13 **Abstract.** The light-absorbing organic aerosol (OA), known as brown carbon (BrC), has important radiative impacts, however
14 its sources and evolution after emission remain to be elucidated. In this study, the light absorption at multiple wavelengths,
15 mass spectra of OA and microphysical properties of black carbon (BC) were characterized at a typical sub-urban environment
16 in Beijing. The absorption of BC is constrained by its size distribution and mixing state, being subtracted from total absorption
17 to obtain the absorption of BrC, then by applying the least-correlation of BC absorption with secondary BrC, the absorption
18 contributed by BC, primary BrC and secondary BrC was apportioned. The multi-linear regression analysis on the factorized
19 OA mass spectra indicated the OA from traffic and biomass burning emission contributed to primary BrC. Importantly, the
20 moderately oxygenated OA ($O/C=0.62$) was revealed to highly correlate with secondary BrC. These OA had higher nitrogen
21 content, in line with the nitrogen-containing functional groups detected by the Fourier transform infrared spectrometer. The
22 photooxidation was found to result in reduced contribution of primary BrC about 20% but enhanced contribution of secondary
23 BrC by 30%, implying the concurrent whitening and darkening of BrC. This provides field evidence that the photochemically
24 produced secondary nitrogen-containing OA can considerably compensate some bleaching effect on the primary BrC, hereby
25 causing radiative impacts.

26 1. Introduction

27 Atmospheric absorbing organic aerosol (OA), known as brown carbon (BrC), is important contributor to shortwave absorption
28 besides black carbon (BC) (Laskin et al., 2015; Liu et al., 2020), particularly at shorter visible wavelengths (Bahadur et al.,
29 2012). Due to complex compositions of OA, the primary sources and subsequent evolution of BrC in the atmosphere remains
30 to be explicitly understood and causes uncertainties in evaluating the radiative impacts of BrC (Liu et al., 2020).

31 The chromophores of BrC are mainly aromatic compounds associated with certain functional groups (Liu et al., 2015c).
32 Particularly, compounds containing nitro, nitrated or other forms of nitrogen-containing functional groups are more absorbing
33 (Nakayama et al., 2013; Jacobson, 1999). It is well established that primary OA, especially from biomass burning, contains a
34 large fraction of BrC (Andreae and Crutzen, 1997; Rizzo et al., 2013; Bond, 2001). These primary BrC had a range of
35 absorptivity, which was found to be controlled by burning phases, with OA co-emitting with BC (the flaming phase) exhibiting
36 a higher absorptivity than OA-dominated smoldering phase (Chakrabarty et al., 2010; Saleh et al., 2014). BrC can experience
37 reactions with atmospheric oxidants after emission. A range of field and laboratory studies found the decrease of BrC
38 absorptivity due to photobleaching on chromophores, with half decay time ranging from a few hours (Zhao et al., 2015; Liu et
39 al., 2021) to a few days (Forrister et al., 2015), which may depend on the concentration of ambient hydroxyl radical (Wang et
40 al., 2014). The absorptivity of BrC could be also enhanced due to addition of functional groups by forming conjugated structure
41 with aromatics. This was supported by a number of laboratory studies that BrC absorptivity could be enhanced when forming
42 nitrogen-containing organic compounds, such as the formation of nitro-aromatics when aromatics reacted with NO_x
43 (Nakayama et al., 2013), or produced organic amine after reacting with ammonia (Updyke et al., 2012). The enhancement of
44 BrC absorptivity could occur on existing chromophores, or by producing secondary organic aerosol (SOA) through gas-phase
45 oxidation.

46 The above findings mean the enhancement or bleaching of BrC absorptivity via photooxidation will coexist. The time scale
47 between both competing processes will ultimately determine the lifetime of BrC in the atmosphere. However, both processes
48 have been rarely investigated in the field to explicitly rule out the BrC components which principally determine the respective
49 enhancement or decrease of its absorptivity, particularly in regions influenced by combined anthropogenic sources.

50 In this study, by measurements using multiple-wavelength absorption and microphysical properties of BC in a sub-urban region,
51 the absorption of BC, primary and secondary BrC was discriminated. In conjunction with source attribution via OA mass
52 spectra, we are able to link the segregated absorption with certain sources and investigate their primary information and
53 subsequent evolution. The competition between photobleaching and secondary formation of BrC was investigated in real world.

54 2. Experimental and instrumentation

55 2.1 Site description and meteorology

56 The experiment was conducted during springtime at the Beijing Cloud Laboratory and Observational Utilities Deployment

57 Base (117.12°E, 40.14°N), which is located in the northeast suburban area in Beijing (Fig S1a). The site is surrounded by the
58 northwest mountain ridge, without significant local primary anthropogenic emissions (Hu et al., 2021). The 72-h backward
59 trajectories with every 3 hours initializing from the site are analyzed by the HYSPLIT model (Draxier and Hess, 1998) using
60 the 3-hourly 1°×1° meteorological field from the GDAS reanalysis product. The obtained backward trajectories were further
61 clustered to group the similar transport pathways (Makra et al., 2011). The meteorological parameters, including the
62 temperature (T) and ambient relative humidity (RH) were measured by a monitoring station on the site.

