19 *Abstract*

20 The biogenic volatile organic compound (BVOC) emission rates of Norway spruces published  
21 vary a lot. In this study we combined published Norway spruce emission rates measured in  
22 boreal forests (Meeningen et al., 2017; Bourtsoukidis et al., 2014a, 2014b; Hakola et al., (2003,  
23 2019)) and added our new, unpublished emission data from southern (SF) and northern Finland  
24 (NF). Standardized summer monthly mean emission potentials of isoprene vary from below  
25 detection limit to  $7 \mu\text{g g}^{-1}_{(\text{dw})} \text{h}^{-1}$ , and monoterpene (MT) and sesquiterpene (SQT) emission  
26 potentials  $0.01\text{--}3 \mu\text{g g}^{-1}_{(\text{dw})} \text{h}^{-1}$  and  $0.03\text{--}2.7 \mu\text{g g}^{-1}_{(\text{dw})} \text{h}^{-1}$ , respectively. In this study, we found  
27 much higher SQT emissions from Norway spruces than measured before and on average SQTs  
28 had higher emission potentials than isoprene or MTs. The highest monthly mean SQT emission  
29 potential  $13.6 \mu\text{g g}^{-1}_{(\text{dw})} \text{h}^{-1}$  was observed in September in southern Finland.

30

31 We found that none of the younger (33–40 years) trees in Hyytiälä, southern Finland, emitted  
32 isoprene, while one 50-year-old tree was a strong isoprene emitter. However, this could not be  
33 confirmed at other sites since all measured small trees were growing in Hyytiälä, so this could  
34 also be due to the same genetic origin. On average, older trees (>80 years) emitted about ten  
35 times more isoprene and MTs than younger ones (<80 years), but no clear difference was seen  
36 in SQT emissions. SQT emissions can be more related to stress effects.

37

38 As shown here for Norway spruce, it is possible that the emission factor of SQTs is significantly  
39 higher than what is currently used in models, which may have significant effects on the  
40 prediction of formation and growth of new particles, since the secondary organic aerosol (SOA)  
41 formation potential of SQTs is high and this may have significant effects on the formation and  
42 growth of new particles. Due to high secondary organic aerosol (SOA) formation potentials of  
43 SQTs the impact on SOA formation and mass could be even higher.

44

## 45 1. Introduction

46 The boreal forest covers about  $11 \cdot 10^6$  km<sup>2</sup> i.e. about 30 % of the global forest (Pan et al.,  
47 2013). The amount of tree species is not very diverse, consisting mainly of conifers such as  
48 pines and spruces and larch species especially in eastern part of Russian boreal forest (Soja  
49 et al., 2007). Some broadleaved deciduous trees are also common and include e.g. *Betula* sp.,  
50 *Alnus* sp. and *Populus* sp. The terrestrial vegetation, mainly trees, emit large amounts of  
51 volatile organic compounds (VOCs) to the atmosphere impacting the formation of ozone,  
52 secondary organic aerosol and clouds. These biogenic emissions (BVOC) dominate global  
53 VOC emissions consisting mainly of isoprene (ISOP), monoterpenes (MT), sesquiterpenes  
54 (SQT), methanol and acetone (Sindelarova et al., 2014). During the last decade the new  
55 technique to measure atmospheric total hydroxyl radical (OH) reactivity has been introduced  
56 to describe the VOC content of the air. By measuring how much OH radicals are consumed in  
57 the reactions and comparing this amount with the measurements of everything we know that  
58 reacts in the air with OH radicals, we can evaluate how much unknown reactive compounds  
59 are in the atmosphere. Total OH reactivity studies have shown that there are lots of unknown  
60 reactivity especially in the air of boreal forests (Yang et al. 2016). This reactivity is not  
61 explained by the traditionally measured BVOCs, their oxidation products or other known  
62 reactive compounds (e.g. CO, CH<sub>4</sub>, NO<sub>x</sub>, O<sub>3</sub>) (e.g. Praplan et al., 2019). A significant fraction  
63 of the unknown reactivity has also been found directly in the emissions of boreal trees  
64 (Nölscher et al. 2013 and Praplan et al. 2020). Therefore, more studies on BVOC emissions  
65 are needed to better understand biosphere-atmosphere interactions.

66  
67 Especially ISOP and MT have been studied quite intensively during past decades in boreal  
68 areas and MTs have been found to dominate ISOP emissions (e.g., Artaxo et al., 2022; Rinne  
69 et al., 2009). There are much more studies on MT and ISOP emissions than SQTs in the boreal  
70 area and the few existing studies show that SQT emissions can be substantial (e.g.,  
71 Bourtsoukidis et al., 2014 a,b; Hakola et al., 2001, 2006, 2017; Hellén et al., 2020, 2021;  
72 Schallhart et al., 2018). SQT emissions, especially  $\beta$ -farnesene, are often related to biotic  
73 stresses and therefore the emissions can be highly variable depending on the stress factors  
74 (Pettersson, 2007; Kännaste et al., 2008; Niinemets, 2010; Joutsensaari et al., 2015; Matsui and  
75 Koeduka, 2016).

76  
77 Emission potentials and compound composition vary a lot between different tree species (Karl  
78 et al., 2009), but there are also large variations in the emission between different individuals of  
79 the same tree species. For example, Bäck et al. (2012) showed that Scots pine trees of the same  
80 age, growing in the same environment, emit very different monoterpene selections. This has  
81 also been found to be true in the emissions of Norway spruce (Hakola et al., 2017). When  
82 considering the atmospheric impact of biogenic emissions, it is essential to know the species-  
83 specific composition of the emission, because for example atmospheric reactivity and aerosol  
84 formation potential of different compounds varies a lot (e.g. Hellén et al., 2018). Since emission  
85 rate and composition within the same tree species is so variable, we collected all available data  
86 of Norway spruce that could be used for emission potential calculations to investigate if e.g.  
87 growing location or age of a tree could explain the variations. In addition to the published data,  
88 we present new data from Hyytiälä, southern Finland from 2019 and 2021 and Pallas, northern  
89 Finland, from 2020.

90  
91 To demonstrate the consequences of emission group selection in new particle formation, we  
92 used this newly measured emission data to model aerosol formation and growth in two different  
93 environments, southern boreal forest in Finland and a sub-Arctic forest in Finnish Lapland. As  
94 a comparison, we simulated the aerosol processes with emissions from MEGAN v 2.1 model

95 (Model of Emissions of Gases and Aerosols from Nature). MEGAN2.1 is a modeling  
96 framework for estimating fluxes of biogenic compounds between terrestrial ecosystems and  
97 the atmosphere and utilizes standardized emission potentials from specific plant functional  
98 types to characterize the emissions (Guenther et al, 2012). Our simulations with real data thus  
99 provide a ‘reality check’ for the tabulated emission potential approach.

