

A point-by-point response to reviewers

Dear Editor,

We are very pleased to submit a revised manuscript entitled with “The density of ambient black carbon retrieved by a new method: implications to CCN prediction” for possible publication in journal of ACP.

I'd like to thank you for your efforts and time on handling the paper. I also would like to thank the reviewers for their valuable comments and suggestions, all of which have been considered carefully during the revision (a point-by-point response to reviewers as follows). We believe all the comments from the reviewers have been addressed, and the paper have been greatly improved after the revision.

Yours sincerely,

Fang Zhang

On behalf of all authors

A point-by-point response to reviewer

Reviewer #1

The manuscript presents a method for retrieving BC density and implications for CCN prediction. Since the BC density is difficult to measure, it is worth trying to develop new methods for retrieving accurate BC density from available measured data. It is quite interesting. However, more work needs to be done with the manuscript before it can be accepted.

It is not clear how the mixing state and the density of BC are retrieved based the description in the methodology section (2.2)?

- The definition of mixing state is especially not clear. What exactly the mixing state is referred to? Internal? External? Do the authors mean the mass size distributions for the internal and external BC?

Re: (1) To make it more clearly that how the mixing state and the density of BC are retrieved, we just have broken the section (2.2) to two parts section 2.2.1 and 2.2.2, to introduce the methods to retrieve the mixing state and density respectively (see the revised text).

And, regarding to the definition of BC mixing state, in this study, the BC mixing state refers to the heterogeneity of the BC aerosol population. Freshly emitted BC particles, are usually externally mixed in the atmosphere, however, they generally undergo aging processes by condensation, coagulation as well as oxidation (Ivleva et al., 2007; Peng et al., 2016) and gradually become internally mixed (coated) with other chemical components. Here, the number or mass concentration fraction of the internally mixed (coated) and externally mixed (uncoated) BC is respectively retrieved from the hygroscopic and hydrophobic mode of Gf-PDF measured by HTDMA system.

Some statements have been added in the revised text, see **Lines 60-69**, or as follows:

“... BC particles, with diesel vehicles, industrial and residential coal combustion as major sources, are ubiquitous in urban environments (Bond et al., 2013; Dameto et al., 2017; Li et al., 2017; Liu et al., 2019a). The mixing state of BC describes the distribution of the bare BC and coating masteries among the aerosol population. Typically, freshly generated BC exists in the form of chain aggregates and initially uncoated, which is known as externally mixed BC (Ex-BC). When the BC particles were emitted, they generally mix with other materials by condensation, coagulation, and other processes (Riemer et al., 2004; Zhang et al., 2008; Liu et al., 2013; Zhang et

al., 2020), forming the internally mixed BC (In-BC) particles consisting of BC core and other chemical components (Cheng et al., 2006; Zhang et al., 2016) ...”

(2) In Section 2.2, the mass size distribution of externally mixed BC (Ex-BC) was fit using the log-normal distribution which was given in the references (Wu et al., 2017; Liu et al., 2019a; Zhao et al., 2022). Detailed description about the method to retrieve the mixing state of BC (the Ex-BC and In-BC) are given in **Lines 183-209**, or as follows:

“... By assuming that the particles are spherical (Rader and McMurry, 1986), the mass size distribution of Ex-BC ($M_{\text{Ex-BC}}$) was obtained as follows:

$$M_{\text{Ex-BC}}(\log D_p) = \frac{\pi}{6} D_p^3 \rho n_{\text{Ex-BC}}(\log D_p) \quad (5)$$

where D_p is the mobility diameter, ρ is the effective density of Ex-BC, and $n_{\text{Ex-BC}}(\log D_p)$ is the function of the number size distribution of Ex-BC, respectively. By reviewing and summarizing the existing results about, we show that typical values of density for the freshly emitted or externally mixed BC observed in the winter of urban Beijing or North China Plain spans over 0.14-0.50 g cm⁻³, with mean of $\sim 0.40 \pm 0.10$ g cm⁻³ (Fig. S3), in the size range of 100 to 300 nm, where the mass concentration of externally mixed BC accounted for a large proportion in urban Beijing (Geller et al., 2006; Peng et al., 2016, 2017; Wu et al., 2019; Liu et al., 2020; Zhao et al., 2022). Therefore, an average $\rho_{\text{Ex-BC}}$ of 0.4 g cm⁻³ was used for calculating the mass concentration of externally-mixed BC in our study. The uncertainty analysis exhibits that the variations of the $\rho_{\text{Ex-BC}}$ could lead to an average deviation of ± 10 % in the calculating In-BC density (Fig. 2e) by increasing the $\rho_{\text{Ex-BC}}$ from 0.1 to 0.6 g cm⁻³, showing a small impact on the retrieved result. Uncertainty analyses due to the variations of $\rho_{\text{Ex-BC}}$ were given in section 2.3.

The mass size distribution of Ex-BC was fit using the log-normal distribution as shown in Fig. S4 (Wu et al., 2017; Liu et al., 2019a; Zhao et al., 2022). Thus, the bulk mass concentration of Ex-BC can be calculated from the integration of the mass size distribution:

$$m_{\text{Ex-BC}} = \int_{D_{\text{start}}}^{D_{\text{end}}} M_{\text{Ex-BC}}(\log D_p) d \log(D_p) \quad (6)$$

$$m_{\text{In-BC}} = m_{\text{BC}} - m_{\text{Ex-BC}} \quad (7)$$

where D_{start} and D_{end} are the lower and upper size limit, $M_{\text{Ex-BC}}(\log D_p)$ is the function of the Ex-BC mass size distribution. We then obtained the bulk mass concentration of internally mixed BC ($m_{\text{In-BC}}$) by subtracting $m_{\text{Ex-BC}}$ from the bulk BC mass

concentration measured by AE33 in equation 7 ...”