63 2.2 Measurements of BC microphysics and absorption coefficient

64 In this study, the ambient aerosol was sampled after a PM_{2.5} impactor (BGI SCC 1.829) and dried by a silica drier before
65 measurement. The single particle soot photometer (SP2, DMT., USA) was used to measure the refractory black carbon (rBC).
66 The SP2 incandescence signal was calibrated using the Aquadag standard (Acheson Inc., USA), and a factor of 0.75 was
67 applied to correct for ambient BC (Laborde et al., 2012). The scattering signal was calibrated by monodispersed polystyrene
68 latex spheres (PSL). The BC core diameter (D_c) was calculated from the measured BC mass by assuming a BC density of 1.8
69 g cm⁻³ (Bond and Bergstrom, 2006). The leading edge only (LEO) method was applied to reconstruct the scattering signal of
70 BC, which was used to determine the coated particle diameter (D_p) by a Mie-lookup table with the inputs of scattering and
71 incandescence signal of each BC particle (Liu et al., 2014; Taylor et al., 2015). The mass median diameter (MMD) is derived
72 from the D_c distribution, below and above which size the rBC mass concentration is equal (Liu et al., 2019b). The bulk coating
73 thickness (D_p/D_c) was calculated as the cubic root of the total coated BC volume weighted by the total volume of rBC.

74 The mass absorption cross section (MAC) (in m² g⁻¹) of each BC can be calculated using the measured coated and uncoated
75 BC sizes by applying the Mie core-shell calculation. The absorption coefficient of BC at certain wavelength, $\sigma_{\text{abs,BC}}(\lambda)$ is
76 determined by multiplying the calculated MAC and rBC mass concentration at each size:

$$77 \sigma_{\text{abs,BC}}(\lambda) = \sum_i \text{MAC}(\lambda, D_{p,i}, D_{c,i}) m(\log D_{c,i}) \Delta \log D_{c,i} \quad (1)$$

78 where $m(\log D_{c,i})$ denotes the BC mass concentration at each logarithmic bin of D_c .

79 The absorption coefficients at wavelengths $\lambda = 375, 470, 528, 635$ and 880 nm were measured by a Micro-Aethalometer
80 (MA200, Aethlabs, San Francisco, CA, USA). Aerosol particles were collected on filter tapes, on which the light attenuation
81 was measured continuously with a time resolution of 30 s. The loading effect of filters was automatically corrected by
82 measuring attenuation at two different sampling flow rates on two spots in parallel (Drinovec et al., 2015). The multiple light
83 scattering effect was excluded by using a multi-scattering correction factor (C-value) of 3.5, 3.2 and 2.4 at the wavelengths
84 370 nm, 528 nm and 880 nm, respectively. It was obtained by comparing the absorption coefficient with a photoacoustic soot
85 spectrometer (PASS-3, DMT) (Hu et al., 2021).

86 2.3 Attribution of primary and secondary BrC absorption

87 The absorption of BC at different λ is calculated using the measured uncoated core and coated size as mentioned above. The

88 absorption of total BrC is obtained by subtracting the BC absorption from the total absorption at certain wavelength, expressed
89 as:

$$90 \sigma_{\text{abs, BrC}}(\lambda) = \sigma_{\text{abs, total}}(\lambda) - \sigma_{\text{abs, BC}}(\lambda) \quad (2)$$

91 where the absorption coefficient of BC ($\sigma_{\text{abs, BC}}$) is obtained from the SP2 measurement, $\sigma_{\text{abs, total}}(\lambda)$ is the total light absorption
92 of aerosols measured by the MA200. The absorption of secondary BrC, the absorption not contributed by primary sources, is
93 obtained by subtracting the absorption of all primary sources from the total absorption, expressed as:

$$94 \sigma_{\text{abs, secBrC}}(\lambda) = \sigma_{\text{abs, total}}(\lambda) - \sigma_{\text{abs, pri}}(\lambda) \quad (3)$$

95 where $\sigma_{\text{abs, pri}}(\lambda)$ is the light absorption from primary sources. Here an assumption is made that light absorption from primary
96 aerosols is all from combustion sources, and these sources necessarily contain BC (Wang et al., 2018). Therefore, the total
97 absorption from primary sources can be obtained by scaling a factor from the mass concentration of BC, expressed as:

$$98 \sigma_{\text{abs, pri}}(\lambda) = \left(\frac{\sigma_{\text{abs}}}{[\text{rBC}]} \right)_{\text{pri}} \cdot [\text{rBC}] \quad (4)$$

99 where [rBC] is the mass concentration of rBC measured by the SP2, $\left(\frac{\sigma_{\text{abs}}}{[\text{rBC}]} \right)_{\text{pri}}$ is the scaling factor to derive the absorption
100 of primary combustion sources from [rBC]. This factor is obtained using the minimum R-squared (MRS) approach (Wu and
101 Yu, 2016), by adjusting the factor until a minimum correlation between $\sigma_{\text{abs, secBrC}}$ and [rBC] is reached because the absorption
102 from secondary sources are least likely to covary with that from primary sources (Wang et al., 2019a). Being different from
103 previous studies, an auxiliary characterization of rBC mass measured by the SP2 is used here to avoid the possible self-
104 interference from the same measurement on absorption. The $\left(\frac{\sigma_{\text{abs}}}{[\text{rBC}]} \right)_{\text{pri}}$ ratio at $\lambda=375$ nm, 470 nm, 528 nm, 635 nm and 880
105 nm is calculated to be 20.7, 17.0, 14.4, 11.7 and 5, respectively (Fig. S2). This scenario assumes a relatively consistent
106 absorption coefficient relative to BC mass concentration from sources during experiment. This however may not include some
107 sporadic events when sources with distinct OA or BC mass fraction may be introduced and alter the single $\left(\frac{\sigma_{\text{abs}}}{[\text{rBC}]} \right)_{\text{pri}}$ ratio.