100

101

## 102 2. Experimental

103

### 104 1.1. Measurement sites and earlier emission measurements

105

106 The measurements were conducted in a southern boreal forest in Hyytiälä (hereafter called  
107 Southern Finland, SF) and in a northern boreal Norway spruce forest, at Pallas, Kenttäröva  
108 (hereafter called Northern Finland, NF). The measurement times and the tree ages are given in  
109 Table 2.

110

111 The NF site (Pallas Kenttäröva, 67.59°N, 24.15°E) lies on a hilltop plateau at an elevation of  
112 347 m a.s.l.. It is a sub-Arctic site which is characterized by the very short and intense growing  
113 season. Forests at these kind of sub-Arctic areas are sparse and the average tree height is much  
114 lower than at the more southern boreal forests. At Pallas site in 2021, the age of the trees varied  
115 from 90 to 250 years. The site is described in detail in Lohila et al. (2015) and in Aurela et al.  
116 (2015).

117

118 We measured altogether three mature spruces. The continuous analyses were conducted in a  
119 container about 2 m from the in-situ measured tree (Fig. 1). In addition to in-situ measurements,  
120 we also measured campaign-wise two trees growing near the container off-line; one growing  
121 by a small forest road shown in Fig. 1 and the other growing deeper in the forest. These off-  
122 line measurements included only present year’s new growth.

123

124 The SF site (SMEAR II station in Hyytiälä, Station for Measuring Forest Ecosystem-  
125 Atmosphere Relations, 61.51° N, 24.18° E, 181 m a.s.l.) is described in Hari and Kulmala  
126 (2005). The vegetation consists of a rather homogeneous Scots pine forest with some birches  
127 and Norway spruces growing in a mixture or understorey. The instrument was located in a  
128 container in a clearing in the forest (Fig. 2). The measured trees are marked on Fig. 2 and the  
129 approximate ages tabulated in Table 2.

130

131 The data include earlier measurements from 2011, 2014 and 2015 that has been published in  
132 Hakola et al. (2017) and new measurements from 2019 and 2021. In 2021, the measurements  
133 covered two different trees. One of the trees was the same one as measured in 2011, because  
134 we wanted to see if the age of the tree would affect its emissions. The other tree measured in  
135 2021 was growing deeper in the forest (ca. 15 m tall, 50 years old, Fig. 2). This tree was  
136 measured using adsorbent tubes, because the big tree was growing too far from the container  
137 to be measured with on-line gas-chromatograph-mass-spectrometer (GC-MS). With this tree  
138 we wanted to see if a big tree would emit differently than smaller ones growing close to the  
139 container. The ages of the trees and measurement times are shown in Table 2 and they are  
140 named as NF/SF and the year of the measurements.

141

142 In addition to the Hyytiälä and Pallas data, two older data sets are also included in the analysis.  
143 Data acquired in Sodankylä (67.25°N, 26.36°E), northern Finland, and Järvenpää (60.28°N,  
144 25.52°E), southern Finland (Hakola et al., 2003). These datasets are named as NF2 2002 and  
145 SF2 2001.

156 XT2 (RGB sensor) on a Drone Matrice 210 V2.

157 2.1. New, unpublished emission measurements

158

159 The emission measurement setup used in these campaigns has been described in detail  
160 previously in e.g. Hakola et al. (2017). Briefly, the measurements used a branch enclosure  
161 consisting of a ca. 6 L fluorinated ethylene propylene (FEP) dynamic chamber, which was  
162 flushed with 3-6 L min<sup>-1</sup> of humidified zero air generated by a commercial catalytic converter  
163 (HPZA-7000, Parker Hannifin Corporation). Two custom-built data loggers were used during  
164 the campaigns. The set-up consisted of a thermistor (Philips KTY 80/110, Royal Philips  
165 Electronics, Amsterdam, Netherlands) for the temperature inside the chamber and a quantum  
166 sensor (LI-190SZ, LI-COR, Biosciences, Lincoln, USA) for the photosynthetically active  
167 radiation (PAR), measured just above the enclosure.

168

169 On-line measurements/in situ analysis was performed using a thermal desorption - gas  
170 chromatograph - mass spectrometer (TD-GC-MS) (a thermal desorption unit Turbo Matrix  
171 350, a gas chromatograph Clarus 680 and a mass spectrometer Clarus SQ8 T, all manufactured  
172 by Perkin-Elmer, Inc. Waltham MA, U.S.A.). It was connected to the chamber via a 7 m long,  
173 3.2 mm (i.d.) tubing heated few degrees above the ambient temperature and pumped with 0.5  
174 – 2.0 L min<sup>-1</sup> make up flow, followed by 2.5 m long, 1.59 mm (i.d.) tube, with a flow of 40 mL  
175 min<sup>-1</sup>. All tubing was made of FEP. The VOC samples were collected directly into a cold trap  
176 filled with Tenax TA (50 %) and Carbopack B (50 %) of the TD-GC-MS for 30 min every hour  
177 or every second hour. The trap was kept at 20-25°C during sampling to prevent water vapour  
178 present in the air from accumulating in the trap. A DB-5MS column (60 m; i.d., 0.25 mm; film  
179 thickness, 0.25 µm from Agilent Technologies, Santa Clara CA, U.S.A.) was used for the  
180 separation. The column was kept 2 min at 60°C and then heated at the rate of 8°C min<sup>-1</sup> to  
181 270°C where it was kept for 2 min. The total time of the analysis was 30.25 min.

182

183 Helin et al. (2020) detected significant losses of β-farnesene within our in-situ TD-GC-MSs,  
184 which have been used in earlier studies of Norway spruce emissions (Hakola et al., 2017). For  
185 the new measurement campaigns conducted in 2019-2021 and presented here, the instrument  
186 was modified by changing the stainless steel lines in the online sampling box of the TD unit  
187 into FEP tubing and by using an empty Silcosteel sorbent tube instead of an empty stainless  
188 steel sorbent tube in the sample path of the TD unit. This increased the recovery of β-farnesene  
189 from ~10 % to >80 %.

190 Additional offline samples taken in Hyytiälä in 2021 and in Pallas in 2020 and also two  
191 previous datasets (NF2 2002 and SF2 2001) were acquired using Tenax TA/Carbopack B  
192 adsorbent tubes with the same method. The sampling flow was ~100 and ~200 ml min<sup>-1</sup> at  
193 Hyytiälä and in Pallas, respectively, and the sampling time was 30 min. The adsorbent tube  
194 samples, which were stored at 4°C until analysis, were analysed later in the laboratory of the  
195 Finnish Meteorological Institute using an automatic TD unit (TurboMatrix 350) connected to  
196 a GC (GC, Clarus 680) coupled to a quadrupole MS (MS, Clarus SQ 8 T), all purchased from  
197 PerkinElmer, Inc. (Waltham, MA, USA). This offline TD-GC-MS method is comparable to  
198 the online method (see e.g. Helin et al., 2020).