- The density is calculated by equation 8, so in the calculations, there must be lots of assumptions for the relevant parameters. How each parameter in the equation is determined? Those need to be clearly described. It is obviously not well illustrated in the current version.

Re: thanks a lot for the comments. In the revision, we just have clarified and added some illustrations for the relevant parameters in equation 8, and an uncertainty analysis of each assumed parameter has been done, see **Lines 210-347**, as follows (see Figs. R1 and R2):

“2.2.2 Retrieving the density of BC

For retrieval of the density of BC, the principal idea is to use the measured κ_{gf} to calculate the density of BC based on the Zdanovskii–Stokes–Robinson (ZSR) mixing rule (Stokes and Robinson, 1966; Zdanovskii, 1948) with the chemical composition measured by AMS (Petters & Kreidenweis, 2007). In the retrieval, several aspects are concerned. First, since the ZSR rule is to assume the aerosol particles are internally mixed, the κ_{gf} value of the more MH mode (κ_{gf-MH}) is thus applied for retrieving the density of internally mixed BC. Second, since the size distribution of BC number concentration is usually with peaks between 100 and 200 nm (Liu et al., 2019a; Yu et al., 2020; Zhao et al., 2022), the κ_{gf-MH} value of particles in accumulation mode was averaged and applied for the retrieval. Previous studies showed an independence of κ_{gf-MH} on particle size when the $D_p > 100$ nm during the campaign period (Fan et al., 2020). Therefore, the average of κ_{gf-MH} in accumulation mode is reasonable for the determination of the In-BC density. In addition, because the inversion including measurements from HTDMA and HR-AMS, a total mass closure of the measured aerosol particles was conducted between the two techniques by comparing the mass concentration of PM_{10} and the results are well consistent (Fig. S5). The density of internally mixed BC (In-BC), ρ_{In-BC} is then derived from the following equations:

$$\kappa_{gf-MH} = \kappa_{chem} = \sum_i \varepsilon_i \kappa_i = \frac{v_{inorg}}{v_{total}} \kappa_{inorg} + \frac{v_{SOA}}{v_{total}} \kappa_{SOA} + \frac{v_{In-POA}}{v_{total}} \kappa_{POA} + \frac{v_{In-BC}}{v_{total}} \kappa_{BC} \quad (8)$$

where κ_{gf-MH} is the hygroscopic parameter of the more hygroscopic (MH) mode, κ_{chem} is the hygroscopic parameter of aerosol particles in the mixed composition and can be calculated based on chemical volume fractions using a simple rule (Stokes and Robinson, 1966; Petters & Kreidenweis, 2007), κ_i is the hygroscopic parameter of each

pure composition and ε_i is the volume fraction of the individual components in the internal-mixed particle. v_{inorg} , v_{SOA} and v_{In-POA} are the volume of the inorganic, SOA and internally mixed POA species, and can be calculated as follows: $v_{inorg} = \frac{m_{inorg}}{\rho_{inorg}}$, $v_{SOA} = \frac{m_{SOA}}{\rho_{SOA}}$, and $v_{In-POA} = \frac{m_{In-POA}}{\rho_{POA}}$. v_{total} is the total volume of all the species and can be written as $v_{total} = \frac{m_{inorg}}{\rho_{inorg}} + \frac{m_{SOA}}{\rho_{SOA}} + \frac{m_{In-POA}}{\rho_{POA}} + \frac{m_{In-BC}}{\rho_{In-BC}}$. In equation (8), κ_{BC} and κ_{POA} are assumed to be 0. Then, the ρ_{In-BC} can be calculated based on its mass concentration and volume as follows:

$$\rho_{In-BC} = \frac{m_{In-BC}}{\left(\frac{m_{inorg} \kappa_{inorg} + m_{SOA} \kappa_{SOA}}{\rho_{inorg} \kappa_{gf-MH}} + \frac{m_{inorg}}{\rho_{inorg}} + \frac{m_{SOA}}{\rho_{SOA}} + \frac{m_{In-POA}}{\rho_{POA}} \right)} \quad (9)$$

where, m_{In-BC} is the mass concentration of internally mixed BC, m_{inorg} and m_{SOA} are the mass concentrations of the inorganic species and SOA, which are measured by the AMS. m_{In-POA} is the mass concentrations of internally mixed POA and can be calculated subtracting the mass fraction of NH-POA from the total mass concentrations of POA. ρ_{inorg} , ρ_{SOA} and ρ_{POA} are the density of the inorganic species, SOA and POA. Since the AMS measures the concentrations of the organic and inorganic ions, including SO_4^{2-} , NO_3^- , NH_4^+ , Cl^- . Here inorganic species were derived by applying a simplified ion pairing scheme (Gysel et al., 2007) to convert mass concentrations of ions to the inorganic salts as follows:

