domain, but the advection of chemical species into the domain through the lateral boundaries must also be considered. The WRF-Chem simulations in this study used the NEI2014v2 emission data re-gridded to the WRF-Chem domain. The initial and boundary conditions of the simulations were updated every 24 hours for each simulations using the CAM-Chem data (Emmons et al., 2020).~~

## 2.4 WRF-Chem simulations

The O<sub>3</sub> formation simulations focus on a 4-day period from Mar 3 to Mar 7, 2017. For all simulations, the model physics and photolysis surface albedos were modified to account for the effect of snow on photolysis in the model. The default photolysis

albedo in the model is 0.15 because the model was primarily developed for summertime photochemistry. The default photolysis albedo is much lower than what is commonly observed during winter when the surface is covered with snow. Under the default albedo of 0.15, the simulations drastically underestimated O<sub>3</sub> formation (as shown in the results below). This study is intended to study *wintertime* photochemistry of O<sub>3</sub>. We thus require a higher albedo to represent a snow-covered surface. Hence, in an effort to simulate a range of potential surface conditions, multiple albedo sensitivity simulations were carried out. A similar study using WRF-Chem with RACM chemistry was carried out by Ahmadov et al. (2015) in the UB, Utah, where they set the surface albedo to 0.85 in their simulations of wintertime O<sub>3</sub> production. As noted by Mansfield and Hall (2013), for the wintertime O<sub>3</sub> formation, factors such as thermal inversion and snow cover play an important role and they vary among the basins. Hence the findings and characteristics of wintertime O<sub>3</sub> formation cannot be extended from one basin to another. Specially, surface albedos of 0.55, 0.65, 0.75, 0.85 and 0.95 were used for the sensitivity study and fixed to 0.85 in the model for further analysis based previous estimates of snow albedo in the region (Ahmadov et al., 2015) and sufficient O<sub>3</sub> formation in the UGRB using 0.85 surface albedo.

In this study, two different chemistry mechanisms are used: (i) the Model for Ozone and Related Tracers (MOZART) and (ii) the Regional Atmospheric Chemistry Mechanism (RACM). The MOZART chemistry mechanism has been widely used model to study O<sub>3</sub> formation and transport around the world (Hauglustaine et al., 1998; Murazaki and Hess, 2006; Beig and Singh, 2007; Yarragunta et al., 2019). In the UB, RACM has been successfully used to simulate O<sub>3</sub> production due to oil and natural gas production in winter when observed levels of VOCs and NO<sub>x</sub> were inputs (Ahmadov et al., 2015). Based on the findings from Ahmadov et al. (2015), the important point noted by Mansfield and Hall (2013), and the MOZART and RACM mechanisms being widely used chemical mechanisms to study O<sub>3</sub> both globally and regionally, the simulations were carried out with these two chemical mechanisms to understand which chemical mechanism provided the best comparison with observed O<sub>3</sub> and its precursors in the UGRB. ~~Hereafter, the simulation using MOZART chemistry will be referred to as MOZI7 and that with RACM chemistry as RACM17 based on the chemistry mechanism used and the year of the study period.~~ The WRF-Chem namelist options used for ~~MOZI7 and RACM17~~ MOZART and RACM are provided in the supplemental section A2 of this paper in Figures A2 and A3, respectively. Despite all the same namelist options used in these models, the simulations with MOZART use photolysis option 4, which is the updated TUV photolysis option that was setup to work with only few chemistry mechanism schemes in WRF-Chem v3.9.1. While the RACM simulations use photolysis option 1, which is the Madronich photolysis scheme. With the current setup for photolysis option 4 in the WRF-Chem v3.9.1 it does not work with RACM chemistry mechanism. This study uses photolysis option 4 for MOZART simulation as it produces higher O<sub>3</sub> compared to when photolysis option 1 was used (Figure not shown).

Additionally, some key points that were considered to achieve the goals of this study and needed to reproduce the results are as follows: (i) sufficient surface albedo to represent the effect of snow cover and depth on the meteorological conditions, (ii) correct photolysis albedo to represent the wintertime conditions for the chemical mechanisms to reproduce sufficient O<sub>3</sub>, and (iii) NEI data as well as CAM-CHEM global emissions data processed separately for each chemical mechanisms, as different mechanisms lump chemical species differently and are also driven by different chemical reactions. ▬

## 2.5 Preprocessing

The EPA anthro emiss tool provided by the Atmospheric Chemistry Observations & Modeling<sup>2</sup> (ACOM) division at the National Center for Atmospheric Research (NCAR) was used for preprocessing the emissions in this study. This tool creates anthropogenic emission files from the NEI datasets for lat/lon grids that can be ingested into the WRF model. The MOZART and RACM chemistry mechanisms use different species grouping; hence, the emission inventory files were processed separately for each mechanism. Mozbc, which is also provided by ACOM, was also used in this study. The mozbc tool maps the species from the Community Atmosphere Model with Chemistry (CAM-CHEM) global dataset to WRF fields that can easily be ingested into WRF-Chem as initial and boundary conditions.

For simulations using the MOZART chemical mechanism, two other WRF-Chem utilities were also used: `exo_coldens` and `wesely`. The `exo_coldens` utility helps read  $O_3$  and  $O_2$  climatological atmospheric column values rather than using fixed values, and this is coupled to an updated photolysis option (`photo_opt=4`). For dry deposition in MOZART, an additional file is required that allows for seasonal changes in dry deposition. The additional information is provided using the `wesely` utility. Both the `exo_coldens` and `wesely` utilities read the WRF input files as well as emission files for the MOZART chemistry mechanism to produce additional data files that can be read by the WRF-Chem model.