199 A four-point calibration was performed using liquid standards in methanol solutions for both  
200 on- and off-line measurements. Standard solutions (5 µl) were injected onto adsorbent tubes  
201 and then flushed with nitrogen (80-100 mL min<sup>-1</sup>) for 10 min to remove the methanol. The  
202 calibration solution included the following MTs: α-pinene, camphene, β-pinene, 3Δ-carene, p-  
203 cymene, 1,8-cineol, limonene, myrcene, terpinolene and linalool and the following SQTs:  
204 longicyclene, iso-longifolene, β-caryophyllene, β-farnesene and α-humulene. Unknown

205 sesquiterpenes were tentatively identified based on the comparison of the mass spectra and  
206 retention indexes (RIs) with NIST mass spectral library (NIST/EPA/NIH Mass Spectral  
207 Library, version 2.0). RIs were calculated for all SQTs using RIs of known SQTs and MTs as  
208 reference. These tentatively identified SQTs were quantified using response factors of  
209 calibrated SQTs having the closest mass spectra resemblance. Isoprene was calibrated using  
210 gaseous standard (National Physical Laboratory, 32 VOC mix at 4 ppb level or terpene mix at  
211 2 ppbv level).

212

### 213 2.3 Emission rate and potential calculations

214

215 The emission rate ( $E$ ) is determined as the mass of compound per needle dry weight and per  
216 time according to

$$217 E = \frac{(C_2 - C_1)F}{m} \quad (1)$$

218 Here  $C_2$  is the concentration in the outgoing air,  $C_1$  is the concentration in the incoming air,  
219 and  $F$  is the flow rate into the enclosure. The dry weight of the foliage mass ( $m$ ) was determined  
220 by drying the needles and shoot from the enclosure at 75 °C for 24 hours.

221

222 A strong dependence of biogenic VOC emissions on temperature has been seen in emission  
223 studies of ISOP, MTs, and SQTs (e.g. Hellén et al., 2021). The temperature dependent emission  
224 potentials for MTs and SQTs were calculated according to Guenther et al. (1993) and isoprene  
225 emission potentials were calculated using the temperature and light dependent algorithm  
226 according to Guenther et al. (2012).

227

### 228 2.4 Modelling impact of VOC emissions on aerosol formation and growth

229

230 Simulations were conducted using the model presented in Taipale et al. (2021). This model  
231 includes modules for emissions of VOCs from stress-free and stressed trees, boundary layer  
232 meteorology, atmospheric chemistry, and aerosol formation and growth. Certain parts of the  
233 model setup used in this study are different from the setup described in Taipale et al. (2021).

234

#### 235 2.4.1 Plant emissions of volatile organic compounds

236

237 In this study, the emissions ( $E_i$ ,  $\mu\text{g m}^{-2} \text{h}^{-1}$ ) of MTs and SQTs ( $i$ ) were modelled as:

238

$$239 E_i = \varepsilon_i * \text{LAI} * \gamma_i, \quad (2)$$

240

241 where  $\varepsilon_i$  ( $\mu\text{g m}^{-2} \text{h}^{-1}$ ) is the emission potential of  $i$ , LAI ( $\text{m}^2 \text{m}^{-2}$ ) is the one-sided leaf area index,  
242 and  $\gamma_i$  (unit-less) is an activity factor which accounts for changes in standard temperature  
243 conditions (Guenther et al., 1993):

244

$$245 \gamma_i = \exp(\beta_i * (T - T_s)) \quad (3)$$

246

247 where  $T$  is temperature (°C),  $T_s$  is the standard temperature (30 °C), and  $\beta_i$  is 0.1 °C<sup>-1</sup> and 0.17  
248 °C<sup>-1</sup> for monoterpenes and sesquiterpenes, respectively (Guenther et al., 2012).