$$\begin{aligned} n_{NH_4NO_3} &= n_{NO_3^-} \\ n_{NH_4HSO_4} &= \min(2n_{SO_4^{2-}} - n_{NH_4^+} + n_{NO_3^-}, n_{NH_4^+} - n_{NO_3^-}) \\ n_{(NH_4)_2SO_4} &= \max(n_{NH_4^+} - n_{NO_3^-} - n_{SO_4^{2-}}, 0) \\ n_{H_2SO_4} &= \max(0, n_{SO_4^{2-}} - n_{NH_4^+} + n_{NO_3^-}) \end{aligned} \quad (10)$$

where n represents the number of moles, then the mass concentrations were obtained by the number of moles times the molar mass of each inorganic salts. Because the maximum value of the $n_{H_2SO_4}$ was zero in this campaign. Three inorganic salts including NH_4HSO_4 , $(NH_4)_2SO_4$, and NH_4NO_3 were applied in our study. The densities for inorganic salts were taken from previous studies (Gysel et al., 2007; Wu et al., 2016). Here the densities for three inorganics are 1.78, 1.769 and 1.72 g cm⁻³, respectively. By summarizing the previous studies (Gysel et al., 2007; Dinar et al., 2006), 1.4 g cm⁻³ was

selected as the density of SOA (ρ_{SOA}). The density of POA (ρ_{POA}) is assumed to be 1.0 g cm^{-3} for urban environments, which is similar to the lubricating oil (Wu et al., 2016). Considering the cooking organic aerosols represent a high contribution to POA in urban environments, a density of 0.85 g cm^{-3} chosen as the mean density for the rapeseed oil and oleic acid (Reyes-Villegas et al., 2018) was also used to evaluated the result as shown in section 2.3. The values of κ for inorganic components are 0.56 for NH_4HSO_4 , 0.48 for $(\text{NH}_4)_2\text{SO}_4$ and 0.58 for NH_4NO_3 , along with the best-fit values for the three inorganic salts (Petters & Kreidenweis, 2007 and Gunthe et al., 2009). The κ_{SOA} is assumed to be 0.15 according to the field studies in urban areas (Chang et al., 2010; Kawana et al., 2016) ...”

“2.3 Uncertainties and limitations

For the retrieval, the assumptions on the values of κ_{SOA} , ρ_{POA} , ρ_{SOA} and $\rho_{\text{Ex-BC}}$ as well as the fraction of primary organic aerosols in non-hygroscopic or hygroscopic mode would add uncertainty in the inferred values of ambient internally mixed BC density. For example, the freshly emitted POA particles might consistently be coated with the secondary particles during the aging process, resulting in changes of the $NF_{\text{NH-POA}}$. However, a real-time variation of the $NF_{\text{NH-POA}}$ is not yet available due to the lack of such measurements data. Applying the rough fractions of hydrophobic POA only under three different atmospheric conditions could still cause uncertainties. Also, the densities of POA and SOA may differ due to their precursors, emission sources and the formation mechanisms in ambient atmosphere (Alfarra et al., 2006; Reyes-Villegas et al., 2018). And the density of Ex-BC is generally characterized by the morphology and size (Wu et al., 2019). In addition, the value of κ_{SOA} spans largely due to the variability in the emissions of gas precursors and formation processes under different atmospheric conditions (Zhang et al., 2015; Liu et al., 2021b). Therefore, we examined the sensitivities of In-BC density to the variations of these factors, as exhibited in Fig. 1 and Fig.2.

The figures show that the In-BC density gradually decreases with the increment of the $NF_{\text{NH-POA}}$, implying the higher fraction of bare POA particles correspond to the early aging stage of aerosol particles. With increase of κ_{SOA} , the In-BC density is generally reduced, but with small fluctuations (Fig.1a, Fig. 2b). This suggests a complex impact of assumptions of κ_{SOA} on the retrieved BC density. In addition, the In-BC density decreases very slightly as $\rho_{\text{Ex-BC}}$ increases (Fig. 2e), suggesting applying a larger $\rho_{\text{Ex-BC}}$ would derive smaller values for In-BC density. The In-BC density is insensitive to the

changes of the density of POA and SOA, showing an almost negligible effect on the retrieved results (Fig. 2c and d).