108 The $\sigma_{\text{abs, secBrC}}$ therefore represents the overall mean value during the experimental period but this ratio will vary with seasons
109 and locations. The σ_{abs} of primary BrC can then be calculated as:

$$110 \sigma_{\text{abs, priBrC}}(\lambda) = \sigma_{\text{abs, BrC}}(\lambda) - \sigma_{\text{abs, secBrC}}(\lambda) \quad (5)$$

111 where $\sigma_{\text{abs, BrC}}$ and $\sigma_{\text{abs, secBrC}}$ is calculated from Equation (2) and (3), respectively.

112 2.4 Composition measurement

113 The mass concentration and chemical composition of non-refractory sub-micron PM (NR-PM₁) including organic aerosols
114 (OA), nitrate (NO₃⁻), sulfate (SO₄²⁻), chloride (Cl⁻) and ammonium (NH₄⁺) were determined with a High-Resolution Time-of-
115 Flight Aerosol Mass Spectrometer (HR-ToF-AMS, Aerodyne Research Inc., USA). The setup, operation, and calibration
116 procedures of the AMS have been described elsewhere (Canagaratna et al., 2007). During this field observation, the AMS was
117 operated in V-mode for the quantification of mass concentrations. The composition-dependent collection efficiencies were

118 applied (Middlebrook et al., 2012), and the ionization efficiency was calibrated using 300 nm pure ammonium nitrate (Jayne
119 et al., 2000). Elemental ratios of OA including oxygen-to-carbon (O/C), hydrogen-to-carbon (H/C) and nitrogen-to-carbon
120 (N/C) were determined to the improved-ambient method (Canagaratna et al., 2015).
121 Positive Matrix Factorization (PMF) (Paatero and Tapper, 1994) was performed on the inorganic and organic high-resolution
122 mass spectra to distinguish OA components from different sources (Zhang et al., 2011; Ulbrich et al., 2009; Decarlo et al.,
123 2010). The mass spectra of the combined matrix for $m/z < 120$ were excluded in PMF analysis. Five OA factors were identified.
124 The diagnostics of PMF is summarized in Text S1 and Fig. S5.

125 2.5 Offline Fourier transform infrared spectrometer (FTIR) analysis

126 Particulate Matter (PM) samples were collected once a day onto prebaked (600°C , 4h) quartz fiber filters (Whatman, QMA,
127 USA) using a large-flow ($1.05\text{ m}^3\text{ min}^{-1}$) air particle sampler (TH-1000C II). The collected filter samples were stored in the
128 refrigerator at -20°C before analysis. The infrared spectra of collected samples were measured by a Fourier transform infrared
129 spectrometer (FTIR, Thermo Scientific, USA) equipped with an iD5 attenuated total reflectance accessory (diamond crystal)
130 to quantify the chemical functional groups over the wavenumbers range of $550\text{--}4000\text{ cm}^{-1}$ with a resolution of 0.5 cm^{-1} . The
131 NO and NO_2 symmetric stretch in the FTIR spectra can characterize the functional groups associated with nitrogen-containing
132 organics (Coury and Dillner, 2008). Fig. S3 shows typical examples of FTIR spectra and the assigned functional groups for
133 the three pollution levels during experiment. The peak at 1110 cm^{-1} corresponds to the background of the quartz fiber filter
134 overlapped with some X-H bending vibrations, which is subtracted for the following analysis. The characteristic organic nitrate
135 spectra appear at wavenumbers 860 cm^{-1} (NO symmetric stretch), 1280 cm^{-1} (NO_2 symmetric stretch) and $1630\text{--}1640\text{ cm}^{-1}$
136 (NO_2 asymmetric stretch) (Bruns et al., 2010). The FTIR peaks of 1630 cm^{-1} and 860 cm^{-1} are integrated the absorption areas
137 above the baseline. The summed integrated area of -NO and - NO_2 are hereby used to indicate the nitrogen-containing organics.

138 3. Results and Discussion

139 3.1 Source attributed OA

140 The overview results are shown in Fig. S1. The organics dominated the aerosol compositions for most time, but occasionally
141 nitrate was the most abundant component (Fig. S1f). Note that the nitrate here may also include components containing in
142 organics besides ammonium nitrate. Backward trajectories (Fig. S1a-d) showed that the most abundant PM_{10} concentration was
143 associated with air masses transported in shorter distance from southern regions (C1), but the longer and faster northerly
144 transported air mass from cleaner north (C2) could dilute the concentrations.