249

250 2.4.2 Environmental conditions and atmospheric chemistry

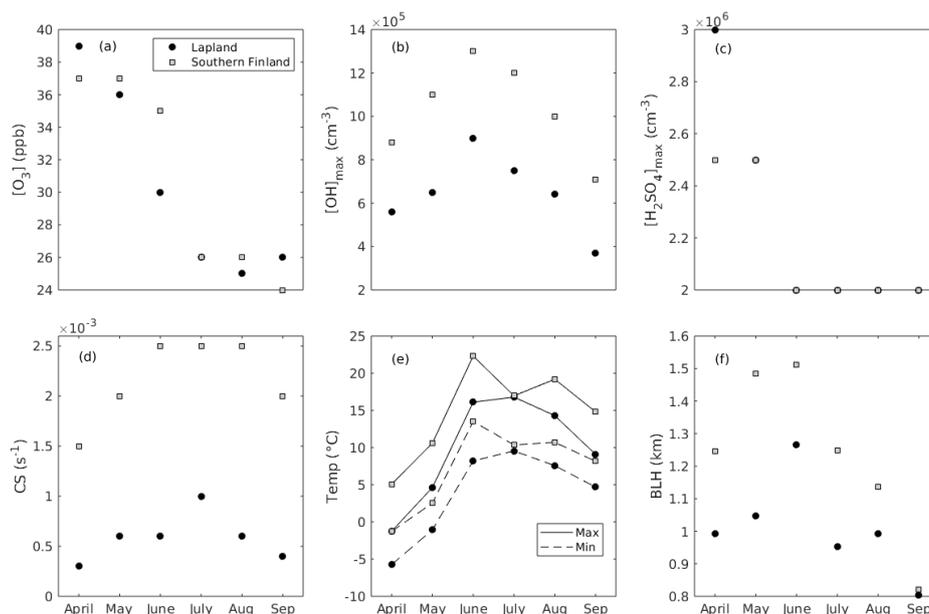

251

252 The model was constrained by environmental and atmospheric values observed in Hyytiälä  
253 (southern Finland, SF), as well as Pallas and Värriö, (northern Finland, NF), due to data  
254 availability (Fig. 3). The aim was to use reasonable values and not simulate one specific year  
255 or location. The one-sided leaf area index of Norway spruce forest stands was fixed to  $6.0 \text{ m}^2$   
256  $\text{m}^{-2}$  (Kalliokoski et al., 2020) and  $3.3 \text{ m}^2 \text{ m}^{-2}$  (Thum et al., 2008) for southern Finland and  
257 Finnish Lapland, respectively. In the simulations the concentration of ozone ( $\text{O}_3$ ) was kept  
258 constant throughout the day. For simulations of Lapland, we used monthly median year 2020  
259  $\text{O}_3$  concentration data from Pallas Sammaltunturi obtained via EBAS. These values are almost  
260 identical to observations from SMEAR I, Värriö, during the same time period  
261 (<http://urn.fi/urn:nbn:fi:att:8b3c67b4-22c0-4589-be00-a3d0341064d5>). For simulations of  
262 southern Finland, we used monthly median year 2020  $\text{O}_3$  concentration data from SMEAR II,  
263 measured at 16.8 m (<https://doi.org/10.23729/62f7ad2c-7fe0-4f66-b0a4-8d57c80524ec>). For  
264 simulations of both environments we calculated the monthly median of daily maximum OH  
265 concentration using the proxy presented by Petäjä et al. (2009) and year 2020 observed UVB  
266 radiation from the SMEAR I ([http://urn.fi/urn:nbn:fi:att:8b3c67b4-22c0-4589-be00-](http://urn.fi/urn:nbn:fi:att:8b3c67b4-22c0-4589-be00-a3d0341064d5)  
267 [a3d0341064d5](http://urn.fi/urn:nbn:fi:att:8b3c67b4-22c0-4589-be00-a3d0341064d5)) and SMEAR II ([https://doi.org/10.23729/62f7ad2c-7fe0-4f66-b0a4-](https://doi.org/10.23729/62f7ad2c-7fe0-4f66-b0a4-8d57c80524ec)  
268 [8d57c80524ec](https://doi.org/10.23729/62f7ad2c-7fe0-4f66-b0a4-8d57c80524ec)) stations, respectively. These daily maximum OH concentrations were used as  
269 input to the model, and the concentration of OH then decreased in the model as a function of a  
270 decrease in available solar light. We used daily maximum sulfuric acid ( $\text{H}_2\text{SO}_4$ ) concentrations  
271 reported by Kyrö et al. (2014) and Asmi et al. (2011) from Lapland, and by Petäjä et al. (2009)  
272 from southern Finland, as input to the model, and let the concentration of sulfuric acid decrease  
273 as a function of a decrease in solar light. In the simulations, the condensation sink (CS) was  
274 kept constant throughout the day. For simulations of Lapland, we used CS data from Vana et  
275 al. (2016), Asmi et al. (2011) and Komppula et al. (2006), while we used CS data from Vana  
276 et al. (2016) for simulations of southern Finland. For simplicity, the daily modelled temperature  
277 pattern followed that of the solar zenith angle with a forward shift of 1 h. For simulations of  
278 both environments, we used the monthly median of daily maximum and minimum temperatures  
279 measured at 15 m (Lapland) and 16.8 m (southern Finland) during the year 2020 at the SMEAR  
280 I (<http://urn.fi/urn:nbn:fi:att:8b3c67b4-22c0-4589-be00-a3d0341064d5>) and SMEAR II  
281 (<https://doi.org/10.23729/62f7ad2c-7fe0-4f66-b0a4-8d57c80524ec>) stations. For simulations  
282 of both environments, we used the monthly median of daily maximum year 2020 ERA5  
283 reanalysis boundary layer height retrieved for the grid cells closest to Pallas and Hyytiälä,  
284 respectively. These maximum values were downscaled by 25 % since one fixed value was used  
285 for the whole day.

286

287

288

289  
 290 **Figure 3.** Model input. (a) Ozone concentration. (b) Daily maximum OH concentration. (c)  
 291 Daily maximum sulfuric acid concentration. (d) Condensation sink. (e) Daily maximum and  
 292 minimum temperatures. (f) Planetary boundary layer height (BLH).

293

294 The following chemical reactions were included in the model:

295

302

303 where T is temperature (K), p indicates particle phase, g indicates gas phase, and OxOrg is the  
 304 sum of all organic compounds which contribute to aerosol processes. Reaction rates for each  
 305 reaction are summarized in Table 1. Reactions with  $\text{NO}_3$  were omitted, because simulations  
 306 were only conducted for daytime conditions.

307

308

309

Table 1: Reaction rates and yields for the reactions 1-6. CS is the condensation sink.

Reaction	Reaction rate	Yield (%)
R1	$1.2 \cdot 10^{-11} \cdot e^{(440/T)} (\text{cm}^3 \cdot \text{molecule}^{-1} \cdot \text{s}^{-1})$	1.7
R2	$8.05 \cdot 10^{-16} \cdot e^{(-640/T)} (\text{cm}^3 \cdot \text{molecule}^{-1} \cdot \text{s}^{-1})$	5.0
R3	$1.2 \cdot 10^{-14} (\text{cm}^3 \cdot \text{molecule}^{-1} \cdot \text{s}^{-1})$	7.7
R4	CS · 0.5	
R5	$1.5 \cdot 10^{-12} (\text{cm}^3 \cdot \text{molecule}^{-1} \cdot \text{s}^{-1})$	
R6	CS	

310

311

312

313

314 Some VOCs, and especially VOCs with endocyclic double bonds, can undergo autoxidation  
315 (Crouse et al., 2013; Ehn et al., 2014) whereby compounds with low volatility and high  
316 molecular mass (HOM: highly oxygenated organic molecules) are formed (e.g., Ehn et al.,  
317 2012, 2014; Jokinen et al., 2015; Berndt et al., 2016; Kurtén et al., 2016; Bianchi et al., 2019;  
318 Zhao et al., 2020). These highly oxygenated organic molecules have been found to be a major  
319 component of secondary organic aerosol (e.g. Ehn et al., 2014; Mutzel et al., 2015; Tröstl et  
320 al., 2016; Roldin et al., 2019). The yields by which HOM are formed are specific for individual  
321 parent molecules and isomers (e.g., Ehn et al., 2014; Bianchi et al., 2019), but they also depend  
322 on the blend of atmospheric molecules, including VOCs (McFiggans et al., 2019). Since HOM  
323 yields have, until now, only been determined for a very limited selection of VOCs, and since  
324 no algorithm to quantify how the concentration blend affects HOM yields have been proposed  
325 so far, mono- and sesquiterpenes were treated as groups of compounds in the model. Thus, in  
326 R1-3,  $\gamma$  is either the reported HOM yield, as defined in Ehn et al. (2014), or the reported SOA  
327 yield divided by 2.2 to account for the fact that SOA yields represent mass yields, and not  
328 molar yields as it is the case of HOM yields.  $\gamma_1$  is based on Jokinen et al. (2015) and Berndt et  
329 al. (2016),  $\gamma_2$  is based on Jokinen et al. (2015) and Ehn et al. (2014), while  $\gamma_3$  is based on Mentel  
330 et al. (2013).

331

332 2.4.3 Formation and growth of new particles

333

334 Clustering and activation of new atmospheric aerosol particles was calculated as (Paasonen et  
335 al., 2010):

336

$$337 J_2 = \alpha_1 * [\text{H}_2\text{SO}_4]^2 + \alpha_2 * [\text{H}_2\text{SO}_4] [\text{OxOrg}] + \alpha_3 * [\text{OxOrg}]^2 \quad (4)$$

338

339 where  $J_2$  ( $\text{cm}^{-3} \text{s}^{-1}$ ) is the formation rate of neutral 2 nm sized clusters, and  $\alpha_{1-3}$  are coefficients  
340 (Table 3 in Paasonen et al., 2010). For simplicity, only one growing aerosol mode was  
341 considered, and a unit-less correction term (KK), which determines how large a fraction of the  
342 activated clusters reaches the growing mode, was therefore included (Kerminen and Kulmala,  
343 2002):