The NEI2014v2 dataset provides emissions covering the model domain, but the advection of chemical species into the domain through the lateral boundaries must also be considered. The WRF-Chem simulations in this study used the NEI2014v2 emission data re-gridded to the WRF-Chem domain. The initial and boundary conditions of the simulations were updated every 24 hours for each simulations using the CAM-CHEM data.

## 2.6 Temperature Inversion Analysis and Surface Meteorology

To study the ability of the model to replicate observed meteorological conditions in the UGRB, we study the temperature inversion, weak winds, and surface temperature. The temperature inversion was studied using the WRF model (without chemistry) for 2011 with the same ~~meteorological setup, while for weak winds and surface temperature model configuration, while the surface meteorology in the~~ WRF-Chem simulations for 2017 were utilized, ~~owing~~. ~~The reason for the discrepancy is due~~ to differences in data availability between the different periods. For model validation, the simulation results were compared with vertical profiles of temperature and  $O_3$  from ozonesonde data collected during two intensive operational period (IOPs) in 2011. The temperature inversion was studied to validate the ability of WRF model meteorology to simulate inversions in the basin. The data from year 2011 was utilized ~~since because~~ the WYDEQ Air Quality Department (AQD) conducted two IOPs in winter 2011 (MSI, 2011, Feb 28 to Mar 2 and Mar 9 to Mar 12). This is the only year for which vertically resolved meteorological data were available from radiosondes. The observed vertical data for the temperature inversion was also obtained from the WYDEQ website. The IOP events were identified based on the conditions (deep snow and large spatial coverage in the study area, development of an inversion, and calm surface winds) that support elevated  $O_3$  concentrations. During each IOP period, 3-4 ozonesondes were launched adjacent to the Boulder station (see Fig. 1) each day, providing vertical profiles of  $O_3$  mixing

<sup>2</sup><https://www2.acom.ucar.edu/wrf-chem/wrf-chem-tools-community>

ratio, temperature, and wind speed. The WRF simulation was carried out for the entire winter of 2011 (Dec 1 2010 to Mar 31 2011), which includes both IOP periods and the high O<sub>3</sub> events of the winter of 2011. We understand that the ability of the model to simulate one event (i.e., the vertical structure for a few days in 2011) does not indicate that it will perform accurately again. However, with the lack of data, we are forced to either not examine the vertical structure at all or instead find an analog that can provide some level of confidence in the model's ability to replicate the vertical structure of the lower troposphere during high-O<sub>3</sub> events. We chose the later and proceeded with the no chemistry simulations for the IOPs in 2011. The simulation will hereafter referred to as IOP11.

## 300 2.7 VOC and NO<sub>x</sub> Sensitivity Study

WYDEQ carried out a winter O<sub>3</sub> study from February to March 2017, coinciding with the high O<sub>3</sub> event that is the focus of this study. On several days during this study speciated VOC canisters were collected between 04:00 to 07:00 MST at Boulder, Big Piney, Juel Spring, and Moxa Arch (MSI, 2017). This study uses the speciated VOC data from Boulder on Mar 3 2017 to compare with the model data. The observed values from the canister and models are shown in Table 5. Three different simulations for each chemistry mechanism were carried out to study the effect of adjusted NO<sub>x</sub> and VOC emissions. The precursors' emissions were adjusted in each simulation based on the factors shown in Table 5. The factors for each VOC species are kept the same in each simulation, while the factors for NO and NO<sub>2</sub> are adjusted for each case. The emissions factors for VOC in Table 5 is calculated by dividing the observed value (canister) by the model-simulated value for the same time period. However, because NO<sub>x</sub> data is available for the entire study period, factors for NO and NO<sub>2</sub> are calculated taking into account the entire study period (Mar 3 to Mar 7 2017), with additional sensitivity simulations performed to 1) constrain NO and NO<sub>2</sub> to the observations and 2) test the sensitivity of O<sub>3</sub> production to NO<sub>x</sub> levels. The time series of NO and NO<sub>2</sub> at Boulder is shown in the supplemental section Figure B3. In the second simulation the factors for VOCs are kept as it is while the factors for NO and NO<sub>2</sub> are reduced to half and in the third simulation the factors for NO and NO<sub>2</sub> are doubled keeping the factors for VOC the same. Dry deposition of gaseous species is turned off in all simulations for the sensitivity study.

315 The adjustments for certain VOC species that are lumped in the model chemistry requires slightly more explanation. For alkanes, the concentration of all observed alkane species larger than propane (butane up to undecane) were summed, and then this sum was used to adjust the lumped model species (bigalk for MOZART and HC5 for RACM). In RACM, the species TOL is a combination of toluene and a fraction (0.293) of benzene. Accordingly, a fraction of the observed benzene was added to the observed toluene to adjust this variable. Also, in RACM, the species HC3 is a combination of methanol, ethanol, and a fraction (0.519) propane. The DEQ observations do not include methanol or ethanol, meaning only the observed propane mixing ratio was used to modify this variable. Finally, in both models the lumped xylene parameter includes trimethylbenzene. Accordingly, the observed concentrations of xylene and trimethylbenzenes were added to create the emission factor for xylene.

### 3 Results and Discussion

325 To simulate O<sub>3</sub> formation in the UGRB, we first validated the WRF model's performance in simulating the observed vertical temperature profile and surface meteorology during strong inversions. After determining that WRF was able to reasonably reproduce the meteorological conditions necessary for O<sub>3</sub> formation, we studied O<sub>3</sub> formation with the WRF-Chem model using two different chemical mechanisms.

