14 **Abstract.** The light-absorbing organic aerosol (OA), known as brown carbon (BrC), has important radiative impacts, however
15 its sources and evolution after emission remain to be elucidated. In this study, the light absorption at multiple wavelengths,
16 mass spectra of OA and microphysical properties of black carbon (BC) were characterized at a typical sub-urban environment
17 in Beijing. The absorption of BC is constrained by its size distribution and mixing state and the BrC absorption is obtained by
18 subtracting the BC absorption from the total aerosol absorption. Aerosol absorption was further apportioned to BC, primary
19 BrC and secondary BrC by applying the least-correlation between secondary BrC and BC. The multi-linear regression analysis
20 on the factorized OA mass spectra indicated the OA from traffic and biomass burning emission contributed to primary BrC.
21 Importantly, the moderately oxygenated OA (O/C=0.62) was revealed to highly correlate with secondary BrC. These OA had
22 higher nitrogen content, in line with the nitrogen-containing functional groups detected by the Fourier transform infrared
23 spectrometer. The photochemical processes were found to reduce the mass absorption cross section (MAC) of primary OA,
24 reducing its contribution to total absorption by 20%, at the same time increasing MAC for secondary OA, which showed a 30%
25 enhancement in contribution to total absorbance, implying the concurrent whitening and darkening of BrC. This provides field
26 evidence that the photochemically produced secondary nitrogen-containing OA can considerably compensate some bleaching
27 effect on the primary BrC, hereby causing radiative impacts.

28 1. Introduction

29 Atmospheric absorbing organic aerosol (OA), known as brown carbon (BrC), is an important contributor to anthropogenic
30 absorption besides black carbon (BC) (Laskin et al., 2015; Liu et al., 2020), particularly at shorter visible wavelengths (Bahadur
31 et al., 2012). Due to complex compositions of OA, the primary sources and subsequent evolution of BrC in the atmosphere
32 remains to be explicitly understood and causes uncertainties in evaluating the radiative impacts of BrC (Liu et al., 2020).

33 The chromophores of BrC are mainly aromatic compounds associated with certain functional groups (Liu et al., 2015c).
34 Particularly, compounds containing nitro, nitrated or other forms of nitrogen-containing functional groups are more absorbing
35 (Nakayama et al., 2013; Jacobson, 1999). It is well established that primary OA, especially from biomass burning, contains a
36 large fraction of BrC (Andreae and Crutzen, 1997; Rizzo et al., 2013; Bond, 2001). These primary BrC has a range of
37 absorptivity, which was found to be controlled by burning phases. OA co-emitting with BC (the flaming phase) exhibited a
38 higher absorptivity than OA-dominated smoldering phase (Liu et al., 2021). BrC can experience reactions with atmospheric
39 oxidants after emission. Previous studies (Satish et al., 2017; Satish and Rastogi, 2019; Dasari et al., 2019) found nitrogenous
40 compounds from biomass burning were responsible for BrC over South Asia and the chromophores were photobleached in the
41 afternoon. Numerous field and laboratory studies found the decrease of BrC absorptivity due to photobleaching of
42 chromophores, with lifetime ranging from a few hours (Zhao et al., 2015; Liu et al., 2021) to a few days (Forrister et al., 2015),
43 which may depend on the concentration of ambient hydroxyl radical (Wang et al., 2014), also influenced by relative humidity
44 and particle volatility (Schnitzler et al., 2020). The absorptivity of BrC could be also enhanced due to addition of functional
45 groups by forming conjugated structure with aromatics. This was supported by a number of laboratory studies that BrC
46 absorptivity could be enhanced when forming nitrogen-containing organic compounds, such as the formation of nitro-
47 aromatics when aromatics reacted with NO_x (Nakayama et al., 2013), or produced organic amine after reacting with ammonia
48 (Updyke et al., 2012). The enhancement of BrC absorptivity could occur either through nitration of existing chromophores, or
49 formation of new secondary organic aerosol (SOA) chromophores through gas-phase oxidation.

50 The above findings mean the enhancement or bleaching of BrC absorptivity via **photochemical processes** will coexist. The
51 time scale between both competing processes will ultimately determine the lifetime of BrC in the atmosphere. However, both
52 processes have been rarely investigated in the field to explicitly determine the BrC components which principally determine
53 the respective enhancement or decrease of its absorptivity, particularly in regions influenced by combined anthropogenic
54 sources.

55 In this study, by measurements using multiple-wavelength absorption and microphysical properties of BC in a sub-urban region,
56 the absorption of BC, primary and secondary BrC was discriminated. In conjunction with source attribution via OA mass
57 spectra, we are able to link the segregated absorption with certain sources and investigate their primary information and
58 subsequent evolution. The competition between photobleaching and secondary formation of BrC was investigated in real world.

59 2. Experimental and instrumentation

60 2.1 Site description and meteorology

61 The experiment was conducted during springtime at the Beijing Cloud Laboratory and Observational Utilities Deployment
62 Base (117.12°E, 40.14°N), which is located in the northeast suburban area in Beijing (Fig S1a). The site is surrounded by the
63 northwest mountain ridge, without significant local primary anthropogenic emissions (Hu et al., 2021). The 72-h backward
64 trajectories with every 3 hours initializing from the site are analyzed by the HYSPLIT model (Draxier and Hess, 1998) using
65 the 3-hourly 1°×1° meteorological field from the GDAS reanalysis product. The obtained backward trajectories were further
66 clustered to group the similar transport pathways (Makra et al., 2011). The meteorological parameters, including the
67 temperature (T), ambient relative humidity (RH), wind speed (WS) and wind direction (WD) were measured by a monitoring
68 station on the site.