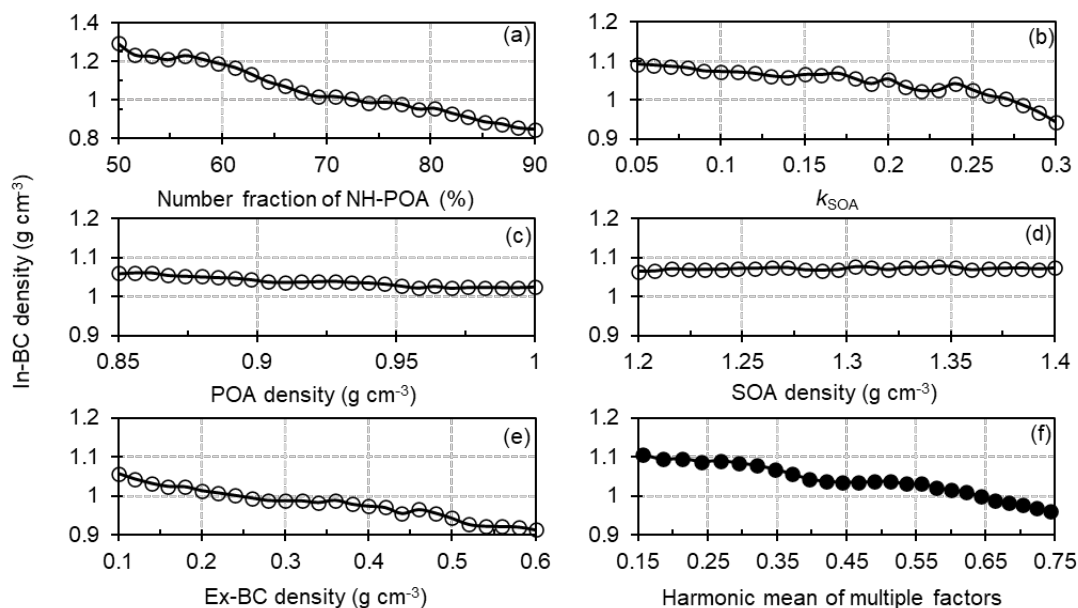

Fig. R1 Sensitivity of the In-BC density to variations in the number fraction of nearly hydrophobic (NH) POA (a), the hygroscopic parameter of SOA (b), the POA density (c), the SOA density (d), the externally mixed BC density (e) and the harmonic mean of multiple factors (f).

The uncertainty analysis shows that, by comparing the results based on the mean fractions of the $NF_{\text{NH-POA}}$ with a typical atmospheric observed range of 50-90 % for the $NF_{\text{NH-POA}}$ (Liu et al., 2021a), we show that the assumption on $NF_{\text{NH-POA}}$ can lead to relative deviations (uncertainty) of -17 %–+27 % for the retrieved BC density (Fig. 3a).

In addition, unlike inorganics (eg., NH_4HSO_4 , $(\text{NH}_4)_2\text{SO}_4$ and NH_4NO_3), which the hygroscopicity has been already well-understood (Petters and Kreidenweis, 2007), the hygroscopicity of organic species varies largely due to the complexity in organic aerosol constituents. Therefore, the assumption of the values of κ_{SOA} will add the uncertainty in the calculation of BC density. Previous studies have suggested that the organics has a wide range of κ values ranging from 0.05 to 0.3 (Jimenez et al., 2009; Mei et al., 2013). Thus, the sensitivity test has also been done to examine the effect due to changes in κ_{SOA} on calculating the density of BC (Fig. 1a). The result shows that the assumption of κ_{SOA} value can cause an average relative deviation of -10 %–+3 % in calculating the density of In-BC (Fig. 3b).

Fig. R2 Relative deviations of the number fraction of nearly hydrophobic (NH) POA to the In-BC density (a), the hygroscopic parameter of OA to the In-BC density (b), the POA density to the In-BC density (c), the SOA density to the In-BC density (d), the externally mixed BC density to In-BC density (e) and the combined deviations based on multiple factors mentioned above (f).

However, the sensitivity test shows that the impact of both the ρ_{POA} and ρ_{SOA} variations on the BC density estimation is very small or even negligible (Fig. 1b, c). By varying the ρ_{POA} from 0.85 to 1.0 $g\ cm^{-3}$ and the ρ_{SOA} from 1.2 to 1.4 $g\ cm^{-3}$ according to the literatures (Noureddini et al., 1992; Alfarrar et al., 2006; Reyes-Villegas et al., 2018), the retrieval uncertainties in the BC density are within $\pm 5\%$ and $\pm 1\%$ respectively (Fig. 3c, d). For ρ_{EX-BC} , it exhibits that the evolution of the ρ_{EX-BC} could lead to an average deviation of $\pm 10\%$ in calculating In-BC density (Fig. 3e) when increasing the values of ρ_{EX-BC} from 0.1 to 0.6 $g\ cm^{-3}$, which represents a typical range in ambient atmosphere (Wu et al., 2019; Liu et al., 2020). A combined uncertainty (δ) caused by the multiple factors (δ_i), which is calculated by equation 12, is -21% – $+29\%$ as shown in Fig. 3f.

$$\delta = \sqrt{\sum_{i=1}^n \delta_i^2} \quad (12)''$$

The authors attribute the density fluctuations of the internally mixed BC and the bulk BC to the mixing state and the rapid aging from the variation of emissions (Fig. 3b&c). However, how the changes of emissions affect the parameters contributing to the density remains unexplored. For example, how the parameters in equation 8 are affected

by changing the emissions? In addition, it is difficult to discriminate the in-BC and ex-BC in Fig. 3a. It is suggested to change the color of the in-BC to increase the contrast between them.

Re: It is a good point to include some discussions about how the changes of emissions affect the parameters contributing to the density. In equation 9 for the revised text, as the reviewer commented, the assumptions on the parameters, e.g. k_{SOA} , ρ_{POA} , can cause errors or bias to the retrieved value of BC density because of the changes in emissions and atmospheric processes of the particles. For example, the aging process may change the number fraction of the nearly-hydrophobic POA particles. Here, the observed fraction of bare POA from the total POA particles (bare POA and POA-containing) from the contemporaneous observations in literature (Liu et al., 2021a) was referred. Also, the variations of $\rho_{\text{Ex-BC}}$ have been demonstrated from the diesel exhaust (Park et al., 2003) to urban environments (Rissler et al., 2014; Wu et al., 2019). Additionally, the density of POA, SOA and the hygroscopic parameter of SOA (k_{SOA}) may also vary in different environments due to the changes in emissions or atmospheric aging processes of particles. For example, Wu et al. (2016) showed that the POA density was like the value of lubricating oil (1.0 g cm^{-3}). As the cooking organic aerosols represent a high contribution to POA in urban environments, the POA density might decrease. Thus, we investigated the sensitivity of variations of ρ_{POA} to the BC density by ranging the ρ_{POA} from 0.85 to 1.0 g cm^{-3} according to the literatures (Noureddini et al., 1992; Alfara et al., 2006; Reyes-Villegas et al., 2018). Similarly, the SOA density may differ due to their precursors and the formation mechanism. For example, the effective density for the 1,3,5-trimethylbenzene SOA ranged from $1.35\text{--}1.40 \text{ g cm}^{-3}$, while that for α -pinene SOA ranged from $1.29\text{--}1.32 \text{ g cm}^{-3}$ (Alfara et al., 2006). The hygroscopicity of OA varies largely depending on the chemical composition, types, and emissions of gas precursors under different environmental conditions (Fan et al., 2020; Zhang et al., 2015), with a wide range of κ values from 0.05 to 0.3 (Jimenez et al., 2009; Mei et al., 2013).