344

$$345 \text{KK} = \exp(\eta * [1/D_p - 1/D_{\text{clus}}]) \quad (5)$$

346

347 where  $D_p$  and  $D_{\text{clus}}$  are the diameters of the growing mode and clusters, respectively, and  $\eta$   
348 (nm) is (Kerminen and Kulmala, 2002):

349

$$350 \eta = 1830 \text{ nm}^2 \text{ s h}^{-1} * \text{CS/GR} \quad (6)$$

351

352 where CS is the condensation sink and GR ( $\text{nm h}^{-1}$ ) is the condensational particle diameter  
353 growth rate. The growth rate of newly formed 2-3 nm particles was calculated as (Nieminen et  
354 al., 2010):

355

$$356 \text{GR}_{2-3 \text{ nm}} = 0.5 \text{ nm h}^{-1} * \text{CC} * 10^{-7} \text{ cm}^3 \quad (7)$$

357

358 where CC is the concentration of condensable vapours which was assumed to be the sum of  
359 sulfuric acid and OxOrg, and where it was assumed that the molar mass of OxOrg are 3.5 times  
360 larger than that of sulfuric acid (Ehn et al., 2014):

361  
362  $CC=[H_2SO_4]+[OxOrg] * 3.5^{1/3}$  (8)

363  
364 The strong dependency of particle growth rates on particle size, which has been observed in  
365 field conditions (Hirsikko et al., 2005; Yli-Juuti et al., 2011; Häkkinen et al., 2013), was also  
366 accounted for (Hirsikko et al., 2005; Yli-Juuti et al., 2011):

367  
368  $GR_{3-7\text{ nm}}=2 * GR_{2-3\text{ nm}}$  (9)

369  $GR_{>7\text{ nm}}=2.3 * GR_{2-3\text{ nm}}$  (10)

370  
371 The increase in the diameter of the growing mode was defined by the growth rate:  
372  $\Delta D_p/\Delta t=GR/3600\text{ s h}^{-1}$  (11)

373  
374 while the increase in the number of new particles ( $N_p$ ,  $\text{cm}^{-3}$ ) was determined by the formation  
375 of new particles which reaches the growing mode and the coagulation of particles in the  
376 growing mode:

377  
378  $\Delta N_p/\Delta t=J_2 * KK - CoagS * N_p$  (12)

379  
380 where the coagulation sink ( $CoagS$ ,  $\text{s}^{-1}$ ) was calculated as (Lehtinen et al., 2007):  
381  $CoagS=CS * (0.71\text{ nm}/D_p)^{1.6}$  (13)

382

### 383 3. Results

#### 384 3.1 Previously unpublished emission rates

385

386 The full time series of unpublished Norway spruce emission rates of MTs, oxygenated  
387 monoterpenoids (OMTs; linalool, 1,8-cineol, and bornylacetate) and SQTs are shown in Fig.  
388 A1 and isoprene and MBO emission rates in Fig. A2 (Appendix 1). Calculated monthly mean  
389 emission potentials (30°C) are presented in Table 2 together with previously published data  
390 that will be reviewed in Sect. 4. The approximate ages of the trees are shown in Table 2.

##### 391 3.1.1 Emission rates at the boreal forest site in Hyytiälä, southern Finland

392

393 In 2019, emissions from a small tree (SF 2019) were measured during the growing season. It  
394 emitted only small amounts of ISOP, and MT and SQT emissions were generally lower than  
395 in the previously reported Norway spruce emissions (Hakola et al., 2003). The statistics of the  
396 daily mean emission rates are shown in Fig. 4. Figure 5 shows the mean diurnal variations  
397 during summer months. Diurnal variation of the emission rates followed the variation of the  
398 temperature being highest in the afternoon and very low or below detection limits during the  
399 night. Isoprene emission rates were very low all the time. MTs were the dominant group in the  
400 emissions in July, but also SQT were important throughout summer.

401

402 The tree measured in Hyytiälä in 2021 (SF 2021) was the same one that was measured in 2011  
403 (SF 2011). In 2011, the SQT measurements were not reliable, but otherwise the results  
404 remained similar after ten years with very low ISOP, MT and OMT emission potentials (Table  
405 2). The comparison between the years is difficult since the measurements are not from the same  
406 periods in 2011 and 2021. In 2021 the measurements were conducted late summer in August,  
407 whereas in 2011 in spring/early summer. Based on these measurements, the aging of the tree

408 did not affect the emissions at least not yet on this ten years period. In 2021, an additional big  
409 tree growing deeper in the forest was measured (SF 2021B) for comparison. The big tree (SF  
410 2021B) emitted isoprene with much higher rate than the small trees (mean  $1498 \text{ ng g}_{\text{dw}}^{-1} \text{ h}^{-1}$ )  
411 and also MT emission rates (mean  $178 \text{ ng g}_{\text{dw}}^{-1} \text{ h}^{-1}$ ) were higher.

412  
413 SQT emissions were substantial compared to ISOP and MT emissions in all trees in Hyytiälä.  
414 The most noteworthy thing is that SQT emission rates greatly increase at the end of a growing  
415 season both in 2019 and 2021 (Fig. 4). For tree SF 2021, the emission rates increased a lot and  
416 the highest rates reached  $3 \mu\text{g g}_{\text{dw}}^{-1} \text{ h}^{-1}$  (Fig. A1). The emissions followed the typical diurnal  
417 variation with highest emission in the afternoon and lowest during the night (Fig. 5). The main  
418 identified SQT was  $\beta$ -farnesene, but significant fraction of the SQTs remained unidentified  
419 (Table 2). One of the major unidentified SQTs was tentatively identified as  $\alpha$ -farnesene.

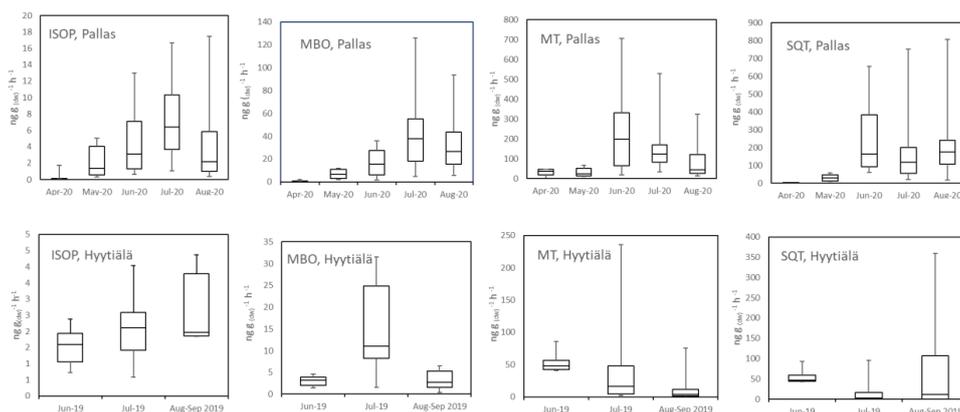

### 420 421 3.1.2 Emission rates at Pallas, northern Finland

422  
423 At Pallas one big tree was measured with the in-situ TD-GC-MS in April-August 2020 (NF  
424 2020) and two additional big trees were measured using adsorbent tubes in July 2020, one of  
425 them was growing by the roadside (NF 2020R) and the other deeper in the forest (NF 2020F).  
426 In these additional measurements only the new growth was measured.