69 2.2 Measurements of BC microphysics and absorption coefficient

70 In this study, the ambient aerosols were sampled by a large-flow (1.05 m³ min⁻¹) air particle sampler (TH-1000C II) with a
71 PM_{2.5} impactor (BGI SCC 1.829) and dried by a silica drier before measurement. The single particle soot photometer (SP2,
72 DMT., USA) used continuous laser at $\lambda=1064$ nm to incandescence light-absorbing aerosols (such as BC) for irradiating detectable
73 visible light. The incandescence signal was used to measure the refractory black carbon (rBC) mass. The SP2 incandescence
74 signal was calibrated using the Aquadag standard (Acheson Inc., USA), and a factor of 0.75 was applied to correct for ambient
75 BC (Laborde et al., 2012). The scattering signal was calibrated by monodispersed polystyrene latex spheres (PSL). The BC
76 core diameter (D_c) was calculated from the measured BC mass by assuming a BC density of 1.8 g cm⁻³ (Bond and Bergstrom,
77 2006). The leading edge only (LEO) method was applied to reconstruct the scattering signal of BC, which was used to
78 determine the coated particle diameter (D_p) by a Mie-lookup table with the inputs of scattering and incandescence signal of
79 each BC particle (Liu et al., 2014; Taylor et al., 2015). The mass median diameter (MMD) is derived from the D_c distribution,
80 which is determined as below and above MMD the rBC mass concentration is equal (Liu et al., 2019b). The bulk coating
81 thickness (D_p/D_c) is calculated as the cubic root of ratio of the total coated BC volume divided by the total volume of rBC.

82 The mass absorption cross section (MAC) (in m² g⁻¹) of each BC particle can be calculated using the measured coated and
83 uncoated BC sizes by applying the Mie core-shell calculation. The absorption coefficient of BC at certain wavelength, $\sigma_{\text{abs,BC}}$
84 (λ) is determined by multiplying the calculated MAC and rBC mass concentration at each size:

$$85 \sigma_{\text{abs,BC}}(\lambda) = \sum_i \text{MAC}(\lambda, D_{p,i}, D_{c,i}) m(\log D_{c,i}) \Delta \log D_{c,i} \quad (1)$$

86 where $m(\log D_{c,i})$ denotes the BC mass concentration at each logarithmic bin of D_c . The SP2 measurement at $\lambda=1064$ nm longer
87 than mostly populated BC size means the derived coatings and subsequent calculation of MAC is relatively independent of
88 particle shape within uncertainty of 21% (Liu et al., 2014; Hu et al., 2021).

89 The absorption coefficients at wavelengths $\lambda= 375, 470, 528, 635$ and 880 nm were measured by a Micro-Aethalometer
90 (MA200, Aethlabs, San Francisco, CA, USA). Aerosol particles were collected on filter tapes, on which the light attenuation
91 was measured continuously with a time resolution of 30 s. The loading effect of filters was automatically corrected by

92 measuring attenuation at two different sampling flow rates on two spots in parallel (Drinovec et al., 2015a). Moreover, a multi-
93 scattering correction factor (C-value) of 3.5, 3.2 and 2.4 at the wavelengths 370 nm, 528 nm and 880 nm, respectively were
94 utilized to correct attenuation for the multiple light scattering effect. It was obtained by comparing the absorption coefficient
95 with a photoacoustic soot spectrometer (PASS-3, DMT) (Hu et al., 2021).

96 2.3 Attribution of primary and secondary BrC absorption coefficient

97 The absorption coefficient of BC at different λ is calculated using the measured uncoated core and coated size as mentioned
98 above. The absorption coefficient of total BrC is obtained by subtracting the BC absorption coefficient from the total absorption
99 at certain wavelength, expressed as:

$$100 \sigma_{\text{abs, BrC}}(\lambda) = \sigma_{\text{abs, total}}(\lambda) - \sigma_{\text{abs, BC}}(\lambda) \quad (2)$$

101 where the absorption coefficient of BC ($\sigma_{\text{abs, BC}}$) is obtained from the SP2 measurement, $\sigma_{\text{abs, total}}(\lambda)$ is the total light absorption
102 of aerosols measured by the MA200. The absorption coefficient of secondary BrC, the absorption not contributed by primary
103 sources, is obtained by subtracting the absorption of all primary sources from the total absorption (Crilley et al., 2015),
104 expressed as:

$$105 \sigma_{\text{abs, secBrC}}(\lambda) = \sigma_{\text{abs, total}}(\lambda) - \sigma_{\text{abs, pri}}(\lambda) \quad (3)$$

106 where $\sigma_{\text{abs, pri}}(\lambda)$ is the light absorption from primary sources. Here an assumption is made that light absorption from primary
107 aerosols is all from combustion sources, and these sources necessarily contain BC (Wang et al., 2018a). Therefore, the total
108 absorption from primary sources can be obtained by scaling a factor from the mass concentration of BC, expressed as:

$$109 \sigma_{\text{abs, pri}}(\lambda) = \left(\frac{\sigma_{\text{abs, total}}}{[\text{rBC}]} \right)_{\text{pri}} \cdot [\text{rBC}] \quad (4)$$

110 where [rBC] is the mass concentration of rBC measured by the SP2, $\left(\frac{\sigma_{\text{abs, total}}}{[\text{rBC}]} \right)_{\text{pri}}$ is the scaling factor to derive the absorption
111 of primary combustion sources from [rBC]. This factor is obtained using the minimum R-squared (MRS) approach (Wu and
112 Yu, 2016), by adjusting the factor until a minimum correlation between $\sigma_{\text{abs, secBrC}}$ and [rBC] is reached because the absorption
113 from secondary sources are least likely to covary with that from primary sources (Wang et al., 2019a). This method has been
114 used in urban and sub-urban environment to obtain the primary BrC associated with combustion sources. Being different from
115 previous studies, an auxiliary characterization of rBC mass measured by the SP2 is used here to avoid the possible interference
116 from absorption measured by the same instrument. There may be different $\left(\frac{\sigma_{\text{abs, total}}}{[\text{rBC}]} \right)_{\text{pri}}$ ratio between traffic and biomass
117 burning sources and this may lead to bias in deriving the subsequent results. We have more carefully investigated the diurnal
118 pattern of hydrocarbon-like OA (HOA) and biomass burning OA (BBOA), and found only a slight morning rush-hour peak
119 for HOA (though bearing considerable variation). A further investigation on the HOA/BBOA ratio found no apparent diurnal
120 pattern (bearing large variation), shown in Fig. S8. The source difference is therefore not considered to have significantly
121 influenced the diurnal pattern of derived parameters. In addition, this method is only valid with sufficient data points thus we