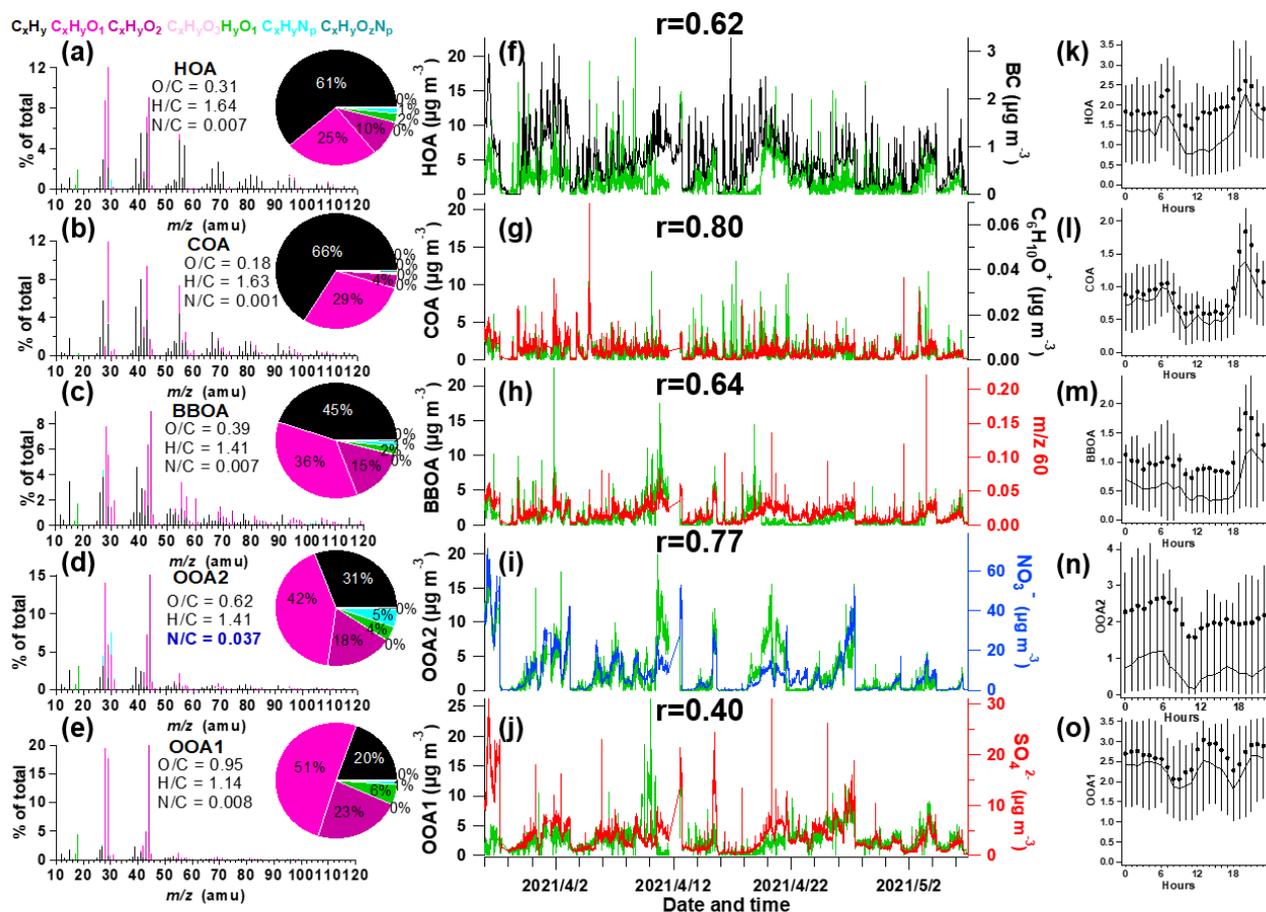

145 The resolved OA factors by the PMF analysis are shown in Fig. 1, including the mass spectra, time series and diurnal profiles
146 of each PMF factor with corresponded external tracers. Three primary OA (POA) were identified as hydrocarbon-like OA
147 (HOA), cooking-related OA (COA), biomass burning OA (BBOA), with O/C of 0.31, 0.18 and 0.39 respectively. These POA

148 had considerable fraction of hydrocarbon fragments (C_xH_y), indicating their less aged status. The HOA concentration correlated
149 well with BC ($r=0.62$), both emitting from traffic emissions. The diurnal variation exhibited strong morning and afternoon
150 rush-hour peaks. The OA from cooking sources (COA) had apparent fragments of both $C_4H_9^+$ and $C_3H_3O^+$, and has a higher
151 ratio of $C_3H_3O^+/C_3H_5O^+$ (3.1), $C_4H_7^+/C_4H_9^+$ (2.2) than HOA (0.9–1.1), with a tracer fragment of $C_6H_{10}O^+$ (m/z 98) (Sun et al.,
152 2011; Mohr et al., 2012). Its minor peak at noon and larger peak in the evening (Fig. 11) also corresponded with the lunch and
153 dinner time respectively.