427  
428 Average emission rates of ISOP, MTs and SQTs from the main tree (NF 2020) were 7, 135 and  
429  $230 \text{ ng g}_{\text{dw}}^{-1} \text{ h}^{-1}$ , respectively. At the time of high emissions, in summer, SQTs were the most  
430 significant compounds group emitted (Table 2 and Fig. 4), although in spring when the  
431 emissions were quite low, MTs dominated. Diurnal variations of all emitted compounds  
432 followed the variations of temperature, as expected (Fig. 5). Significant emissions of MTs and  
433 SQTs were detected also during nighttime, while emissions of ISOP and MBO decreased close  
434 to or below detection limits. ISOP and MBO emissions are known to be light dependent (Harley  
435 et al., 1998; Guenther et al., 1997) and even though there is midnight sun at this sub-Arctic site  
436 in summer, PAR decreased down to  $<10 \mu\text{mol s}^{-1} \text{ m}^{-2}$  in the middle of the night.

437  
438 The emissions of the main tree and two additional trees with new growth measurements  
439 differed a lot. The additional tree growing deeper in the forest (NF 2020F) emitted about 10  
440 times more MTs than the other two trees, and also SQT emission rates were higher (Table 2).  
441 We have no explanation for this difference. ISOP emissions were very low all the time from  
442 all trees. The branches were searched for possible diseases, but nothing was found. However,  
443 all three trees in Pallas had quite similar emission composition (Table 2).  $\beta$ -farnesene was the  
444 dominant SQT and other abundant compounds were  $\alpha$ -pinene,  $\beta$ -pinene, limonene and  $\Delta^3$ -  
445 carene.

446  
447

448

450 Fig. 4. Monthly mean box and whisker plots of ISOP, MBO, MT, and SQT calculated from  
451 daily mean emission rates of trees in Pallas in 2020 (NF 2020) and in Hyttiälä in 2019 (SF  
452 2019). Boxes represent second and third quartiles and horizontal lines in the boxes median  
453 values. Whiskers show the highest and the lowest daily means.

483 Table 2: Mean monthly emission potentials (30 °C) from the present study and from literature  
 484 (ng g<sup>-1</sup><sub>(dw)</sub> h<sup>-1</sup>). da=degraded in the analysis, na=not available. Van Meeningen et al. (2017)  
 485 reported measurements from several heights, 1-2 m measurements are included here, since  
 486 they best correspond to our measurements. For Norunda, Sweden, the height is 3 m and  
 487 Järvelja, Estonia 16 m.  $\beta$  is the coefficient describing temperature dependence according to  
 488 Eq. 3.

504

505 3.2 Comparison of Norway spruce emission potentials

506

507 3.2.1. Sources of data for Norway spruce emission potentials

508 To study the variations of the Norway spruce VOC emission potentials and factors affecting  
509 them, emission potentials at 30 °C from earlier literature and from new measurements presented  
510 in the previous section were collected (Table 2). First, it includes data obtained in Hyytiälä  
511 during campaigns in 2011, 2014, and 2015 (Hakola et al., 2017), as well as the new data from  
512 2019 and 2021, described above, and two older data sets; one from Sodankylä, northern Finland  
513 and one from Järvenpää, southern Finland.

514 On top of emission rates measured by our group, we included results from van Meeningen et  
515 al. (2017) and Bourtsoukidis et al. (2014a, 2014b). van Meeningen et al. (2017) reported  
516 isoprenoid emissions rates of Norway spruce at seven different sites, distributed from Ljubljana  
517 (46°06 N), Slovenia, to Piikkiö (60°23 N), Finland, to study the effect of latitude. Bourtsoukidis  
518 et al. (2014b) reported spruce emission measurements from Germany in Taunus Observatory  
519 on top of Kleiner Feldberg. There, the dominant spruce trees reached a maximum height of  
520 about 17 m, but the measurements were conducted at 2 m height at the edge of the forest.  
521 Bourtsoukidis et al. (2014a) measured spruce emissions also in Estonia during autumn. The  
522 age of the tree is not mentioned, but the measurements were conducted at 16 m height, so it is  
523 labeled as a “big tree”.

524 The mean of all emission potentials of Norway spruce emissions measured during summer  
525 months (June-August) at different sites presented (Table 2) was 760, 630 and 870 ng g<sub>dw</sub><sup>-1</sup> h<sup>-1</sup>  
526 for ISOP, MTs, and SQTs, respectively, but the variation between the trees and sites was very  
527 high. These are discussed in more details in the following subsections.

528 3.2.2. Variations in spruce BVOC emission potentials

529 The compiled ISOP emissions potentials ranged from below detection limit to 7138 ng g<sub>dw</sub><sup>-1</sup> h<sup>-1</sup>  
530 <sup>1</sup>. No clear link between the emissions potentials and the latitude, or the season could be  
531 observed, but none of the smaller trees investigated emitted ISOP. The trees with the largest  
532 emissions were NF2 2002, SF2 2001, and SF 2021B, in June and July. Their ISOP emission  
533 potentials were larger than the one reported by van Menningen et al. (2017), except for the tree  
534 in Norunda (60°23N), Sweden. While this could indicate that ISOP emission potentials might  
535 be higher at higher latitudes, the trees in Pallas (NF 2020, NF 2020R, NF 2020F) and in  
536 Hyytiälä (SF 2019, SF 2021) and reported by Bourtsoukidis et al. (2014a, 2014b) also exhibited  
537 low ISOP emission potentials. According to our observations, latitude is not a main driver for variations in  
538 emission potentials, which is also in accordance with van Menningen et al. (2017) who found only minimal  
539 differences in emission potentials between sites and across latitude. Van Menningen et al. (2017) studied  
540 the effects of branch height, the season and variation between years on observed emission  
541 pattern was also investigated. There were indications of potential influences of all three factors.  
542 However, due to different experimental setups between measurement campaigns, it was  
543 difficult to draw any robust conclusions. The effect of branch height has not been explicitly  
544 studied in our campaigns as only the lowest branches were measured.

545 3.2.3. Variation in MT emission potentials

546 We found larger variations of MT emission potentials ( $9\text{--}2909\text{ ng g}_{\text{dw}}^{-1}\text{ h}^{-1}$ ) compared to van  
547 Menning et al. (2017) and Bourtsoukidis et al. (2014a, 2014b), again with no clear trend with  
548 changes in latitude. Even for the summer months (June to August), the variations were large  
549 ( $39\text{--}2909\text{ ng g}_{\text{dw}}^{-1}\text{ h}^{-1}$ ). Here, it seems that, in general, younger trees (less than 80 years old)  
550 had lower MT emission potentials ( $9\text{--}1960\text{ ng g}_{\text{dw}}^{-1}\text{ h}^{-1}$ ), compared to older trees ( $91\text{--}2909$   
551  $\text{ng g}_{\text{dw}}^{-1}\text{ h}^{-1}$ ), with a large overlap of values. Whenever seasonal data is available, MT emission  
552 potentials were higher in spring and summer. This confirms the findings from Bourtsoukidis et  
553 al. (2014a), in which the highest MT ( $977.5\pm 140.7\text{ ng g}_{\text{dw}}^{-1}\text{ h}^{-1}$ ) emission potentials were  
554 detected during spring with a decline towards autumn.