#### 3.1 Validation of WRF Model Meteorology

##### 330 3.1.1 Temperature Inversion

Owing to the importance of thermal inversions for the build up of O<sub>3</sub> in wintertime events, we first explored the ability of the model to simulate temperature inversions within the selected modeling framework. Vertical profiles of the observed temperature and O<sub>3</sub> mixing ratio during the most recent ~~intensive operating periods (IOP)~~ IOP (Feb 28 to Mar 2 and Mar 9 to Mar 12 2011) were compared with the simulated vertical temperature profiles from simulations with WRF during the same time period  
335 (IOP11, Figure 2). Although 7 days were identified as the IOP period, the results from only 4 days are discussed due to ozonesonde data availability. Because these ~~runs~~ simulations were completed to compare meteorology and not chemistry, the WRF model without chemistry was used, and simulated O<sub>3</sub> is not available. We did not aim to simulate O<sub>3</sub> events from 2011 because emissions have changed dramatically since 2011 and there is not a good inventory that includes oil and gas sources for that period. Observed O<sub>3</sub> is presented only to demonstrate how O<sub>3</sub> formation follows the inversion events.

340 A shallow mixing height can be seen in each profile. The residual layer above the ground appears to be well mixed early in the simulation; hence, we can see fairly uniform O<sub>3</sub> concentrations in the vertical. High concentrations of O<sub>3</sub> were observed on Mar 1-2, 2011. On these days, a strong inversion is observed with a shallow mixing height of around 500 m agl, which prevents vertical mixing thus leading to a build up of O<sub>3</sub> precursors that then lead to high concentrations of O<sub>3</sub> that increase in the afternoon MSI (2011). On Mar 2, 2011 (third row), higher morning O<sub>3</sub> was observed compared to the previous day,  
345 presumably due to the persistent inversion, which is validated by the observation of high hydrocarbon concentrations in the afternoon of Mar 2 (MSI, 2011).

For the days discussed here, the simulated temperature is 2 to 4 °C warmer than the observed temperature, except for Mar 9, 2011 (Figure 2, last row), where it is 2 to 5 °C colder than the observed temperature near the surface. During the morning hours, the simulated temperatures follow the observed temperatures fairly well; however, the simulated inversion height is slightly  
350 elevated. In both the observations and the model, the inversion height increases through the day and the inversion strength (difference in maximum vs. surface temperature) decreases. However, the model seems to increase the inversion height slightly too much while also decreasing the strength of the inversion. Overall the model simulation of the inversion events was deemed adequate to proceed.

### 3.1.2 Surface Meteorology

355 Given the model's ability to relatively accurately represent temperature inversions, at least based on our comparison with  
available data from 2011, we further assess the model's ability to predict surface meteorology focusing on the target period  
of high O<sub>3</sub> in March 2017. It is important to highlight again that vertical data are not available for the selected time period.  
We utilize observations from the high O<sub>3</sub> events of 2017 because the seven ground stations measure basic meteorological  
parameters. It is crucial for the photochemical model to simulate low temperatures and calm winds to be able to replicate high  
360 O<sub>3</sub> concentrations (Schnell et al., 2009).

The observed 2-m temperature data for Pinedale were unavailable, hence the temperature correlation for only six stations  
are shown in Figure 3. Both simulations show good correlation with the observed temperatures, and the correlation coefficients  
do not show any sensitivity to the different chemistry mechanisms at the [Boulder, Moxa Arch, and South Pass](#) [Juel Spring  
and Moxa Arch](#) stations. However, [RACM17-RACM](#) shows higher correlation coefficients compared to [MOZ17-MOZART](#) at  
365 other stations. Although the difference in the correlation coefficients for the different chemistry mechanism is small, it is likely  
due to radiation feedbacks between the chemistry and meteorology in these mechanisms and internal model variability (Bassett  
et al., 2020). Furthermore, the temperature bias between the observed and simulated datasets is below 3 °C at all stations (Table  
3), and all of the data points lie in close proximity to the one-to-one lines. Overall, the simulations show good correlation with  
the observed 2-m temperatures.

370 As mentioned earlier, calm wind speeds are an essential meteorological condition for the photochemical production of win-  
tertime O<sub>3</sub> because they are necessary for the accumulation of O<sub>3</sub> precursors. The correlation between observed and simulated  
wind speeds is shown in Figure 4. The correlation coefficients are calculated for each data point (hourly) for the entire study  
period, although only wind speeds from 0 to 10 m s<sup>-1</sup> are shown given the focus of the study is calm periods. For all stations  
except South Pass, a majority of the data points are clustered below or around 4 m s<sup>-1</sup>, which means that for the majority of  
375 the time, both the observed and simulated wind speeds are less than or equal to 4 m s<sup>-1</sup>. The differences in the correlation  
coefficient between different simulations are due to internal model variability of the model (Bassett et al., 2020). Therefore, the  
relatively low correlation coefficients may be the result of small variations of low wind speeds. To test this idea and to verify  
that calm periods were successfully simulated when they occurred, Table 4 shows the percentage of the times the simulated  
and observed wind speeds are less than or equal to different thresholds (3, 4 and 5 m s<sup>-1</sup>). For example, at [Big Piney Boulder](#),  
380 both the simulated wind speed from [MOZ17-MOZART](#) and the observed wind speed are less than or equal to 3 m s<sup>-1</sup> for  
[91.8998.33%](#) of the hourly periods analyzed, while for [RACM17-RACM](#) this figure is [90.6790.77%](#). Again, the chosen thresh-  
olds are based on the interest in studying calm wind speed in the basin, which enable pollutant accumulation near the surface.  
Therefore, even though the correlation coefficients between the modeled and observed winds are relatively low, we conclude  
from the results in Table 4 that WRF with either chemistry mechanism is able to successfully predict low winds the large  
385 majority of the time they occur. [An analysis of the diurnal variability of winds showed good qualitative agreement between the  
model and observations in terms of the timing of increasing and decreasing wind speeds each day \(Figure not shown\).](#)