154 The biomass burning OA (BBOA) was identified to contribute to about 13% of the total OA. Biomass (Cheng et al., 2013) and
155 solid fuel burning emissions (Sun et al., 2014) have been widely observed to importantly contribute to the primary OA in this
156 region. This off-road combustion sources were particularly abundant during wintertime for residential heating activities (Shen
157 et al., 2019; Yang et al., 2018; Liu et al., 2016), while boiler for industry use (mostly using coal as fuel) was in operation
158 throughout the year (Liu et al., 2015b). During the springtime of the experiment, the residential heating activities dropped due
159 to increased ambient temperature thus the BBOA may be mainly contributed by the industry sector.

160 Two types of oxygenated organic aerosols (OOA) were identified, in moderate (OOA2, $O/C=0.62$) and high oxidation state
161 (OOA1, $O/C=0.95$), respectively. The significantly higher mean OOA2 than median value in the diurnal pattern indicated that
162 this OA type was largely associated with pollution events. Both OOA1 and OOA2 showed nighttime peak due to the dark
163 oxidation chemistry under high relative humidity. OOA1 showed particularly high correlation with sulfate ($r=0.40$) because
164 of their similar volatilities (Huffman et al., 2009; Jimenez et al., 2009). The slight enhancement at noon for OOA1 (also for
165 OOA2) soon after morning rush-hour indicated the likely rapid formation of SOA through photooxidation. Notably, OOA2
166 had a substantially higher N/C than other factors ($N/C=0.037$), and had highest correlation with nitrate ($r=0.77$) and with
167 $C_xH_yN_z$ and $C_xH_yN_zO_p$ fragments ($r=0.83$). This factor therefore tends to largely result from nitrogen-containing OA.

173 3.2 Segregated aerosol absorption

174 Fig. 2 shows the time series of BC properties, including the BC mass concentration, D_p/D_c , D_c , MAC and light absorption of
 175 BC (section 2.2). The MMD of BC core varied between 93 – 274 nm which may correspond to the source-specific information
 176 (Liu et al., 2019a) or coagulation process during ageing. The coating of BC (indicated by D_p/D_c) showed sporadic enhancement
 177 which was closely associated with enhanced PM concentration (Fig. 2a). This was consistent with previous studies that high
 178 coatings of BC occurred during heavier pollution due to the enhanced secondary formation of condensable materials to particle
 179 phase (Ding et al., 2019; Zhang et al., 2018). This clearly indicates the variation of mixing state of BC and this will potentially
 180 influence its MAC and absorption Ångström exponent (AAE) (Liu et al., 2015a). It will introduce considerable uncertainties
 181 to use consistent MAC or AAE to derive the absorption of BC at multiple wavelengths. The calculated MAC using the
 182 measured BC core size and coatings (Fig. 2c) is thus used to derive the $\sigma_{\text{abs,BC}}$ (section 2.2, shown in Fig. 2d). MAC of BC at