#### 555 3.2.4. Variation in OMT emission potentials

556 Studies from other groups have not reported OMT emission potentials separately. In our studies  
557 emission potentials of OMTs have ranged from below detection limit to  $19\text{ ng g}_{\text{dw}}^{-1}\text{ h}^{-1}$ . The  
558 largest emission potentials were found in July for the trees NF 2020F, NF2 2002 and NF 2020.

#### 559 3.2.5. Variation in SQT emission potentials

560 As was shown in Helin et al. (2020), the SQT measurements from our early campaigns in  
561 Hyytiälä in 2011 and 2014 were underestimated, since  $\beta$ -farnesene, usually the main SQT  
562 emitted from Norway spruce, was degraded during the analysis. The SQT emission potentials  
563 from 2011 and 2014 are therefore not shown in Table 2. The SQT emissions potentials based  
564 on the rest of our measurement campaigns varied between below detection limit and  $13664\text{ ng}$   
565  $\text{g}_{\text{dw}}^{-1}\text{ h}^{-1}$  (between  $34$  and  $3243\text{ ng g}_{\text{dw}}^{-1}\text{ h}^{-1}$  for the summer months). Bourtsoukidis et al. (2014a)  
566 reported highest SQT emission potentials in spring ( $352.9\pm 56.1\text{ ng g}_{\text{dw}}^{-1}\text{ h}^{-1}$ ), declining towards  
567 autumn, similarly to MT emission potentials from the same study. All our measurements which  
568 continued until late summer/early autumn have different trends with increasing emission  
569 potentials towards the end of the growing season (Table 2). Table 4 shows the mean values of  
570 emission potentials of the trees measured in Finland (this study and older data) and the standard  
571 deviation between the trees are shown. We did not take into account the results by  
572 Bourtsoukidis et al. (2014 a,b) or van Meeningen et al. (2017), because the standardization was  
573 not done with same  $\beta$  values and the ages of the trees in the measurements by Bourtsoukidis et  
574 al. (2014a) was not reported.

575

#### 576 3.2.6. Overall conclusions of the comparison

577

578 Van Meeningen et al. (2017) concluded that spruce isoprenoid emission is potentially more  
579 determined by genetic diversity than by adaptation to local growth conditions. This conclusion  
580 is holding up in view of the review done here, even though weak trends could be identified  
581 regarding the age and size of the trees.

582

583 Generally, we found that older trees ( $>80\text{y}$ ) emit more isoprene and MT than younger trees  
584 ( $<80\text{y}$ .) However, age does not seem to affect SQT emissions. This is reflected in the full  
585 review presented here, where comparing mean values of all measured trees older than 80 years  
586 and younger than 80 years. The old trees were found to emit about ten times more ISOP and  
587 MTs than younger trees (Table 4), while SQT emissions do not seem to vary with the age of  
588 the tree. SQT emissions are often related to stress effects as has been suggested in many studies  
589 (e.g. Petterson, 2007; Kännaste et al., 2008; Niinemets Ü, 2010; Joutsensaari et al., 2015;  
590 Matsui and Koeduka, 2016).

591

592 While we found some indication that smaller trees have lower emission potentials, all the small  
593 trees measured were growing in Hyytiälä, so this could also be due to the same genetic origin.  
594 Big trees can be divided into two groups: three trees growing in NF emitted considerable  
595 amounts of MTs and SQTs, but small amounts of isoprene (as also the trees measured in  
596 Estonia and Germany by Bourtsoukidis et al. (2014a, b) and big trees growing in SF and one  
597 growing in NF emitted additionally lots of isoprene.

598 Table 4: Mean values of emission potentials for the trees (> 80 years, <80 years) measured in  
599 Finland (this study and older data) and the standard deviation between the trees. Number of  
600 trees measured each season is given in parentheses. bdl=below detection limit, Na=not

#### 606 4. Impact of Norway Spruce emissions on aerosol formation and 607 growth 608

609 Recognizing this observed large variability in spruce BVOC emissions (precursors for new  
610 particle formation processes), there is a need to test the consequences of this variability in  
611 simulations of aerosol formation. For Southern Finland (SF) spruce forest emission potentials  
612 obtained from Hyytiälä were used, while for Northern Finland (NF) emission potentials  
613 obtained from Pallas were used. As a comparison, simulations were also conducted using  
614 standard emission potentials for Needleleaf Evergreen Boreal Tree from MEGAN v2.1.  
615 Simulations were run first by including all measured compounds and then either MT or SQT  
616 emissions were set to zero to study relative impacts of MTs and SQTs.

617

618 The emission potentials used in the simulations are listed in Table 5. ISOP was excluded from  
619 model simulations, since previous measurements as well as the measurements presented in this  
620 paper show that the emission of ISOP from Norway spruce is negligible or very low most of  
621 the time. Furthermore, the emission factor for ISOP for Needleleaf Evergreen Boreal Tree in  
622 MEGAN is very high ( $600 \mu\text{g m}^{-2} \text{h}^{-1}$  for a one-sided LAI of  $1 \text{ m}^2 \text{ m}^{-2}$ , Guenther et al., 2012),

623 due to the high emission of ISOP from other tree species within the same plant functional type  
624 (Guenther, 2013). Additionally, the role of ISOP in aerosol formation and growth processes is  
625 unclear. ISOP has a small HOM yield ( $\sim 0.01\text{--}0.03\%$ , Jokinen et al., 2015) and it has been  
626 suggested that it suppresses the formation of new particles (Kiendler-Scharr et al., 2009, 2012;  
627 Lee et al., 2016; McFiggans et al., 2019; Heinritzi et al., 2020). On the other hand, oxidation  
628 products of ISOP (e.g. IEPOX) have been proposed to promote the growth of existing new  
629 particles ( $D_p > 3$  nm, e.g., Surratt et al., 2010; Lin et al., 2013), while others have found the  
630 growth of small particles ( $D_p > 3.2$  nm) to be unaffected by the concentration of ISOP (Heinritzi  
631 et al., 2020).

632  
633  
634

635 **Table 5.** Emission potentials ( $\mu\text{g m}^{-2} \text{h}^{-1}$ ) used in the simulations. MT = monoterpenes,  
636 including oxygen-containing monoterpenes, SQT = sesquiterpenes.