For these reasons, we have investigated the sensitivities of In-BC density to the variations of the assumptions on the parameters in **Section 2.3 (Lines 316-346, Fig. R2)** or as follows:

“... The uncertainty analysis shows that, by comparing the results based on the mean fractions of the $NF_{\text{NH-POA}}$ with a typical atmospheric observed range of 50-90 % for the $NF_{\text{NH-POA}}$ (Liu et al., 2021a), we show that the assumption on $NF_{\text{NH-POA}}$ can lead

to relative deviations (uncertainty) of -17 %–+27 % for the retrieved BC density (Fig.3a).

In addition, unlike inorganics (eg., NH_4HSO_4 , $(\text{NH}_4)_2\text{SO}_4$ and NH_4NO_3), which the hygroscopicity has been already well-understood (Petters and Kreidenweis, 2007), the hygroscopicity of organic species varies largely due to the complexity in organic aerosol constituents. Therefore, the assumption of the values of κ_{SOA} will add the uncertainty in the calculation of BC density. Previous studies have suggested that the organics has a wide range of κ values ranging from 0.05 to 0.3 (Jimenez et al., 2009; Mei et al., 2013). Thus, the sensitivity test has also been done to examine the effect due to changes in κ_{SOA} on calculating the density of BC (Fig. 1a). The result shows that the assumption of κ_{SOA} value can cause an average relative deviation of -10 %–+3 % in calculating the density of In-BC (Fig. 3b).

However, the sensitivity test shows that the impact of both the ρ_{POA} and ρ_{SOA} variations on the BC density estimation is very small or even negligible (Fig. 1b, c). By varying the ρ_{POA} from 0.85 to 1.0 g cm^{-3} and the ρ_{SOA} from 1.2 to 1.4 g cm^{-3} according to the literatures (Noureddini et al., 1992; Alfarra et al., 2006; Reyes-Villegas et al., 2018), the retrieval uncertainties in the BC density are within $\pm 5\%$ and $\pm 1\%$ respectively (Fig. 3c, d). For $\rho_{\text{EX-BC}}$, it exhibits that the evolution of the $\rho_{\text{EX-BC}}$ could lead to an average deviation of $\pm 10\%$ in calculating In-BC density (Fig. 3e) when increasing the values of $\rho_{\text{EX-BC}}$ from 0.1 to 0.6 g cm^{-3} , which represents a typical range in ambient atmosphere (Wu et al., 2019; Liu et al., 2020). A combined uncertainty (δ) caused by the multiple factors (δ_i), which is calculated by equation 12, is -21 %–+29 % as shown in Fig. 3f ...”

(2) According to the reviewer's suggestion, the color of the Fig 3a has been adjusted (Fig. R3 or Fig. 4) as follows,

Fig. R3 (a) Time series of the mass fraction of the retrieved internal- and external-mixed BC; (b) Time series of the retrieved density of the bulk and internal- mixed BC (In-BC); (c) Diurnal variation of the retrieved density of bulk and In-BC; (d) Comparison of the results of the derived In-BC density in this study with that reported in literatures.

Pertinent to comment #2, what factors determine the retrieved BC density? Are they explicit in equation 8? How the correlations between those factors and the BC density? Can the authors explore more on this?

Re: Thanks for the comments. For the retrieval, the assumptions on the values of κ_{SOA} , ρ_{POA} , ρ_{SOA} and ρ_{Ex-BC} as well as the fraction of primary organic aerosols in non-hygroscopic or hygroscopic mode would add uncertainty in the inferred values of ambient internally-mixed BC density. To investigate the main factors determining the retrieved BC density, we evaluate the sensitivities of In-BC density to the variations of these factors in Section 2.3. The results suggest that the number fraction of non-hygroscopic POA (NF_{NH-POA}) and the hygroscopic parameter of SOA have larger

impacts on the estimation of BC density compared to other factors. The correlations between $NF_{\text{NH-POA}}$, κ_{SOA} , ρ_{POA} , ρ_{SOA} as well as $\rho_{\text{Ex-BC}}$ and the In-BC density are quantified as shown in **Fig. R1** or Fig. 2.