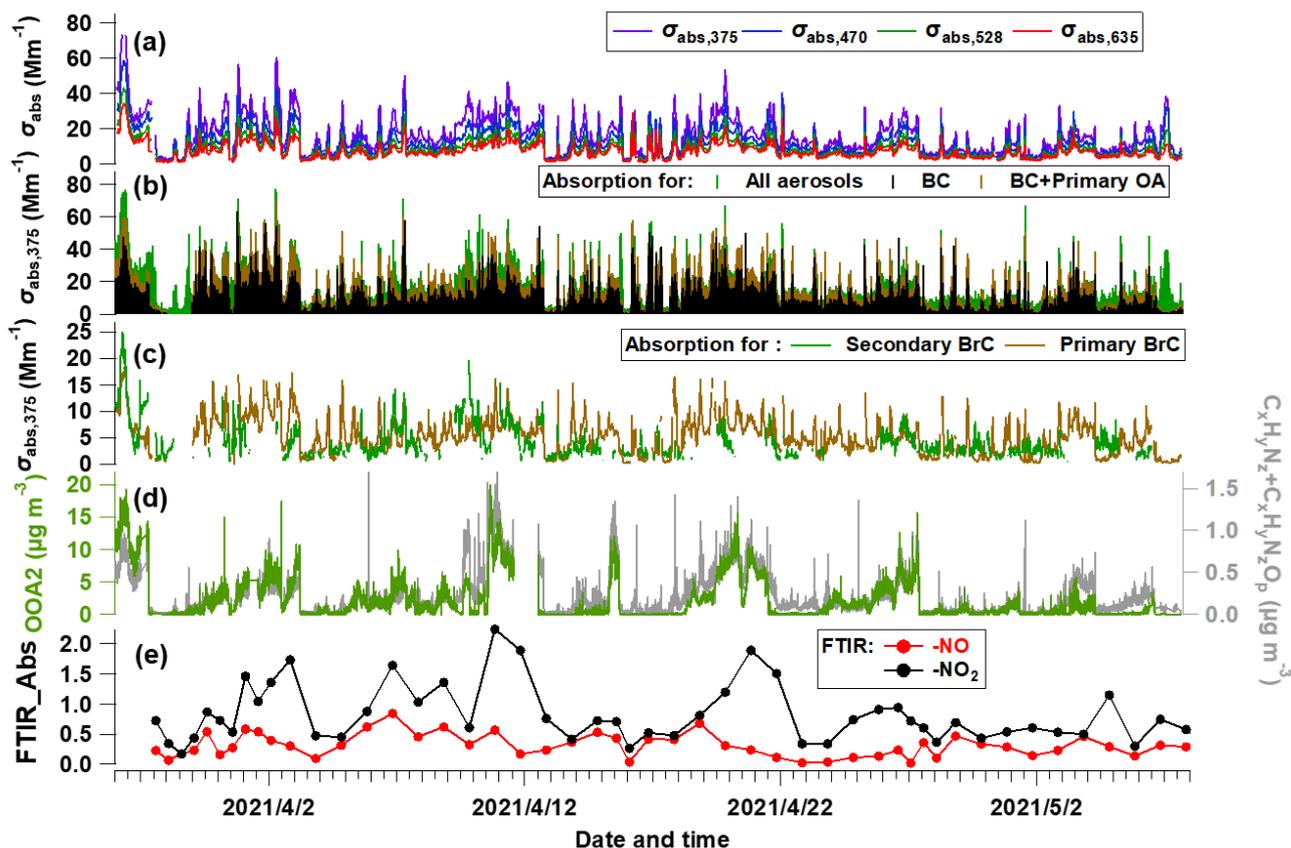

183 $\lambda=375\text{nm}$ is showed to be at $8.4\text{--}16.6\text{ m}^2\text{ g}^{-1}$ with enhanced absorption when high coatings.

184
185 **Figure 2. Temporal evolution of BC-related properties. (a) rBC and PM₁ mass concentration, (b) BC core diameter and bulk coating**
186 **thickness (D_p/D_c), (c) calculated mass absorption cross section (MAC) at $\lambda=375\text{nm}$, (d) absorption coefficient of BC.**

187 Using the calculated $\sigma_{\text{abs,BC}}$ above, the derived σ_{abs} for primary and secondary BrC (section 2.3) at $\lambda=375\text{nm}$ is shown in Fig.
188 3b-c. In Fig. 3b, the brown and green shades above the adjacent tracer indicate the σ_{abs} of primary and all aerosols, respectively.
189 Fig. 3c shows that $\sigma_{\text{abs,priBrC}}$ is higher than $\sigma_{\text{abs,secBrC}}$ for most time, but for certain periods they are equivalent or secondary BrC
190 occasionally exceeds. The mean contribution of absorption for BC, primary BrC and secondary BrC is 50.8%, 27.4% and 21.8%
191 in this study. The tracers associated with nitrogen-containing organics, such as OOA2 (with highest N/C), $\text{C}_x\text{H}_y\text{N}_z$ and
192 $\text{C}_x\text{H}_y\text{N}_z\text{O}_p$ fragments and FTIR measured $-\text{NO} + -\text{NO}_2$ bond vibration, are also shown in Fig. 3d-e.

198 3.3 Source attribution of BrC absorption

199 A multiple linear regression (MLR) analysis is performed to apportion the absorption coefficient of BrC with the PMF
 200 attributed OA factors, expressed as:

$$201 \sigma_{\text{abs,BrC}} = a_0 + a_1 \cdot [\text{OOA1}] + a_2 \cdot [\text{OOA2}] + a_3 \cdot [\text{BBOA}] + a_4 \cdot [\text{COA}] + a_5 \cdot [\text{HOA}] \quad (6)$$

202 where a_0 to a_5 represents the regression coefficients for each factor. The contribution of each source-specific OA factor to
 203 $\sigma_{\text{abs,BrC}}$ can be obtained. This analysis is performed for the total BrC, primary and secondary BrC respectively. The results are
 204 shown in Table 1. MLR on the total BrC shows high correlation ($r > 0.4$) with the factors of HOA, BBOA and OOA2, suggesting
 205 the potential importance of the primary biomass burning and traffic source, in addition to OOA2 in contributing to the
 206 absorption of BrC. MLR analysis on the primary BrC distinguishes its high correlation with BBOA ($r = 0.40$) and HOA ($r = 0.46$),
 207 while MRL on the secondary BrC has a high correlation with OOA2 only ($r = 0.44$). The MRL analysis links the apportioned
 208 absorption by measurements of physical properties with source-attributed chemical compositions, therefore validating and

209 identifying the sources of primary and secondary BrC.

210 **Table 1. Results of the multilinear regression analysis (MLR) between $\sigma_{\text{abs},375}$ and the five PMF-resolved OA factors, with $\sigma_{\text{abs},375}$ of**
 211 **total BrC, primary and secondary BrC as dependent, respectively. All regression coefficients have passed the significance test with**
 212 **$p < 0.01$. Partial correlations above 0.4 are marked in red. Since negative values appear when the COA participates, which is thus not**
 213 **included in the final regression but the values using COA factor are shown in brackets.**

Dependent	$\sigma_{\text{abs,BrC}}$		$\sigma_{\text{abs,pri BrC}}$		$\sigma_{\text{abs,sec BrC}}$	
	Regression coefficient	Partial correlation	Regression coefficient	Partial correlation	Regression coefficient	Partial correlation
Constant	2.26		1.67		1.47 (1.52)	
OOA1	0.57	0.23	0.04	0.02	0.46(0.46)	0.24 (0.24)
OOA2	1.22	0.53	0.37	0.25	0.74 (0.74)	0.44 (0.44)
BBOA	2.59	0.46	1.22	0.40	1.14 (1.18)	0.29 (0.29)
COA	1.30	0.22	1.45	0.36	/ (-0.25)	/ (-0.05)
HOA	1.70	0.47	1.17	0.46	0.49 (0.52)	0.20 (0.21)
R ²	0.77		0.63		0.55 (0.55)	