### 3.2 ~~Control Baseline~~ Simulation and O<sub>3</sub> Production

Given the aforementioned ability of the model to ~~accurately~~ adequately simulate the key meteorological conditions needed for O<sub>3</sub> production and accumulation, we now turn to the chemical mechanisms and their ability to produce the observed hourly periods with high O<sub>3</sub>. At first O<sub>3</sub> formation was simulated in the UGRB using the MOZART chemistry mechanism and it was noted that the modeled concentrations were dramatically below observed O<sub>3</sub>. However, the default WRF-Chem model has a low photolysis albedo (0.15) as it was intended to simulate summertime O<sub>3</sub>, which does not typically occur over high-albedo surfaces. We modified the photolysis albedo in the model based on Ahmadov et al. (2015), who noted that in the UB, it was necessary to increase the photolysis albedo to simulate O<sub>3</sub> production. In an effort to understand the sensitivity of O<sub>3</sub> formation to the photolysis albedo in the WRF-Chem model, we performed a sensitivity test. As described in the methods section, we carried out several albedo sensitivity simulations with various albedo settings ranging from 0.55 to 0.95 (spanning albedos representative of partially snow-covered vegetation to fresh, deep snow) and compared the results to the results with the default albedo of 0.15. All of the albedo sensitivity tests used the ~~MOZART~~ RACM chemical mechanism. Figure 5 compares the default albedo (0.15) with different photolysis albedo settings (0.65 and 0.85). It is evident that the default photolysis albedo produces much lower O<sub>3</sub> concentrations at all stations. However, when the model is altered to use an albedo of 0.85, the diurnal variation and high O<sub>3</sub> peaks are captured relatively well. ~~Additionally, results from different albedo settings (0.55, 0.65, 0.75, 0.85 and 0.95) are shown in the supplemental section of the paper (Figure ??) although there is some variability from station to station.~~ For the remainder of the simulations in this paper, a photolysis albedo of 0.85 is used, which is the same albedo used by Ahmadov et al. (2015) in the UB.

Setting a fixed photolysis albedo of 0.85, we next compared simulations using two different chemistry mechanisms available in WRF-Chem: MOZART and RACM. Figure 6 compares the time series of simulated hourly O<sub>3</sub> concentrations from ~~three different simulations MOZI17, RACM17, and RACM~~ four different simulations with dry deposition ~~turned on for all gas-phase species at the seven~~ of gas species included and not included in both MOZART and RACM simulations at several UGRB monitoring stations. ~~MOZART chemistry adjusts the dry deposition rates over snow surfaces (owing to the use of wesely pre-processing tool that adjust the season change in dry deposition), where the loss is expected to be greatly reduced. On the contrary, RACM does not adjust the dry deposition rate over such surfaces, hence the additional simulation with deposition turned off to mimic the very slow deposition of gas-phase species over a snow-covered surface (i.e., RACM17).~~ The hourly averaged observed background daily O<sub>3</sub> mixing ratio is approximately 55 ppb at all stations. During the afternoon hours, most of the stations have hourly O<sub>3</sub> mixing ratios greater than 70 ppb, ~~the 8-hour NAAQS~~. The observed O<sub>3</sub> concentrations are highest at the Boulder site, which is likely because it lies in close proximity to the PAJF production facilities and is thus closer to the main sources of VOC precursors than the other sites. For Moxa Arch and South Pass, the observed O<sub>3</sub> concentrations are lower because they do not lie in close proximity to the wells and also lie further from the basin.

~~The RACM simulation with the default dry~~ It is important to note that one difference between the MOZART and RACM simulations used in this study is the photolysis option (phot\_opt = 4 for MOZART and phot\_opt = 1 for RACM), which could affect O<sub>3</sub> deposition of gas-phase species does not produce sufficient production. As RACM is not coupled to phot\_opt = 4,

an addition sensitivity simulation was performed using option 1 with MOZART, which led to less O<sub>3</sub> to replicate the observed compared with using option 4, albeit with better agreement with the observations. As such, we elected to use phot\_opt = 4 for subsequent simulations but note that some of the difference between RACM and MOZART may be attributed to the photolysis scheme used with the former leading to less O<sub>3</sub> concentrations (Figure 6; purple lines)-production.