Some discussions about this have been included in the revised paper, see **Lines 298-306**, as follows:

“...The figures show that the In-BC density gradually decreases with the increment of the $NF_{\text{NH-POA}}$, implying the higher fraction of bare POA particles correspond to the early aging stage of aerosol particles. With increase of κ_{SOA} , the In-BC density is generally reduced, but with small fluctuations (Fig.1a, Fig. 2b). This suggests a complex impact of assumptions of κ_{SOA} on the retrieved BC density. In addition, the In-BC density decreases very slightly as $\rho_{\text{Ex-BC}}$ increases (Fig. 2e), suggesting applying a larger $\rho_{\text{Ex-BC}}$ would derive smaller values for In-BC density. The In-BC density is insensitive to the changes of the density of POA and SOA, showing an almost negligible effect on the retrieved results (Fig. 2c and d) ...”

The calculation of critical size is based on pure water assumption for the surface tension and water density, which may cause uncertainties. The authors should discuss the uncertainties associated with the assumption.

Re: It is true that there may be some uncertainties by assuming the surface tension (σ) and water density in calculating the critical diameter. The organic matter in particles can act as surfactants to lower the surface tension of the particles and hence increase the CCN activity (Ovadnevaite et al., 2017). The effect of the surface tension on CCN activity have been explored in both field and laboratory studies (McFiggans et al., 2006; Meng et al., 2014; Ovadnevaite et al., 2017; Cai et al., 2018; Hu et al., 2020). For example, Ovadnevaite et al. (2017) found that a reduction of σ from 0.072 to 0.049 J m⁻² was required to meet with the CCN measurement for the higher supersaturations (SS). Cai et al. (2018) also suggested that the CCN number concentration would be undepreciated if the surface tension of pure water was used. Meng et al. (2014) showed that the surface tension depression may be more pronounced at small particle sizes, which is because the organics are more concentrated on small particles. These results suggest that the usage of the surface tension of pure water would overestimate the critical diameter and underpredict CCN number concentration but more pronounced at small particle sizes. In our study, the SS for CCN activity was set to 0.23 % and 0.40 %, which represent the common supersaturation conditions for stratiform or moderately convective clouds (Moteki et al., 2019), with larger critical diameters of about 90 nm

and 70 nm. Some discussions about their effect on the critical diameter and CCN number concentration have been included in the revised paper, see **Lines 459-469**, as follows:

“... It should be noted that the assumption of the surface tension of water would overestimate the critical diameter and underpredict CCN number concentration. While the surface tension depression might be more obvious for the small size particles (<60 nm), as the fraction of organics are higher at small particles size (Meng et al., 2014; Cai et al., 2018). Here, in this study, we calculated the critical diameters at supersaturations of 0.40 % and 0.23 %, typical values in cloud, corresponding to larger sizes (> 70 nm and 90 nm) of aerosols. Therefore, the uncertainties from the application of the surface tension of pure water should be negligible (< 10 %). Here, three schemes were assumed to evaluate the effect of BC density and mixing state on prediction of CCN number concentrations. The detailed calculation methods are presented in the supporting information (SI: Methods) or referenced from Ren et al., 2018 ...”

In addition, the density of water would change with temperature, which might bring some bias in calculating the critical size. Here, in our study, to make the results comparable, all the parameters were adjusted to standard conditions in the κ -Köhler relationship (eg., temperature, density water) (Petters & Kreidenweis, 2007). Some introductions about the uncertainty of water density have been added in the **supplement**, or as follow:

“... By applying the hygroscopicity parameter κ_{chem} into κ -Köhler relationship (Petters & Kreidenweis, 2007), the critical diameter or activation diameter (D_{cut}) can be obtained at a given supersaturation (S). Thus, the CCN concentration can be predicted by using the critical diameter and particle number size distribution.

The equations used in the estimating N_{CCN} are as follows,

$$CCN_{pre} = \int_{D_{cut}}^{D_{end}} n(\log D_p) d \log D_p \quad (1)$$

where D_{cut} is the critical diameter, D_{end} is the upper size limit of the particle number size distribution (PNSD), $n(\log D_p)$ is the function of the aerosol number size distribution.

$$D_{cut} = \sqrt[3]{\frac{4A^3}{27\kappa \ln^2 S}}, \quad A = \frac{4\sigma_{s/a} M_w}{RT\rho_w} \quad (2)$$

where κ is the hygroscopicity parameter, S is a given supersaturation, M_w is the molecular weight of water, $\sigma_{s/a}$ is the surface tension of pure water, ρ_w is the density of water, R is the gas constant, and T is the absolute temperature. Here the parameters T and ρ_w were adjusted to standard conditions ($T=298.15K$) ...”

In Fig. 5, what is the measured N_{CCN} . What method is this based on? Are they the same for the N_{CCN} in Fig. 5 and Fig. 6? How are the differences between the CCN number concentration predicted based on the retrieved BC density and based on the HTDMA? Can the authors discuss more on this?

Re: The N_{CCN} in Fig. 5 was measured by a Droplet Measurement Technologies CCN counter (CCNc, DMT; Lance et al., 2006), which is widely used in the measurement of CCN number concentration. During the field campaigns, atmospheric particles were sampled after a $PM_{2.5}$ impactor and then dried by a Nafion tube before being measured by instrument. The relative humidity of the sample flow was below 30 %. Polydisperse dry aerosol was neutralized with a Kr-85 diffusion charger and introduced into a differential mobility analyzer (DMA, TSI 3081) to output mono-dispersed particle. The mono-dispersed aerosol is then split between a condensation particle counter (CPC, TSI 3772) with flow rate of 0.5 L min^{-1} and a Cloud Condensation Nucleus counter (CCNc, DMT) with flow rate of 0.5 L min^{-1} . At each particle dry size, the CCN number concentration measured by the CCNc can be obtained, hereby the N_{CCN} was obtained by integrating over the size range. Detailed description about the instrument and data correction can be found in Ren et al., 2018 and here a brief introduction was given in this study. The measured N_{CCN} in Fig. 5 and Fig. 6 are same.