214 Importantly, an oxygenated secondary OA factor (OOA2) is identified to significantly contribute to the secondary BrC. This
 215 OOA has a moderate O/C (0.62) and a highest N/C of 0.037 among all factors. The high N/C means this factor contains the
 216 most abundant nitrogen-containing fragments, implied as its high correlation with the $\text{C}_x\text{H}_y\text{N}_z$ and $\text{C}_x\text{H}_y\text{N}_z\text{O}_p$ fragments ($r=0.83$,
 217 Fig. 3d) and with the FTIR absorption for -NO₂ and -NO bonds ($r=0.69$, Fig. S4). The -NO bond is mostly related to the
 218 organic nitrates (RONO₂), and -NO₂ peak could result from both organic nitrates and nitro-organics (Bruns et al., 2010). There
 219 is no discernable peak for organic amines. These all consistently imply that the OOA2 factor contained substantial fraction of
 220 nitrogen-containing organics, and these compounds have contributed to the absorption of secondary BrC.

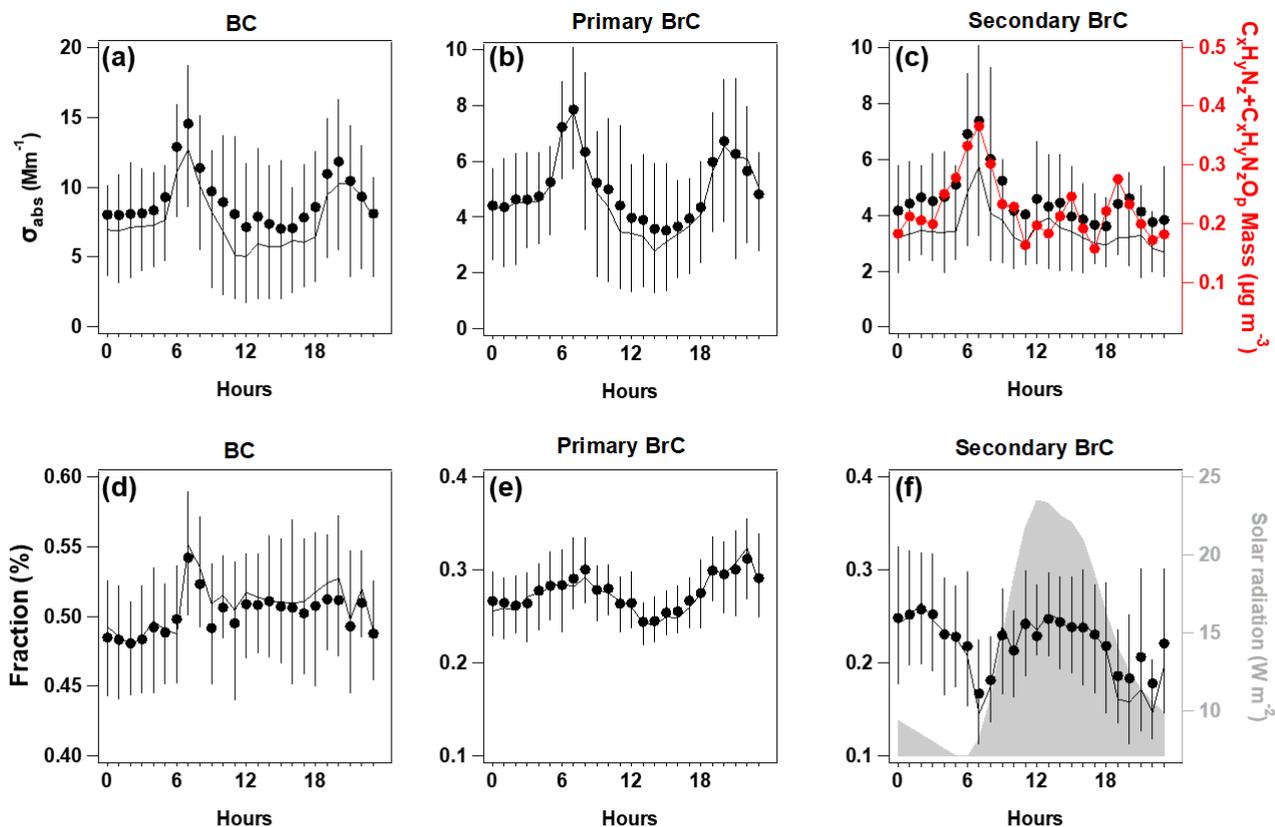

221 3.4 Simultaneous whitening and darkening process of BrC

222 The diurnal variation of $\sigma_{\text{abs},375}$ for BC and primary BrC showed consistent morning rush-hour peaks at 6:00-8:00 and the night-
 223 time enhancement due to reduced boundary layer. This was in line with the morning peak of HOA and night peak of BBOA.
 224 The traffic source in this region, in particular the diesel vehicles, was reported to emit considerable OA with certain
 225 chromophores, such as aromatics (Yao et al., 2015) and heterocyclic organic compounds (Gentner et al., 2017; Schuetzle,
 226 1983). In the morning rush-hour, BC and primary BrC occupied 51±4% and 29±4% in the total $\sigma_{\text{abs},375}$ respectively, with the
 227 remaining 20±2% classified as secondary BrC. The night had contributions from BC and primary BrC at 50±2% and 30±3%
 228 respectively, with 20±3% as secondary BrC. Fig. 4b showed the decrease of primary BrC absorption tended to be more rapid
 229 than the HOA and BBOA mass (even a slight increase for HOA), which indicated the likely photobleaching process causing