122 may only obtain a single mean value for the entire experiment, which represents the mean $\left(\frac{\sigma_{abs,total}}{[rBC]}\right)_{pri}$ in this environment
 123 during the experimental period. Previous studies using this method also derived the mean value of $\left(\frac{\sigma_{abs,total}}{[rBC]}\right)_{pri}$ for the urban
 124 environment influenced by multiple sources including traffic, coal combustion and biomass burning (Wang et al., 2019c; Wang
 125 et al., 2020; Gao et al., 2022). The $\left(\frac{\sigma_{abs,total}}{[rBC]}\right)_{pri}$ ratio at $\lambda=375$ nm, 470 nm, 528 nm, 635 nm and 880 nm is calculated to be
 126 20.7, 17.0, 14.4, 11.7 and 5, respectively (Fig. S2), which falls within the reported values from previous studies 11-50 (Zhang
 127 et al., 2020; Wang et al., 2019a). This scenario assumes a relatively consistent absorption relative to BC mass concentration
 128 from sources during experiment. This however may not include some sporadic events when sources with distinct OA or BC
 129 mass fraction may be introduced and alter the single $\left(\frac{\sigma_{abs,total}}{[rBC]}\right)_{pri}$ ratio. The $\sigma_{abs,secBrC}$ therefore represents the overall mean
 130 value during the experimental period but this ratio will vary with seasons and locations. The σ_{abs} of primary BrC can then be
 131 calculated as:

$$132 \sigma_{abs,priBrC}(\lambda) = \sigma_{abs,BrC}(\lambda) - \sigma_{abs,secBrC}(\lambda) \quad (5)$$

133 where $\sigma_{abs,BrC}$ and $\sigma_{abs,secBrC}$ is calculated from Equation (2) and (3), respectively.

134 2.4 Composition measurement

135 The mass concentration and chemical composition of non-refractory sub-micron PM (NR-PM₁) including organic aerosols
 136 (OA), nitrate (NO₃⁻), sulfate (SO₄²⁻), chloride (Cl⁻) and ammonium (NH₄⁺) were determined with a High-Resolution Time-of-
 137 Flight Aerosol Mass Spectrometer (HR-ToF-AMS, Aerodyne Research Inc., USA). The setup, operation, and calibration
 138 procedures of the AMS have been described elsewhere (Canagaratna et al., 2007). During this field observation, the AMS was
 139 operated in V-mode for the quantification of mass concentrations. The composition-dependent collection efficiencies were
 140 applied ((Middlebrook et al., 2012), and the ionization efficiency was calibrated using 300 nm pure ammonium nitrate (Jayne
 141 et al., 2000). Elemental ratios of OA including oxygen-to-carbon (O/C), hydrogen-to-carbon (H/C) and nitrogen-to-carbon
 142 (N/C) were determined to the improved-ambient method (Canagaratna et al., 2015).

143 Positive Matrix Factorization (PMF) (Paatero and Tapper, 1994) was performed on the inorganic and organic high-resolution
 144 mass spectra to distinguish OA components from different sources (Zhang et al., 2011; Ulbrich et al., 2009; Decarlo et al.,
 145 2010). The mass spectra of the combined matrix for $m/z < 120$ were excluded in PMF analysis. Five OA factors were identified.
 146 The diagnostics of PMF is summarized in Text S1 and Fig. S6.

147 2.5 Offline Fourier transform infrared spectrometer (FTIR) analysis

148 Particulate Matter (PM) samples were collected once a day onto prebaked (600°C, 4h) quartz fiber filters (Whatman, QMA,
 149 USA) using a large-flow (1.05 m³ min⁻¹) air particle sampler (TH-1000C II). The collected filter samples were stored in the

150 refrigerator at -20°C before analysis. The infrared spectra of collected samples were measured by a Fourier transform infrared
151 spectrometer (FTIR, Thermo Scientific, USA) equipped with an iD5 attenuated total reflectance accessory (diamond crystal)
152 to quantify the chemical functional groups over the wavenumbers range of 550-4000 cm⁻¹ with a resolution of 0.5 cm⁻¹. The
153 NO and NO₂ symmetric stretch in the FTIR spectra can characterize the functional groups associated with nitrogen-containing
154 organics (Corry and Dillner, 2008). Fig. S3 shows typical examples of FTIR spectra and the assigned functional groups for
155 the three pollution levels during experiment. The peak at 1110 cm⁻¹ corresponds to the background of the quartz fiber filter
156 overlapped with some X-H bending vibrations, which is subtracted for the following analysis. The characteristic organic nitrate
157 spectra appear at wavenumbers 860 cm⁻¹ (NO symmetric stretch), 1280 cm⁻¹ (NO₂ symmetric stretch) and 1630-1640cm⁻¹
158 (NO₂ asymmetric stretch) (Bruns et al., 2010). After baseline calibration, The FTIR peaks of 1630cm⁻¹ and 860cm⁻¹ are
159 integrated the absorption areas above the baseline. The summed integrated area of -NO and -NO₂ are hereby used to indicate
160 the nitrogen-containing organics. There was no discernable peak of carbonyl group for our infrared spectrum, and the peak of
161 OH at 2500 cm⁻¹ - 3400 cm⁻¹ for the carboxylic acid is not discernable neither, thus the influence of ketone and carboxylic acid
162 may be of less importance for our dataset.

163 3. Results and Discussion

164 3.1 Source attributed OA

165 The overview results are shown in Fig. S1. The organics dominated the aerosol compositions for most time, but occasionally
166 nitrate was the most abundant component (Fig. S1g). Note that the nitrate here may also include components containing in
167 organics besides ammonium nitrate. Backward trajectories (Fig. S1a-d) showed that the most abundant PM₁ concentration was
168 associated with air masses transported in shorter distance from southern regions (C1), but the longer and faster northerly
169 transported air mass from cleaner north (C2) could dilute the concentrations.