425 To better understand the chemistry mechanism's mechanisms' sensitivity to dry deposition, we compare the diurnal variation of O<sub>3</sub> concentrations from the simulation with the default dry deposition in RACM to the RACM17 simulation, where dry deposition is turned off (Figure 6; red lines) at the MOZART and RACM with dry deposition turned on and off in both simulations at the 7 monitoring stations. Although, the O<sub>3</sub> concentrations from the MOZ17 simulation are still higher than in RACM17, turning off the monitoring stations. The RACM simulation with dry deposition in RACM results in significantly  
430 higher O<sub>3</sub> of gas-phase species (RACM\_ddOn) does not produce sufficient O<sub>3</sub> to replicate the observed O<sub>3</sub> concentrations than when dry deposition is allowed. The O<sub>3</sub> concentrations in MOZ17 dissipate more slowly at night compared to RACM17. The higher concentrations of observed concentrations (Figure 6; orange lines). However, when dry deposition of gas species is included in MOZART (MOZ\_ddOn; Figure 6; purple lines), the simulation performs better compared to RACM\_ddOn. In MOZART, when dry deposition is turned on, adjusts the deposition rate over snow surfaces (owing to the use of the wesely  
435 pre-processing tool that adjust the season change in dry deposition), where the loss is expected to be greatly reduced. On the contrary, RACM does not adjust the dry deposition rate over such surfaces, hence the simulation with dry deposition turned off to mimic the very slow deposition of gas-phase species over a snow-covered surface (i.e., RACM\_ddOff). Despite this markable differences in the results from the simulations when the dry deposition of gas species is included, when dry deposition is turned off, both MOZART (MOZ\_ddOff; Figure 6; blue lines) and RACM (RACM\_ddOff; Figure 6; red lines)  
440 produces similar concentrations of O<sub>3</sub> are well captured in the MOZ17 simulation. At.

Focusing on individual sites, at Big Piney and Daniel South, which are located on the eastern side of the Wyoming range, both all four simulations overestimate the first O<sub>3</sub> event (Mar 03 2017 at 15:00 locals local time). The MOZ17 simulation captures the Moreover, the MOZ\_ddOff and RACM\_ddOff simulations capture the diurnal cycle of O<sub>3</sub> reasonably well at Boulder, while they overestimate the high O<sub>3</sub> event at Pinedale on Mar 03 2017, 17:00 local time, which is well captured  
445 by MOZ\_ddOn. However, the simulations miss the higher O<sub>3</sub> concentrations at Juel Spring. Overall, both the MOZ17 and RACM17 MOZ\_ddOff and RACM\_ddOn simulations do reasonably well at simulating the O<sub>3</sub> mixing ratios in the UGRB for the selected study period and capturing the diurnal variation of the O<sub>3</sub> concentration, a first for a photochemical model using an existing emissions inventory, although it is important to remember that this was only possible after adjusting the photolysis albedo in the model and, in the case of RACM, turning of dry deposition of gas-phase species. Due to their better performance  
450 in estimating observed O<sub>3</sub> the results from MOZ\_ddOff and RACM\_ddOff simulations will be discussed in the following analyses and the simulations will be referred to as MOZ17 and RACM17 respectively.

To better understand the differences in the simulated and observed O<sub>3</sub> concentrations, we next looked at the precursor (NO<sub>x</sub>) concentrations. Figure 7 shows the time series of hourly NO<sub>x</sub> at the 7 monitoring stations along with results from MOZ17 and RACM17. The observed hourly mixing ratios of NO<sub>x</sub> at Big Piney, Boulder and Pinedale are higher than the other  
455 stations. These three stations are all near small towns in the region with Pinedale being the largest of the towns and Pinedale

having notably higher  $\text{NO}_X$  than the others. The  $\text{NO}_X$  mixing ratio is primarily affected by its emission rate in the region. At Pinedale, the higher observed concentrations are most likely due to the fact that the station is near the city of Pinedale where there are sources of  $\text{NO}_X$  that are not related to oil and gas, most notably residential wood burning. However, residential wood burning is not well represented in the emission inventory; thus, the model is expected to underestimate  $\text{NO}_X$  from this source.

460 The elevated observed  $\text{NO}_X$  concentrations compare well with the observed  $\text{PM}_{2.5}$  concentrations at Pinedale (Figure B2), which supports that wood burning is a strong  $\text{NO}_X$  source in these areas. The simulated concentrations of  $\text{NO}_X$  ~~do not show any sensitivity seems less sensitive~~ to the different chemical mechanisms, emphasizing that the emissions dominate concentrations, not chemical loss mechanisms. The ~~lower~~- $\text{NO}_X$  mixing ratios are ~~well captured at stations such as Boulder, Juel Spring and Moxa Areh underestimated by both simulations~~ even during the high  $\text{O}_3$  events. ~~The simulations overestimate the~~ Although the simulated  $\text{NO}_X$  concentrations at Daniel South ~~, although the  $\text{NO}_X$  observations at this station are missing about half the time is higher compared to other stations, the observed data are missing~~. The observed and simulated  $\text{NO}_X$  concentrations at South Pass are low and show little variability, emphasizing that this station is ~~removed~~ further from the oil and gas production region. Overall, the simulations underestimate the observed  $\text{NO}_X$  concentrations to varying degrees depending on the location and do not capture the diurnal cycle well. ~~However, the simulated  $\text{NO}_X$  concentrations are relatively close to the observations at the stations with high  $\text{O}_3$  events other than at Pinedale where  $\text{NO}_X$  concentrations are consistently low. The  $\text{NO}_X$  concentrations are very similar between the RACM and MOZART chemical mechanisms.~~

465 simulated  $\text{NO}_X$  concentrations at Daniel South ~~, although the  $\text{NO}_X$  observations at this station are missing about half the time is higher compared to other stations, the observed data are missing~~. The observed and simulated  $\text{NO}_X$  concentrations at South Pass are low and show little variability, emphasizing that this station is ~~removed~~ further from the oil and gas production region. Overall, the simulations underestimate the observed  $\text{NO}_X$  concentrations to varying degrees depending on the location and do not capture the diurnal cycle well. ~~However, the simulated  $\text{NO}_X$  concentrations are relatively close to the observations at the stations with high  $\text{O}_3$  events other than at Pinedale where  $\text{NO}_X$  concentrations are consistently low. The  $\text{NO}_X$  concentrations are very similar between the RACM and MOZART chemical mechanisms.~~