Therefore, in this study, the effect of BC density on CCN activity was investigated through the CCN closure of the measured N_{CCN} and the predicted N_{CCN} . The measured N_{CCN} is based on the measurement of CCN counter, not HTDMA. The predicted N_{CCN} is calculated by using the critical diameter and the particle number size distribution. The critical diameter is calculated based on Köhler theory and ZSR rule. For a multicomponent particle, the Zdanovskii–Stokes–Robinson (ZSR) mixing rule (Stokes and Robinson, 1966) can also estimate κ_{chem} using chemical composition data:

$$\kappa_{chem} = \sum_i \varepsilon_i \kappa_i \quad (1)$$

where ε_i and κ_i are the volume fraction and κ for the i th chemical component, respectively.

The BC density was retrieved based on the closure between the κ_{gf} from HTDMA and κ_{chem} . The κ_{gf} is derived using κ -Köhler theory based on hygroscopic growth factor (Gf) (Petters and Kreidenweis, 2007). The κ_{chem} is calculated based on chemical volume fractions by using the ZSR rule according to the equation 1.

Minor comments: there are a lot of typos, ill-sentences which need to be cleared in the revised version.

- Title: I am not quite sure this is a new method
Re: Previously, the BC density are usually directly measured by several techniques, such as an integrated system of a volatility tandem differential mobility analyzer and a single particle soot photometer (VTDMA-SP2) (Zhang et al., 2016), or a differential mobility analyzer with a SP2 (DMA-SP2) (Olfert et al., 2007; Rissler et al., 2014; Wu et al., 2019), and a differential mobility analyzer–centrifugal particle analyzer–single-particle soot photometer (DMA–CPMA–SP2) system (Liu et al., 2019b; Yu et al., 2020), etc. To our knowledge, this is, for the first time, we derived the BC density by using the by combining field measured hygroscopic growth factor and aerosol chemical composition and Köhler theory. Therefore, we think it is a new method.

A point-by-point response to reviewer

Reviewer #2

This study attempts to derive the “density” of BC from the hygroscopic growth factor measured by the HTDMA and total BC mass by the aethalometer. I appreciate the authors’ effort to derive the density of BC from measurements not directly linking with BC. This is indeed challenging from a bulk HTDMA measurement to derive BC information, as the BC only constitutes of a small fraction of ambient atmospheric particles. However, the current method is still not convincing. The crucial points are:

1) The total hydrophobic particle number was measured, and a fixed fraction of 70% of hydrophobic OA is used to obtain the hydrophobic BC from the total. This fixed “70%” is obviously not correct. Additionally, how have you got the number concentration of OA.

Re: Thanks a lot for the comments.

(1) It is true that, the POA particles would be mixed with the secondary inorganic or organic particles during the aging process. The number fraction of the nearly-hydrophobic POA would change with the emission and aging processes. As the reviewer commented, instead of using a fixed fraction of 70%, we just have applied different values for fractions of hydrophobic POA under clean, moderately polluted, and heavily polluted conditions by referring the literature (Liu et al., 2021a). Updated results have been given in the revised manuscript. However, a real-time variation of the fractions of hydrophobic POA is not yet available due to the lack of such measurements data. Using the variable fractions of hydrophobic POA only under three different atmospheric conditions could still cause uncertainties. An uncertainty analysis has also been conducted (**Section 2.3**), showing that the assumption on $N_{F_{NH-POA}}$ can lead to relative deviations (uncertainty) of -17 %–+27 % for the retrieved BC density (Fig. R1 or Fig. 2a).

Some discussions about this issue have been included in the revised paper, see section **2.3** or **Lines 298-319**, as follows:

“... The figures show that the In-BC density gradually decreases with the increment of the $N_{F_{NH-POA}}$, implying the higher fraction of bare POA particles correspond to the early aging stage of aerosol particles. With increase of κ_{SOA} , the In-BC density is generally reduced, but with small fluctuations (Fig.1a, Fig. 2b). This suggests a complex impact of assumptions of κ_{SOA} on the retrieved BC density. In

addition, the In-BC density decreases very slightly as $\rho_{\text{Ex-BC}}$ increases (Fig. 2e), suggesting applying a larger $\rho_{\text{Ex-BC}}$ would derive smaller values for In-BC density. The In-BC density is insensitive to the changes of the density of POA and SOA, showing an almost negligible effect on the retrieved results (Fig. 2c and d).