170 The resolved OA factors by the PMF analysis are shown in Fig. 1, including the mass spectra, time series and diurnal profiles
171 of each PMF factor with corresponded external and internal tracers. Three primary OA (POA) were identified as HOA,
172 cooking-related OA (COA), BBOA, with O/C of 0.31, 0.18 and 0.39 respectively. These POA had considerable fraction of
173 hydrocarbon fragments (C_xH_y), indicating their less aged status. The HOA profile was characterized by higher contributions
174 of aliphatic hydrocarbons and has dominated ion tracers such as *m/z* 41 (C₃H₅⁺), 43 (C₃H₇⁺), 55 (C₄H₇⁺) and 57 (C₄H₉⁺). The
175 HOA concentration correlated with BC (*r*=0.62), which emits from traffic emissions. The diurnal variation exhibited strong
176 morning and afternoon rush-hour peaks of mass concentration. This factor was consistent with the mass spectra of previously
177 measured HOA from on-road vehicle emissions in urban cities (Zhang et al., 2005; Aiken et al., 2009; Sun et al., 2016; Hu et
178 al., 2017), which has *m/z* peaks characteristic of hydrocarbon fragments in series of C_nH_{2n+1}⁺ and C_nH_{2n-1}⁺. The mass spectrum
179 of HOA shows overall similarity to those of primary OA emitted from gasoline and diesel combustion sources (*r*=0.68) (Elser
180 et al., 2016).

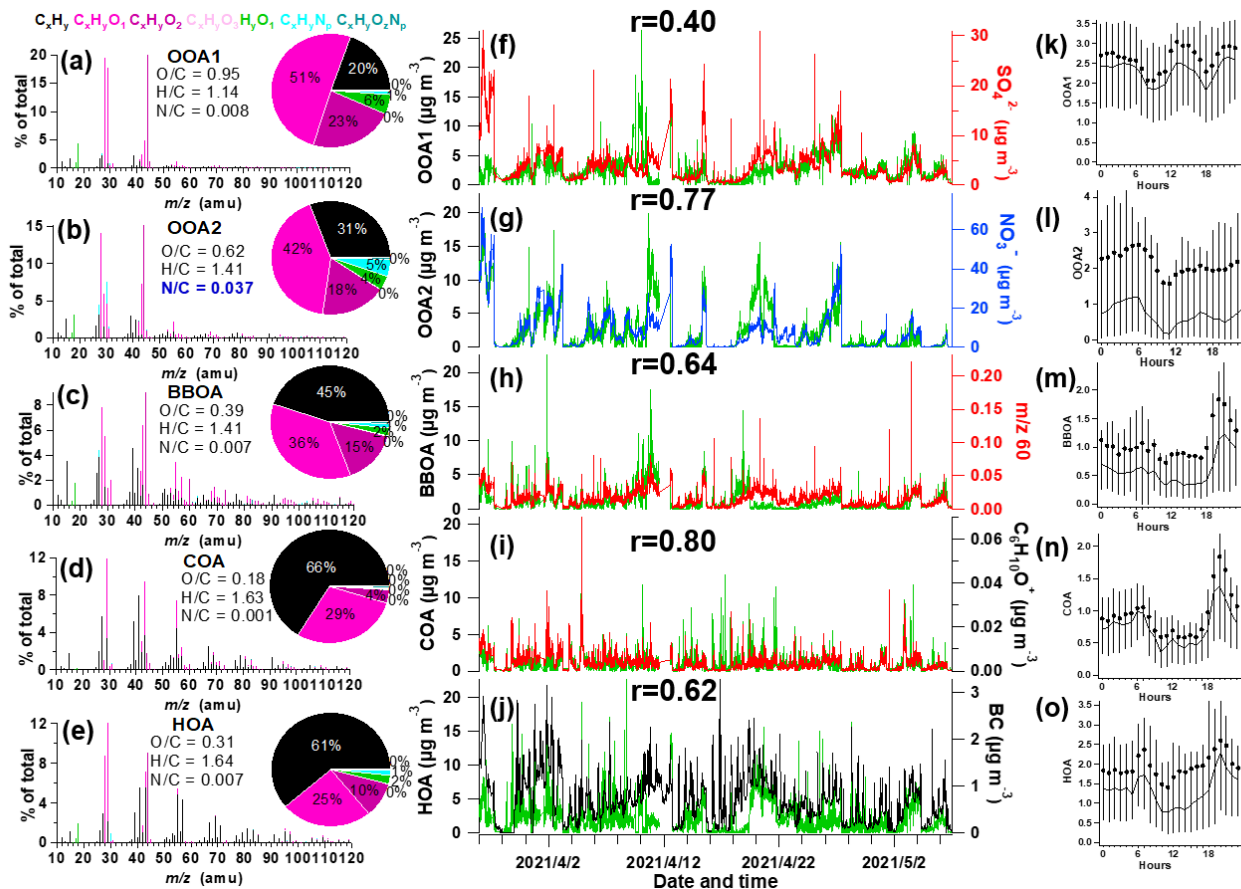

181 The OA from cooking sources (COA) is also characterized by prominent hydrocarbon ion series, however, with higher signal
182 at $C_nH_{2n-1}^+$ than $C_nH_{2n+1}^+$. COA had apparent fragments of both $C_4H_9^+$ and $C_3H_3O^+$, and has a higher ratio of $C_3H_3O^+/C_3H_5O^+$
183 (3.1), $C_4H_7^+/C_4H_9^+$ (2.2) than HOA (0.9–1.1), with cooking-related fragments of $C_5H_8O^+$ (m/z 84), $C_6H_{10}O^+$ (m/z 98) and
184 $C_7H_{12}O^+$ (m/z 112) (Sun et al., 2011b; Mohr et al., 2012). The COA shows overall similar spectral pattern to the reference
185 spectra of COA ($r=0.92$) (Elser et al., 2016). Its minor peak at noon and larger peak in the evening (Fig. 11) also corresponded
186 with the lunch and dinner time respectively. There was only a minor peak at noon for COA, which may be due to the sub-urban
187 nature of the site where the major aerosols from cooking sources may have been processed and lost the signature near source.
188 The feature of this factor was also observed in sub-urban environment (Huang et al., 2021).

189 The BBOA factor was identified based on the prominent signals of m/z 60 ($C_2H_4O_2^+$) and 73($C_3H_5O_2^+$), which are known
190 fragments of levoglucosan (Cubison et al., 2011). And BBOA also correlated with potassium (K^+ , $r = 0.80$), which are indicator
191 of biomass burning (Pachon et al., 2013; Brown et al., 2016). The m/z 60 and 73 together with a unique diurnal variation have
192 been shown to be a robust marker for the presence of aerosols from biomass burning emissions in many urban locations (Sun
193 et al., 2016). The BBOA shows very similar mass spectral patterns to previously reported reference spectra of biomass burning
194 ($r=0.94$) (Elser et al., 2016). The BBOA factor that was identified in spring accounted for 12.8% of the total OA in Beijing,
195 similar to previous reports (Hu et al., 2017). Biomass (Cheng et al., 2013) and solid fuel burning emissions (Sun et al., 2014)
196 have been widely observed to importantly contribute to the primary OA in this region. This off-road combustion source was
197 particularly abundant during wintertime for residential heating activities (Shen et al., 2019; Yang et al., 2018; Liu et al., 2016),
198 while boiler for industry use (mostly using coal as fuel) was in operation throughout the year (Liu et al., 2015b). During the
199 springtime of the experiment, the residential heating activities dropped due to increased ambient temperature thus the BBOA
200 may be mainly contributed by the industry sector.