470 ~~are very similar between the RACM and MOZART chemical mechanisms.~~

The top panel in Figure 8 compares the simulated NMHC concentrations (plotted on the left; primary  $y$ -axis) and observed NMHC concentrations at the Boulder station (plotted on the secondary  $y$ -axis). The Boulder station is the only monitoring site in the basin that measures either NMHC or  $\text{CH}_4$ . In addition, the MOZART<sup>3</sup> and RACM<sup>4</sup> chemical mechanisms lump

475 the VOC species differently. The bottom panel of Figure 8 shows the observed  $\text{O}_3$  concentrations at the Boulder station during the same time period showing that the accumulation of NMHC leads to the production of  $\text{O}_3$ . The magnitudes of the simulated NMHC concentrations are lower by a factor of approximately 6 compared the observation. Both RACM17 and MOZ17 give very similar NMHC mixing ratios. In fact, the chemical production of  $\text{O}_3$  does not remove a large amount of the NMHC present. When it was discovered that the model simulated VOC mixing ratios were dramatically different from the

480 observations at the Boulder site, we employed University of Wyoming mobile laboratory data to confirm that the Boulder site does not record anomalously high mixing ratios relative to the surrounding area that would all be within the same grid-cell in the model (as the station sits in a small valley). The mobile lab does not measure NMHC, but both the mobile lab and the

Boulder station measure CH<sub>4</sub>, enabling us to see if CH<sub>4</sub> measurements made by the lab in the region surrounding the Boulder site were significantly different than those reported by the site. Hence, we analyzed the CH<sub>4</sub> concentrations (a proxy for VOC concentrations) collected by the mobile lab during an O<sub>3</sub> event in 2020, the closest year to our study period for which data are available. The WYDEQ Boulder site data were within 25% of the data collected by the mobile lab near the monitoring site (Figure A1). This observation indicates that the difference between simulated and observed NMHC is not the result of anomalously high mixing ratios at the Boulder site, but concluded that the NMHC mixing ratio measured at the Boulder site is an accurate representation in the region. Although the overall temporal trend in the NMHC mixing ratio is well captured by the simulations, both MOZ17 and RACM17 dramatically underpredict the NMHC mixing ratios.

It is very intriguing that both chemical mechanisms are able to reasonably replicate the O<sub>3</sub> concentrations at the monitoring sites despite the fact that NMHC concentrations in the model are approximately 6 times lower than those observed at the Boulder monitoring site. The mobile lab results strongly suggest that this discrepancy is not due to non-representative measurements at the Boulder monitoring site. This leaves the possibilities that the simulated NMHC are much more reactive than the actual NMHC, that some other feature of the chemistry is too active in the model, and/or that the UGRB will continue to experience high O<sub>3</sub> events even at much lower NMHC levels, or finally that the models are extremely sensitive to the exact because ozone production is predominantly determined by NO<sub>x</sub> levels. ~~The last seems improbable given the relatively good simulations of NO<sub>x</sub> mixing ratios at some sites. Investigation of the other possibilities is an area that needs future study, but is beyond the scope of this paper. It is availability.~~ In terms of the possibility that the chemistry in the model is too active, it is important to note that the RACM17 chemistry successfully simulated O<sub>3</sub> events in the UB when observed NO<sub>x</sub> and speciated VOCs were input (Ahmadov et al., 2015). The sensitivity to adjustments in speciated VOC and NO<sub>x</sub> emission is discussed later in the manuscript in Section 4.

The spatial variation in the formation and dissipation of O<sub>3</sub> and its precursors for the high O<sub>3</sub> event on Mar 4, 2017, is shown in Figures 9, 10, and 11 for O<sub>3</sub>, NO<sub>x</sub>, and VOCs, respectively, from the MOZ17 simulation, and similarly, Figures 12, 13, and 14 show the results from RACM17. In both simulations, the formation and build up of O<sub>3</sub> is seen around noon local time (Figure 9c and Figure 12c), In the late afternoon (at 16:00 local time) the O<sub>3</sub> concentration reaches its maximum ~~110 of 124~~ ppb in MOZ17 (Figure 9d) and ~~95-138~~ ppb in RACM17 (Figure 12d). ~~The 0~~ Although higher O<sub>3</sub> concentration concentrations are found locally in RACM17 ~~dissipates~~, these dissipate rather quickly compared to MOZ17, demonstrating that there are subtle differences in the chemical mechanisms. For both simulations, the highest O<sub>3</sub> concentration is seen closer to the Big Piney, Boulder, Daniel South and Pinedale stations, though none of the stations are simulated to ~~observe~~ have the highest concentrations. If compared closely with the well locations in Figure 1, the highest O<sub>3</sub> concentrations overlap the location of the wells. The simulations show a similar temporal trend in O<sub>3</sub> formation, which can also be seen in Figure 6, although the highest concentrations differ by approximately ~~30-10~~ ppb. The O<sub>3</sub> mixing ratios at Juel Spring, Moxa Arch, and South Pass are comparatively lower. The wind speeds are also stronger (> 5 ms<sup>-1</sup>) around these stations (Figure 9d and 12d). Particularly, around South Pass, the wind speeds are around 15 ms<sup>-1</sup>. With the lack of mountains surrounding these stations and comparatively higher wind speeds, pollutant concentrations can be easily diluted and dissipated.