230 the decreased absorption efficiency per unit mass for primary BrC. This is consistent with a recent chamber study that the
231 primary BrC could be bleached to half of the initial absorptivity in 2-3 hours for biomass burning plumes (Liu et al., 2021).
232 Besides the morning rush-hour peak, there was an early afternoon peak for the absorption of secondary BrC, prevailing the
233 dilution effect of daytime boundary layer (Fig. 4c). The night and morning peak of OOA2 and the morning peak of $\sigma_{\text{abs,secBrC}}$
234 may result from primarily emitted moderately oxygenated OA, which was reported from some diesel sources (Dewitt et al.,
235 2015; Gentner et al., 2012). The fraction of secondary BrC thus had a pronounced early afternoon peak soon after the peak
236 solar radiation (Fig. 4g) and a peak after midnight soon after the nighttime peak of primary BrC (Fig. 4f). This shift of peaking
237 time from primary to secondary BrC demonstrates the likely process of SOA formation from gases, and these SOA compounds
238 containing nitrogen (i.e., the OOA2) considerably contributed to the light absorption. This ageing or oxidation occurred at
239 early afternoon through photooxidation or likely aqueous processes at nighttime when high RH (Fig. 4h). The oxidized volatile
240 organic compounds (VOCs) with nitrogen chemistry involved could condense to produce additional mass in particle phase
241 (Ehn et al., 2014; Finewax et al., 2018). Due to the high NO_x emission, photooxidation of traffic VOCs may have largely
242 involved nitrogen chemistry. Previous studies found the NO_x -involved SOA could produce considerable chromophores (Lin et
243 al., 2015; Siemens et al., 2022), such as the traffic VOCs may produce SOA in a time scale of hours, containing nitro-aromatics
244 (Wang et al., 2019b; Keyte et al., 2016). The daytime formation of organic nitrate may follow the gas-phase photooxidation
245 mechanism, in which the excess NO could add to the peroxy radical to produce organic nitrate (Liebmann et al., 2019). The
246 nighttime chemistry involving NO_3 through the oxidation of NO_2 by O_3 , contributed to the important formation of organic
247 nitrate by initializing the production of nitrooxy peroxy radicals (Ng et al., 2008; Rollins et al., 2012). Laboratory studies
248 (Nakayama et al., 2013; Liu et al., 2015c) also widely observed the rapid production of nitrogen-containing OA involving NO_x
249 chemistry could contribute to light absorption of aerosols.

250 Overall, by apportioning the absorption of primary and secondary BrC, we found the photooxidation led to an enhanced
251 contribution of secondary BrC by 30% but reduced contribution of primary BrC about 20% in the semi-urban environment.
252 This revealed that the whitening and darkening of BrC had simultaneously, and the secondary BrC produced by photooxidation
253 may compensate some bleaching effect of primary BrC. The dominance of both competing processes may depend on the
254 timescale and location in the atmosphere. For example, the enhanced BrC fraction observed above the planetary boundary
255 layer may be explained by the enhanced secondary BrC (Tian et al., 2020), while further ageing may bleach the produced
256 chromophores of these SOA.

Figure 4. Diurnal variations of absorption coefficient at $\lambda=375\text{nm}$ ($\sigma_{\text{abs},375}$) for BC (a), primary BrC (b), and secondary BrC (c), along with the $\text{C}_x\text{H}_y\text{N}_z$ and $\text{C}_x\text{H}_y\text{N}_z\text{O}_p$ fragments; the respective fraction in total for the segregated $\sigma_{\text{abs},375}$ (d-f), with direct radiation shown in shade. In each plot, the lines, dots and whiskers denote the median, mean and the 25th/75th percentiles at each hour respectively.

261 4. Conclusion

262 This study apportioned the shortwave absorption of BC, primary and secondary BrC, through concurrent measurements of BC
263 microphysical properties and OA mass spectra. The apportioned primary BrC absorption was linked with traffic and biomass
264 burning emissions, while secondary BrC was found to be associated with an oxygenated secondary OA factor with higher
265 nitrogen content. The enhancement of secondary BrC and decrease of primary BrC simultaneously occurred via daytime
266 photooxidation. The results emphasize the importance of nitrogen-containing OA in contributing to BrC. These OA could
267 primarily emit as aerosol phase, or in gas phase which requires further oxidation to be in aerosol phase to serve as BrC. The
268 NO_x -involved chemistry is prone to add nitrogen element to the existing OA and enhance the absorptivity of chromophores.
269 The anthropogenic NO_x emission could be therefore an important source in producing shortwave absorbing components in the
270 atmosphere, which may offset some of the conventionally-thought photobleaching of BrC.