201 Two types of oxygenated organic aerosols (OOA) were identified, in moderate (OOA2, $O/C=0.62$) and high oxidation state
202 (OOA1, $O/C=0.95$), respectively, which is very similar to the spectra of OOA factors resolved in other cities (Hayes et al.,
203 2013; Ulbrich et al., 2009). The average mass spectrum of OOA2 in this study is characterized by m/z 29 (mainly CHO^+), 43
204 (mainly $C_2H_3O^+$) and m/z 44 (CO_2^+), similar to the semi-volatile OOA spectrum identified in other locations (Sun et al., 2011a;
205 Zhou et al., 2016). On average, OOA2 accounts for 42% and 18% of $C_xH_yO^+$ and $C_xH_yO_2^+$ ions, respectively (Fig. 1b). These
206 results clearly indicate that OOA2 was primarily composed of less oxygenated, possibly freshly oxidized organics. Notably,
207 OOA2 had a substantially higher N/C than other factors ($N/C=0.037$), and had highest correlation with nitrate ($r=0.77$) and
208 with $C_xH_yN_z$ and $C_xH_yN_zO_p$ fragments ($r=0.83$). This factor therefore tends to largely result from nitrogen-containing OA and
209 its elevation at night may be also associated with dark oxidation by nitrate radical.

210 The mass spectrum of OOA1, which was characterized by a dominant peak at m/z 44 (mainly CO_2^+), a highest O/C (0.95). On
211 average, OOA1 contributes 51% of the $C_xH_yO^+$ signal and 23% of the $C_xH_yO_2^+$ signal (Fig. 1a). OOA1 showed particularly
212 high correlation with sulfate ($r=0.40$) because of their similar volatilities (Huffman et al., 2009; Jimenez et al., 2009). The
213 slight enhancement at noon for OOA1 (also for OOA2) soon after morning rush-hour indicated the likely rapid formation of
214 SOA through **photochemical processes**. This significantly higher mean OOA2 than median value in the diurnal pattern

215 indicated that this OA type was largely associated with pollution events. Both OOA1 and OOA2 showed nighttime peak maybe
 216 due to reduced boundary layer.

222 3.2 Segregated aerosol absorption

223 Fig. 2 shows the time series of BC properties, including the BC mass concentration, D_p/D_c , D_c , MAC and light absorption
 224 coefficient of BC (section 2.2). The MMD of BC core varied between 93 – 274 nm which may correspond to the source-
 225 specific information (Liu et al., 2019a) or coagulation process during aging. The coating of BC (indicated by D_p/D_c) showed
 226 sporadic enhancement which was closely associated with enhanced PM concentration (Fig. 2a). This was consistent with
 227 previous studies that high coatings of BC occurred during heavier pollution due to the enhanced secondary formation of
 228 condensable materials to particle phase (Ding et al., 2019; Zhang et al., 2018). This clearly indicates the variation of mixing
 229 state of BC and this will potentially influence its MAC and absorption Ångström exponent (AAE) (Liu et al., 2015a). It will
 230 introduce considerable uncertainties to use constant MAC or AAE to derive the absorption coefficient of BC at multiple

231 wavelengths. The MAC estimated using the measured BC core size and coatings (Fig. 2c) is thus used to derive the $\sigma_{\text{abs,BC}}$
 232 (section 2.2, shown in Fig. 2d). The $\sigma_{\text{abs,BC}}$ was $9.1 \pm 7.3 \text{ Mm}^{-1}$ during experimental period. MAC of BC at $\lambda=375\text{nm}$ showed to
 233 be at $8.4 - 16.6 \text{ m}^2 \text{ g}^{-1}$ with enhanced absorption when high coatings, which was consistent with previous studies which reported
 234 MAC_{BC} of $8-10 \text{ m}^2 \text{ g}^{-1}$, and higher value of $9.7 - 17.2 \text{ m}^2 \text{ g}^{-1}$ under polluted condition (Ding et al., 2019; Hu et al., 2021). The
 235 uncertainty of $\left(\frac{\sigma_{\text{abs,total}}}{[\text{rBC}]_{\text{pri}}}\right)$ is 4% for the data points over 1.5 according to (Wang et al., 2019a). The measurement of rBC
 236 mass from the SP2 had uncertainty of 20% (Schwarz et al., 2008), with relative coating thickness having uncertainty of 23%
 237 (Taylor et al., 2015), hereby resulting in a uncertainty of 27% for calculated MAC_{BC} . The above results in uncertainties of 31%
 238 and 20% for $\sigma_{\text{abs,BC}}$ and $\sigma_{\text{abs,pri}}$, respectively. The absorption measurement by MA200 had uncertainty of 25% (Drinovec et al.,
 239 2015b; Duesing et al., 2019). All these uncertainties propagates the uncertainties of $\sigma_{\text{abs,BrC}}$, $\sigma_{\text{abs,priBrC}}$ and $\sigma_{\text{abs,secBrC}}$ as 40%, 37%
 240 and 32% respectively. These are summarized in Table S1.