To better understand the formation, accumulation, and dissipation of O<sub>3</sub> precursors, i.e., NO<sub>x</sub> and VOCs, the diurnal and spatial variations are shown for both simulations (Figures 10, 11, 13 and 14). The simulations suggest that, as expected, most NO<sub>x</sub> sources are in the production region for oil and gas, though the Pinedale results show that the inventory is missing some anthropogenic sources of NO<sub>x</sub>, especially residential wood burning. The high concentrations of NO<sub>x</sub> along the bottom of the figures are due to Interstate 80-I-80 and not oil and gas infrastructure. Both chemical mechanisms show a similar trend in NO<sub>x</sub> with the build up of NO<sub>x</sub> concentrations in the morning at 08:00 local time (Figures 10b and 13b) the higher concentrations at noon local time (Figures 10c and 13c), a few hours before the higher concentrations of O<sub>3</sub> are simulated, and the lower pollutant concentration at 16:00 local time (Figures 10d and 13d) when the O<sub>3</sub> concentrations are the highest. It is important to note that the simulations capture the lower underestimates the NO<sub>x</sub> concentrations reasonably well and the simulated NO<sub>x</sub> concentrations do not vary largely among the simulations using different chemical mechanisms. Similar to the diurnal NO<sub>x</sub> profile, the diurnal profile of VOCs from both simulations (Figures 11 and 14) also shows a similar trend in the distribution of VOCs in the basin, with higher VOC concentrations occurring a few hours before the higher O<sub>3</sub> concentrations are simulated. Overall the simulations capture the diurnal variation of the O<sub>3</sub> and its precursors reasonably well, however, the simulated concentrations of the precursors are lower compared to the respective observations.

#### 4 VOC and NO<sub>x</sub> Sensitivity Analysis

The results from the baseline simulations using both the MOZART and RACM chemistry mechanisms show that despite the low NO<sub>x</sub> and VOC concentrations found in the model using the NEI2014v2 emissions, both models produce O<sub>3</sub> enhancements during the observed ozone episodes. To understand the potential sensitivity of O<sub>3</sub> formation in the UGRB to VOC and NO<sub>x</sub> levels, additional simulations were performed by comparing the baseline simulation results to observed VOC and NO<sub>x</sub> levels, adjusting the emissions by the ratio between modeled and observed values, and rerunning the model, as outlined in Section 2.7. The factors used to adjust the emissions are displayed in Table 5. Of note is that data from the Boulder station during the entire model run period was used to adjust NO<sub>x</sub> concentrations because continuous NO<sub>x</sub> data is available while VOC data is only available during the collection period described in Section 2.7. It is clear from Table 5 that significant enhancements are required for all VOC species, but especially large adjustments had to be made to the aromatic species. This result indicates that not only are the modeled VOC emissions too small, but that the resulting mixture has less aromatic species than what is observed, making the modeled VOC significantly less reactive than the observed VOC mixture.

Figure 15 compares the time series of O<sub>3</sub> concentration at seven monitoring stations among different NO<sub>x</sub> sensitivity simulations. All simulations were done with the same amount of VOC, which was increased to match observations according to Table 5. The model run with NO<sub>x</sub> and VOC increased to observed levels does increase ozone formation, but perhaps by less than would have been anticipated given the dramatic increases in VOC. In fact, these runs do an excellent job of replicating the ozone observed at the Boulder site in the RACM model while moderately overpredicting ozone formation with the MOZART chemistry. Doubling the NO<sub>x</sub> causes a large jump in the ozone predicted at all sites by both the RACM and MOZART chemistry schemes, while cutting the NO<sub>x</sub> in half reduces ozone formation at all sites. These model runs strongly suggest

550 that ozone formation in the basin is predominantly limited by the NO<sub>x</sub> available rather than being controlled mainly by VOC concentrations. The runs suggest that if more NO<sub>x</sub> was available the basin might see higher levels of ozone than currently observed.

## 5 Conclusions

Over the past decade, there have been a number of elevated wintertime O<sub>3</sub> events in the UGRB, WY, with concentrations often exceeding 70 ppb ~~and occasionally exceeding the 8-hour NAAQS~~. Ozone events, though much less severe than ~~previously observed a decade ago~~, have continued despite significant efforts to reduce emissions from oil and gas production. This fact drives the need for a photochemical model to better understand what is happening and to determine what emission reductions might effectively reduce ozone. This study, to the best of the authors' knowledge, is the first to utilize the EPA-NEI2014v2 emissions inventory with a fully coupled meteorology and chemistry model (WRF-Chem) to simulate O<sub>3</sub> events in the UGRB. The utilization of NEI2014v2 is key because this is the first NEI version to integrate non-point oil and gas sources, which are a dominant driver of the ozone formation in the UGRB. Additionally, this study compared the results of two different chemistry mechanisms (MOZART and RACM), focusing on their ability to replicate the concentrations of O<sub>3</sub>. Neither chemistry mechanism can reproduce these high O<sub>3</sub> events without modifying the default surface albedo of the base model. Furthermore, the dry deposition of gas species in RACM ~~was needed to be~~ modified to better represent slower losses to snow surfaces for this chemistry to create similar amounts of ozone to the MOZART model, which accounts for dry deposition changes with snow cover. When dry deposition is turned off in both chemistry schemes, they produce similar amounts of ozone.