Sept	13	384			290	48

637 <sup>a</sup>: The values have been converted from  $\text{ng g}_{\text{dw}}^{-1} \text{h}^{-1}$  (shown in Table 2) to  $\mu\text{g m}^{-2} \text{h}^{-1}$  assuming  
638 a specific (one-sided) leaf weight of  $0.15 \text{ kg m}^{-2}$ . <sup>b</sup>: Needleleaf Evergreen Boreal Tree, the  
639 values have been decreased by a factor of 5, accounting for the fact that emission factors in  
640 MEGAN are standardised to a one-sided LAI of  $5 \text{ m}^2 \text{ m}^{-2}$ .

641  
642

643 Our data indicates that the Norway spruce dominated forests, especially in Northern Finland,  
644 are expected to have much higher SQT emissions than predicted by the standard emission  
645 potentials for Needleleaf Evergreen Boreal Tree in MEGAN 2.1. On the other hand, the ISOP  
646 and MT emission potentials obtained from our measurements are lower than those used in  
647 MEGAN v2.1. This can have significant impacts on predictions of formation and growth of  
648 new particles as shown in our model simulations.

649

650 According to our modeling efforts, oxidation products of primary BVOC emissions from  
651 spruce contribute significantly more to aerosol processes in northern Finland than in southern  
652 Finland. In the simulations of southern Finland, the sum of organic compounds contributing  
653 to aerosol processes (OxOrg) is 65 % smaller when using the emission potentials obtained  
654 from Hyttiälä compared to when using emission factors from MEGAN (Fig 6a). Using either  
655 emission potentials obtained from Pallas or from MEGAN reached comparable results when  
656 simulating northern Finland (Fig. 6a). Simulations conducted with and without MTs and  
657 SQTs showed that SQTs are the main contributors to OxOrg production in both southern and  
658 northern Finland when emission potentials obtained from Hyttiälä and Pallas are used, while

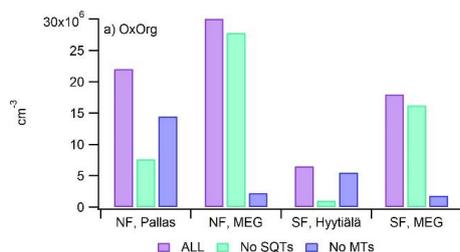

659 MTs are the main contributors when emission factors from MEGAN are instead used (Fig.  
660 6a). The dominance of SQTs is also displayed in the formation rate of new particles (Fig 6b),  
661 number of newly produced particles (Fig 6c) and the rate at which they grow (Fig 6d).  
662

663 It is possible that spruce SQT emissions have been underpredicted in earlier studies due to  
664 difficulties in the quantitative measurements of their emissions. Based on our model  
665 simulations, these SQT emissions may have strong impacts on the formation and growth of  
666 new particles. However, neither emissions nor atmospheric processes of SQTs are well  
667 described, and more research would be needed to better characterize their atmospheric impacts  
668 and role in the biosphere-atmosphere interactions especially at Northern latitudes.

677 Fig. 6. Results from the simulations of the formation and growth of new particles  
678 from the emissions of Norway spruce forests in Southern Finland (SF) and in  
679 Northern Finland (NF). Mean local emission potentials measured in Hyytiälä and  
680 Pallas or standard emission potentials for Needleleaf Evergreen Boreal Tree from  
681 MEGAN v2.1 (MEG) were used. a) sum of oxidation products of MT and SQT  
682 emissions contributing to aerosol processes (OxOrg), b) formation rate of neutral 2  
683 nm sized clusters ( $J_2$ ), c) number of new particles in the growing mode (Np), d)  
684 growth rate of newly formed particles (GR). All values are means of summer medians  
685 (June-August). Local environmental conditions are used in all simulations as  
686 described in the method section.

687  
688

## 689 5. Conclusions

690

691 We studied VOC emissions from eight different Norway spruces growing in northern and  
692 southern Finland and reviewed the available VOC emission data of Norway spruces measured  
693 elsewhere. The outcome was that emissions were highly variable between individual trees. For  
694 MT and SQT ~80 times differences were found between the emission potentials of the highest  
695 and lowest emitting trees in summer. For isoprene the difference was even higher. No clear  
696 reason for the differences were found, but there were some indications of the impact of size/age  
697 of the trees and of the seasonality of emissions.

698

699 We found that none of the younger trees in Hyytiälä emitted isoprene, while one 50 year old  
700 tree growing in Hyytiälä was a strong isoprene emitter. This could perhaps indicate that young  
701 Norway spruce trees do not emit isoprene in contrast to older trees, but we cannot confirm this  
702 since all measured small trees were growing in Hyytiälä, thus the cause might be that the trees  
703 were of the same genetic origin. In addition, at other sites some big trees did not emit significant  
704 amounts of isoprene either. On average, older trees (>80 years) emitted about ten times more  
705 isoprene and MTs than younger ones (<80 years), but no clear difference was seen in SQT  
706 emissions. SQT emissions can be more related to stress effects as has been suggested in many  
707 studies (e.g. Petterson, 2007; Kännaste et al., 2008; Niinemets Ü, 2010; Joutsensaari et al.,  
708 2015; Matsui and Koeduka, 2016).

709

710 It is also significant that SQT emission rates greatly increased at the end of the growing season  
711 in all of the measurements conducted in Finland, but in the measurements by Bourtsoukidis et  
712 al., (2014b), high SQT emissions were measured during the early growing season. One tree  
713 (SF 2021) had an enormous increase in September when the highest emission rates reached 25  
714  $\mu\text{g g}^{-1}_{\text{dw}} \text{h}^{-1}$ . Increase of sesquiterpene emissions towards the late summer has also been seen  
715 in Scots pine branches (Tarvainen et al., 2005; Hakola et al., 2006).

716

717 With improved measurement methods in this study, we found much higher SQT emissions  
718 from Norway spruces than measured before and on average SQTs had higher emission  
719 potentials than isoprene and MTs. Due to difficulties in quantitative measurements, SQT  
720 emissions from other plant species may also be much higher than earlier thought. As shown  
721 here for Norway spruce, if the emission factors of SQTs are in reality higher than what is  
722 currently used in models, this may have very significant effects on predictions of aerosol  
723 dynamics, including the evolution of aerosol number size distribution via new particle  
724 formation and subsequent particle growth. Due to the high SOA formation potentials of SQTs

725 (Griffin et al., 1999; Lee et al., 2006; Frosch et al., 2013; Mentel et al., 2013), the impact on  
726 SOA formation and mass could be even higher. Therefore, more studies should focus on  
727 quantifying the emission and atmospheric impacts of SQTs.

1064 Acknowledgments: The financial support by the Academy of Finland projects (project no.  
1065 316151, 307957 and 337549) and Academy of Finland Postdoctoral Researcher grant  
1066 (323255) are gratefully acknowledged. The authors thank Dr. Juho Aalto for determining the  
1067 tree ages, the needles and Dr. Pavel Alekseychik (National Resources Institute Finland), for  
1068 providing us the figure taken using a drone (Fig. 2).