241
 242 **Figure 2. Temporal evolution of BC-related properties. (a) rBC and PM₁ mass concentration, (b) BC core diameter and bulk coating**
 243 **thickness (D_p/D_c), (c) calculated mass absorption cross section (MAC) at $\lambda=375\text{nm}$, (d) absorption coefficient of BC.**

244 Using the method above, the total ($\sigma_{\text{abs,total}}$) and attributed absorption of BC ($\sigma_{\text{abs,BC}}$), primary ($\sigma_{\text{abs,priBrC}}$) and secondary BrC

245 ($\sigma_{\text{abs,secBrC}}$) at $\lambda=375\text{nm}$ are shown in Fig. 3a-c. In Fig. 3b, the brown and green shades above the adjacent tracer indicate the
 246 absorption coefficient of primary and secondary BrC, respectively. Fig. 3c shows that the absorption coefficient of primary
 247 BrC was higher than secondary BrC for most time, but for certain periods they were equivalent or secondary BrC occasionally
 248 exceeds primary BrC. The mean contribution of absorption coefficient for BC, primary BrC and secondary BrC is 51%, 27%
 249 and 22% in this study. The tracers associated with nitrogen-containing organics, such as OOA2 (with highest N/C), $\text{C}_x\text{H}_y\text{N}_z$
 250 and $\text{C}_x\text{H}_y\text{N}_z\text{O}_p$ fragments, and the FTIR measured $-\text{NO} + -\text{NO}_2$, are also shown in Fig. 3d-e.

251
 252 **Figure 3. Temporal evolution of segregated absorbing properties.** (a) Absorbing coefficients (σ_{abs}) at multiple wavelengths measured
 253 by the aethalometer, (b) σ_{abs} at $\lambda=375\text{nm}$ ($\sigma_{\text{abs,375}}$) for all aerosols, primary OA and BC, (c) $\sigma_{\text{abs,375}}$ for primary BrC and secondary
 254 BrC. (d) mass concentration of OOA2 and the $\text{C}_x\text{H}_y\text{N}_z$ and $\text{C}_x\text{H}_y\text{N}_z\text{O}_p$ fragments measured by the AMS. (e) FTIR-measured
 255 absorption of $-\text{NO}$ and $-\text{NO}_2$ bonds.

256 3.3 Source attribution of BrC absorption

257 A multiple linear regression (MLR) analysis is performed to apportion the absorption coefficient of BrC with the PMF
 258 attributed OA factors, expressed as:

$$259 \sigma_{\text{abs,BrC}} = a_0 + a_1 \cdot [\text{OOA1}] + a_2 \cdot [\text{OOA2}] + a_3 \cdot [\text{BBOA}] + a_4 \cdot [\text{COA}] + a_5 \cdot [\text{HOA}] \quad (6)$$

260 where a_1 to a_5 represents the regression coefficients for each factor. These coefficients can be associated with the absorptivity

261 of each factor, i.e., a larger coefficient implies a higher MAC for the source associated with that OA factor (Kasthuriarachchi
 262 et al., 2020; Wang et al., 2021). The BBOA was found to have the highest MAC at $2.59 \text{ m}^2 \text{ g}^{-1}$, consistent with previous studies
 263 which also found significantly higher absorption for biomass burning source (Qin et al., 2018; Wang et al., 2019b; Zhang et
 264 al., 2022). The other POA factors generally have a higher MAC than SOA (the MAC of HOA and COA are $1.70 \text{ m}^2 \text{ g}^{-1}$ and
 265 $1.30 \text{ m}^2 \text{ g}^{-1}$, respectively). Particularly, the OOA2 has a relatively high MAC of $1.22 \text{ m}^2 \text{ g}^{-1}$, which is likely to result from the
 266 production of secondary BrC as discussed below. The contribution of each source-specific OA factor to $\sigma_{\text{abs,BrC}}$ can also be
 267 obtained. This analysis is performed for the total BrC, primary and secondary BrC respectively. The results are shown in Table
 268 1. MLR on the total BrC shows relatively higher correction ($r > 0.4$) with the factors of HOA, BBOA and OOA2, suggesting
 269 the potential importance of the primary biomass burning and traffic source along with OOA2 in governing absorption of BrC.
 270 MLR analysis on the primary BrC distinguishes its substantial correlation with BBOA ($r = 0.40$) and HOA ($r = 0.46$), while MLR
 271 on the secondary BrC has a high correlation with OOA2 only ($r = 0.44$). The MLR analysis links the apportioned absorption of
 272 physical properties with source-attributed chemical compositions, therefore validating and identifying the sources of primary
 273 and secondary BrC.

274 **Table 1. Results of the multilinear regression analysis (MLR) between $\sigma_{\text{abs,375}}$ and the five PMF-resolved OA factors, with $\sigma_{\text{abs,375}}$ of**
 275 **total BrC, primary and secondary BrC as dependent, respectively. All regression coefficients have passed the significance test with**
 276 **$p < 0.01$. Partial correlations above 0.4 are marked in bold. Since negative values appear when the COA participates, which is thus**
 277 **not included in the final regression but the values using COA factor are shown in brackets.**

Dependent	$\sigma_{\text{abs,BrC}}$		$\sigma_{\text{abs,priBrC}}$		$\sigma_{\text{abs,secBrC}}$	
	Regression coefficient	Partial correlation	Regression coefficient	Partial correlation	Regression coefficient	Partial correlation
Constant	2.26		1.67		1.47 (1.52)	
OOA1	0.57	0.23	0.04	0.02	0.46(0.46)	0.24 (0.24)
OOA2	1.22	0.53	0.37	0.25	0.74 (0.74)	0.44 (0.44)
BBOA	2.59	0.46	1.22	0.40	1.14 (1.18)	0.29 (0.29)
COA	1.30	0.22	1.45	0.36	/ (-0.25)	/ (-0.05)
HOA	1.70	0.47	1.17	0.46	0.49 (0.52)	0.20 (0.21)
R ²		0.77		0.63		0.55 (0.55)

278 Importantly, an oxygenated secondary OA factor (OOA2) is identified to significantly contribute to the secondary BrC. This
 279 OOA has a moderate O/C (0.62) and a highest N/C of 0.037 among all factors. The high N/C means this factor contains the
 280 most abundant nitrogen-containing fragments, implied as its high correlation with the $\text{C}_x\text{H}_y\text{N}_z$ and $\text{C}_x\text{H}_y\text{N}_z\text{O}_p$ fragments ($r = 0.83$,
 281 Fig. 3d) and with the FTIR absorption for -NO₂ and -NO bonds ($r = 0.69$, Fig. S4). The -NO bond is mostly related to the
 282 organic nitrates (RONO₂), and -NO₂ peak could result from both organic nitrates and nitro-organics (Bruns et al., 2010). There

283 is no discernable peak for organic amines. These all consistently imply that the OOA2 factor contained substantial fraction of
284 nitrogen-containing organics, and these compounds have contributed to the absorption of secondary BrC.