~~For our analysis, we focused on a several-day period in 2017 in which the O<sub>3</sub> concentrations exceeded 70 ppb repeatedly (Mar 3 to Mar 7, 2017). The WRF-Chem simulations were compared with the observations from 7 weather and air quality monitoring stations operated by WYDEQ and located in the basin.~~

570 The ~~model meteorology was first validated using the vertical profile performance of the model meteorology in the vertical was validated using vertical profiles~~ of observed temperature during two IOP periods from a earlier study (Feb 28 to Mar 2 and Mar 9 to Mar 12 2011). Vertical data is only available from this time period. Although the simulated temperature is 2 to 4 °C warmer than the observed temperature, the simulation captured the inversion layer near the surface. ~~Furthermore, to~~ To validate the the model's ability to predict the surface meteorology, 2-m temperature and wind speed from two WRF-Chem simulations (MOZ17 and RACM17) were compared with the observations at 7 weather stations during the 2017 period. The simulated 2-m temperature showed a good correlation with ~~the observation observations~~ at all stations. The simulated periods of low wind speeds also showed good agreement with the observed calm winds, though variability in the exact magnitude of the low winds results in relatively poor correlation coefficients.

To study the model's ability to replicate high O<sub>3</sub> events, we analyzed concentrations of O<sub>3</sub> and its precursors (NO<sub>x</sub> and VOCs). The baseline simulations captured the high O<sub>3</sub> concentrations ~~on Mar 4~~ reasonably well at most of the stations. ~~The MOZ17 simulation better matched the observed O<sub>3</sub> concentrations, whereas the RACM17 simulation underpredicted the high O<sub>3</sub> concentrations. While the simulations captured essential trends in, even though simulated levels of~~ NO<sub>x</sub> and NMHC, they

underestimated the concentrations, especially for NMHC. The lower VOCs were dramatically lower than observations. The low modeled concentrations of NO<sub>x</sub> were simulated well, but the higher concentrations were underpredicted, presumably because of missing sources in the inventory. Both chemistry mechanisms underpredicted NMHC by a factor of 6, suggesting that the inventory poorly quantifies these emissions, and VOCs suggest that emissions in NEI2014v2 are too low in the UGRB. Spatial plots of O<sub>3</sub> and its precursors show the predicted spatial extent of O<sub>3</sub> formation and that the models suggest the monitoring sites are close to, but not at, the location of maximum O<sub>3</sub>.

Overall, the WRF-Chem simulations (MOZ17 and RACM17) were able to simulate O<sub>3</sub> formation during this event, which is somewhat surprising given that the models had NMHC levels roughly six times lower than indicated by the observations. This suggests emissions in the NEI2014v2 dataset are too low and perhaps sources are missing in the emission inventory. Further study of the sensitivity of the simulations to Sensitivity studies where the levels of NO<sub>x</sub> and VOCs were adjusted to better match observations demonstrate that dramatically increasing VOC emissions and increasing the reactivity of the VOC mixture does not dramatically increase simulated ozone concentrations (though they do go up). Rather, the ozone levels appear to be predominantly controlled by NO<sub>x</sub> mixing ratios and NMHC mixing ratios and reactivity are needed availability. Because the RACM chemistry has previously been shown to perform reasonably well at simulating O<sub>3</sub> events in the UB (Ahmadov et al., 2015) and again performs well in the current study when VOC and NO<sub>x</sub> levels are adjusted to match observations, this study presents the possibility that O<sub>3</sub> might be able to be formed in the UGRB at significantly lower NMHC levels than are currently observed, though further study is needed to confirm this.

*Code and data availability.* The WRF and WRF-Chem models are freely available online (<https://github.com/wrf-model/WRF>). The emission preprocessing tools and NEI emission data can be found at <https://www2.aom.ucar.edu/wrf-chem/wrf-chem-tools-community>. The WYDEQ data can be obtained from <https://www.wyvisnet.com>.

*Author contributions.* SG, ZL, and SM designed the study and conducted the model simulations, analysis, and comparison with observations. TT and SR assisted with the model configuration and setup.

<sup>a</sup>Sum of i-Butane, n-Butane, i-Pentane, n-Pentane, 2-Methylpentane, 3-Methylpentane, n-Hexane, 2,4-Dimethylpentane, 3-Methylhexane, 2,2,4-Trimethylpentane, n-Heptane, 2-Methylheptane, n-Octane, n-Nonane, n-Decane and Undecane

<sup>b</sup>Sum of m,p-Xylene, o-Xylene, 1,3,5-Trimethylbenzene and 1,2,4-Trimethylbenzene

## Appendix A: Data and methods

### A1 Comparison with Mobile Laboratory Data

- 710 Methane ( $\text{CH}_4$ ) data from Picarro Cavity Ringdown Spectrometer (CRDS; model G2204) on-board University of Wyoming mobile laboratory Robertson et al. (2020) were used to validate the  $\text{CH}_4$  concentrations from the Wyoming Department of Environmental Quality (WYDEQ) Boulder station. The CRDS was modified by Picarro Inc. to sample at 2-Hz. The National Institute of Standards and Technology (NIST) traceable ( $\pm 1\%$ )  $\text{CH}_4$  in an ultrapure air mixture with a  $\text{CH}_4$  concentration of 2.576 ppm was used to calibrate the Picarro instrument Robertson et al. (2020).
- 715 Due to data availability, we compared the hourly  $\text{CH}_4$  data from WYDEQ with the 1-s data from the UW mobile laboratory. The data were from 11:00 am to 8:00 pm local time; the time period when UW mobile laboratory was driving in and around the UGRB.

**Figure A1.** Time series comparison of CH<sub>4</sub> from the UW mobile laboratory (red) and WYDEQ Boulder site (blue) for Feb 20, 2020. The black vertical lines mark the times when the mobile laboratory was passing through the WRF grid box where the WYDEQ Boulder site is located.

## A2 Chemistry namelist options used for MOZART and RACM chemistry mechanism