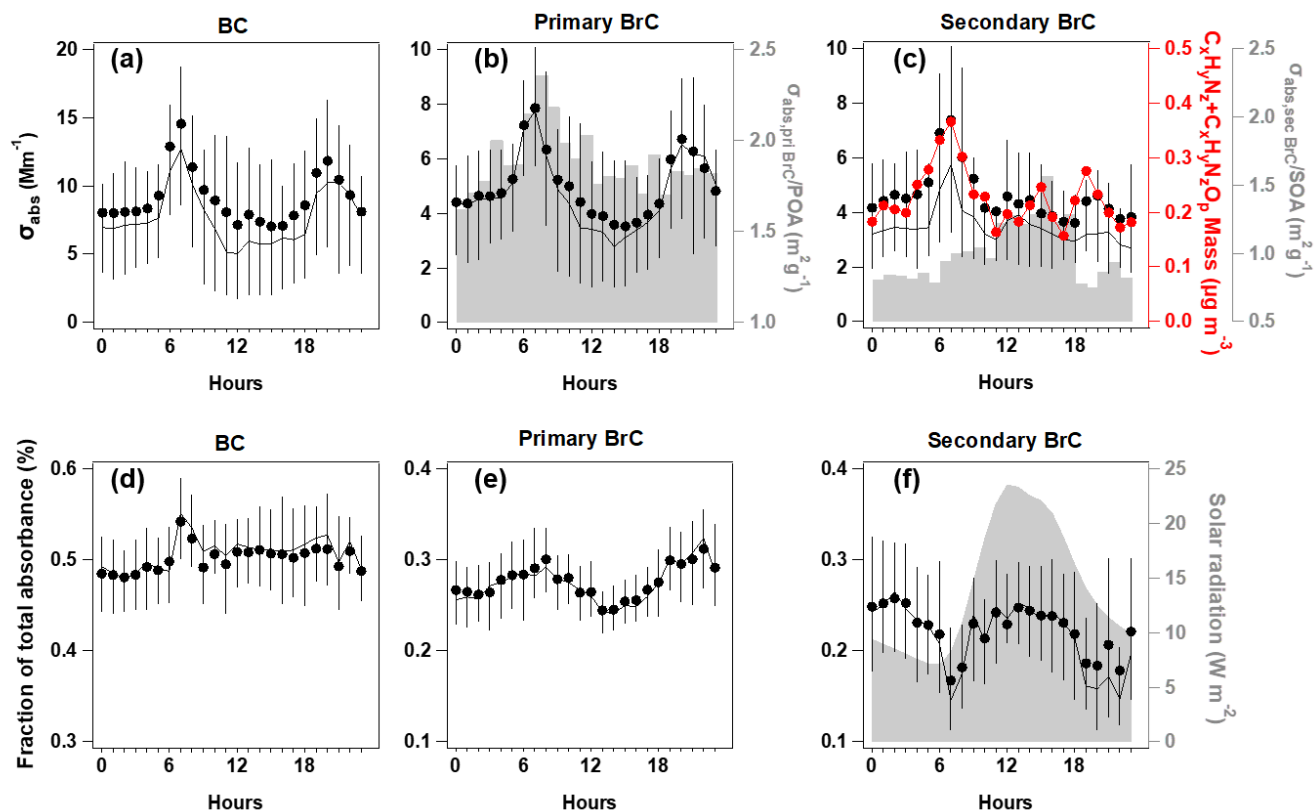

285 **3.4 Simultaneous whitening and darkening process of BrC**

286 The relative contribution and diurnal variation of primary and secondary BrC measured by MA200 at 470, 528 and 635nm
287 wavelengths are similar to those at 375nm wavelengths, but with decreased fraction of BrC absorption with increased
288 wavelength. The mean AAE of total BrC, primary BrC and secondary BrC is obtained by power fitting on the mean absorption
289 coefficient during the experiment (Fig.S7), which is 6.16, 5.69 and 6.40 respectively. This is consistent with other studies that
290 SOA usually had a higher AAE than POA (Gilardoni et al., 2016; Jiang et al., 2022). Due to the high contribution of BC to total
291 absorption (>50% even at shortest wavelength), the spectral dependence of absorption in bulk has not shown apparent diurnal
292 variation. The diurnal variation of $\sigma_{\text{abs},375}$ for BC and primary BrC and their fractions showed consistent morning rush-hour
293 peaks at 6:00-8:00 and the night-time enhancement due to reduced boundary layer (Fig. 4a-b). This was in line with the morning
294 peak of HOA and night peak of BBOA. The traffic source in this region, in particular the diesel vehicles, was reported to emit
295 considerable OA with certain chromophores, such as aromatics (Yao et al., 2015) and heterocyclic organic compounds (Gentner
296 et al., 2017; Schuetzle, 1983). In the morning rush-hour, BC and primary BrC accounted for $51\pm4\%$ and $29\pm4\%$ in the total
297 $\sigma_{\text{abs},375}$ respectively, with the remaining $20\pm2\%$ classified as secondary BrC. The morning peak coinciding with the primary
298 BrC may result from the rapid formation of BrC from sources when emitted gases condensed and formed aerosols. These may
299 lead to high cooccurrence between primary and secondary BrC. Previous studies in urban environment also observed
300 concurrent peaks of primary and secondary BrC, which usually occurred at morning rush hour (Zhang et al., 2020).
301 Furthermore, the assumption of the method used to apportion primary and secondary BrC will cause some error in the
302 distinction of absorption coefficient, it is possible that some of the primary sources are being attributed to secondary sources
303 and vice versa. This maybe a possible reason for the simultaneous peak observed for primary and secondary BrC during
304 morning rush hour. The night had contributions from BC and primary BrC at $50\pm2\%$ and $30\pm3\%$ respectively, with $20\pm3\%$ as
305 secondary BrC. Fig. 4b showed the decrease of primary BrC absorption tended to be more rapid than the HOA and BBOA
306 mass (even a slight increase for HOA Fig. 1m and Fig. 1o) in the midday, leading to decreased absorption coefficient per unit
307 mass of primary BrC (shade in Fig. 4b), which indicates the decrease of BrC absorptivity likely due to photochemistry. This
308 may involve the OH radical reaction with existing chromophores in aerosol phase (Schnitzler et al., 2020) or by enhanced
309 evaporation of aerosols to gas phase (Palm et al., 2020) leading to further decrease of BrC absorptivity during midday. In
310 addition to photobleaching, it possible that some primary species transformed into less absorbing secondary BrC species.
311 During this period, the type of HOA or BBOA that contribute to absorption may also have a lower absorptivity. In this context,
312 a recent chamber study reported that the primary BrC from biomass burning plumes could be bleached to half of the initial
313 absorptivity in 2-3 hours (Liu et al., 2021). The reaction of BrC with OH radical has been widely recognized as the main
314 pathway for the loss of primary BrC absorptivity (Liu et al., 2020), and was parameterized as an exponential decrease with

315 time at certain OH radical concentration in global scale (Wang et al., 2018b).
316 The night and morning peak of OOA2 and the morning peak of the absorption coefficient of secondary BrC ($\sigma_{\text{abs,secBrC}}$) may
317 result from primarily emitted moderately oxygenated OA, which was reported from some diesel sources (Dewitt et al., 2015;
318 Gentner et al., 2012). Besides the morning rush-hour peak, there was an early afternoon peak for $\sigma_{\text{abs,secBrC}}$ prevailing the
319 dilution effect of daytime boundary layer (Fig. 4c-S5). The fraction of $\sigma_{\text{abs,secBrC}}$ in total σ_{abs} thus had a pronounced early
320 afternoon peak soon after the peak solar radiation (Fig. 4f), and a peak after midnight soon after the nighttime peak of primary
321 BrC (Fig. 4e).

322 Fig. 4b-c showed that the MAC of POA decreased after the morning peak, but the MAC of SOA had an afternoon peak. This
323 indicated the enhancement of absorptivity of secondary BrC, which occurred in a few hours after the peak solar radiation.
324 These results implied the photochemical processes decreased the absorptivity of POA but increase for of SOA. Fig 4e-f showed
325 the photochemical processes led to an enhanced contribution of secondary BrC to the total absorption by 30% from the morning
326 rush-hour to midday, but during the same time reduced the contribution of primary BrC to the total absorption about 20%.
327 Though other processes such as aqueous-phase reactions may cause changes to the MAC of BrC at nighttime, the apparent
328 change in aerosol absorption observed in this study can play an important role on the radiative impacts due to intensive solar
329 radiation during daytime.

330 Table 1 showed the SOA compounds containing nitrogen (i.e., the OOA2) considerably contributed to the light absorption.
331 The shift of peaking time from primary to secondary BrC demonstrates the possible processes of SOA formation, such as from
332 gases. This aging or oxidation likely occurred through photochemical processes during early afternoon and aqueous processes
333 (high RH conditions) during nighttime. The oxidized volatile organic compounds (VOCs) with nitrogen chemistry involved
334 could condense to produce additional mass in particle phase (Ehn et al., 2014; Finewax et al., 2018). The high NO_x emission
335 of traffic VOCs may have largely involved nitrogen chemistry in the photochemical processes. Previous studies found the
336 NO_x -involved SOA could produce considerable chromophores containing nitro-aromatics in hours (Wang et al., 2019d; Keyte
337 et al., 2016). The daytime formation of organic nitrate may follow the gas-phase photochemical processes in which the excess
338 NO could add to the peroxy radical to produce organic nitrate (Liebmann et al., 2019). The nighttime chemistry involves NO_3
339 radical through the oxidation of NO_2 by O_3 , through which the organic nitrate could be produced by initializing the production
340 of nitrooxy peroxy radicals (Ng et al., 2008; Rollins et al., 2012). Laboratory studies also widely observed the rapid production
341 of nitrogen-containing OA through NO_x chemistry, which could contribute to light absorption of aerosols (Nakayama et al.,
342 2013; Liu et al., 2015c).

Figure 4. Diurnal variations of absorption coefficient at $\lambda=375\text{nm}$ ($\sigma_{\text{abs},375}$) for BC (a), primary BrC and absorption efficiency of primary BrC ($\sigma_{\text{abs,pri BrC}}/\text{POA}$) is shown in shade (b), secondary BrC and absorption efficiency of secondary BrC ($\sigma_{\text{abs,sec BrC}}/\text{SOA}$) is shown in shade, along with the $\text{C}_x\text{H}_y\text{N}_z$ and $\text{C}_x\text{H}_y\text{N}_z\text{O}_p$ fragments (c); the respective fraction in total for the segregated $\sigma_{\text{abs},375}$ (d-f), with direct radiation shown in shade. In each plot, the lines, dots and whiskers denote the median, mean and the 25th/75th percentiles at each hour respectively.

349 4. Conclusion

350 This study apportioned the shortwave absorption of BC, primary and secondary BrC, through concurrent measurements of BC
351 microphysical properties and OA mass spectra. The apportioned primary BrC absorption was linked with traffic and biomass
352 burning emissions. Primary OA generally had a higher MAC than secondary OA. OA from biomass burning was found to have
353 the highest MAC in POA factors. Secondary BrC was found to be associated with an oxygenated secondary OA factor with
354 higher nitrogen content. We found the photochemical processes decreased the MAC of POA but increased the MAC of SOA,
355 resulting in an enhanced contribution of secondary BrC to total absorbance by 30% but reduced contribution of primary BrC
356 about 20% in the semi-urban environment. This revealed that the whitening and darkening of BrC occurred simultaneously,
357 and the secondary BrC produced by photochemical processes may compensate some bleaching effect of primary BrC. The
358 dominance of both competing processes may depend on the timescale and altitude in the atmosphere. For example, the
359 enhanced BrC fraction observed above the planetary boundary layer may be explained by the enhanced secondary BrC (Tian

360 et al., 2020), while further aging may bleach the produced chromophores of these SOA.

361 The results emphasize the importance of nitrogen-containing OA in contributing to BrC. The NO_x-involved chemistry is prone
362 to add nitrogen element to the existing OA and enhance the absorptivity of chromophores. The anthropogenic NO_x emission
363 could be therefore an important source in producing shortwave absorbing components in the atmosphere, which may offset
364 some of the conventionally-thought photobleaching of BrC by photochemistry. The production of secondary BrC should be
365 considered when assessing the environment and climate impacts of light-absorbing aerosols.