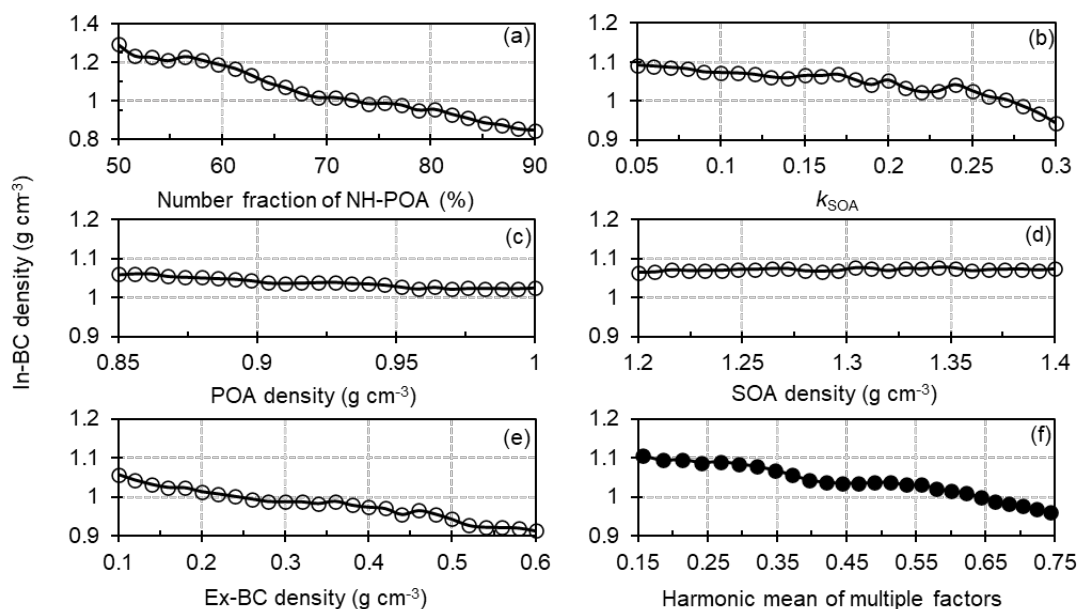

Fig. R1 Sensitivity of the In-BC density to variations in the number fraction of nearly hydrophobic (NH) POA (a), the hygroscopic parameter of SOA (b), the POA density (c), the SOA density (d), the externally mixed BC density (e) and the harmonic mean of multiple factors (f).

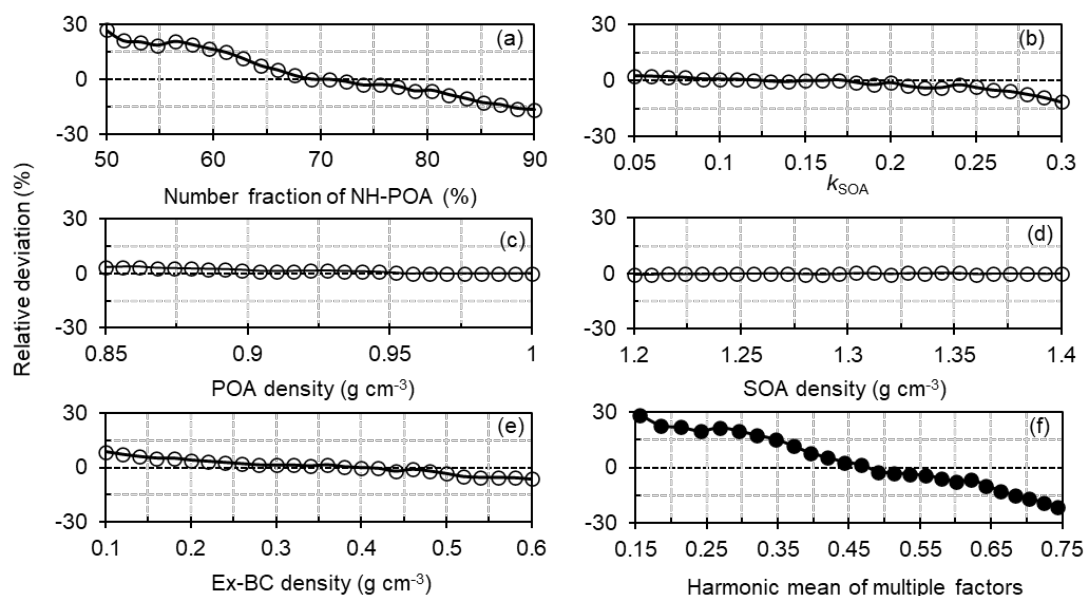

Fig. R2 Relative deviations of the number fraction of nearly hydrophobic (NH) POA to the In-BC density (a), the hygroscopic parameter of OA to the In-BC density (b), the

POA density to the In-BC density (c), the SOA density to the In-BC density (d), the externally mixed BC density to In-BC density (e) and the combined deviations based on multiple factors mentioned above (f).

The uncertainty analysis shows that, by comparing the results based on the mean fractions of the NF_{NH-POA} with a typical atmospheric observed range of 50-90 % for the NF_{NH-POA} (Liu et al., 2021a), we show that the assumption on NF_{NH-POA} can lead to relative deviations (uncertainty) of -17 % +27 % for the retrieved BC density (Fig.3a).”

(2) method to obtain the number fraction of POA

Some description about the method to calculating the number of POA has been given in the revised text, see **Lines 162-176** or as follows:

“... The nearly hydrophobic mode consists of both externally mixed POA (Ex-POA or bare POA) and externally mixed BC (Ex-BC). Since the number fraction of the nearly-hydrophobic POA would change with the emission and aging processes, in this study, we have applied different values for the number fractions of hydrophobic POA (NH-POA) under clean (91 %), moderately polluted (70 %), and heavily polluted conditions (31 %) by referring the literature (Liu et al., 2021a), as shown in Fig. S2. The number concentration of Ex-BC was then calculated using the total number fraction of NH mode minus the number of NH-POA.

$$N_{POA-containing} = N_{total} \times NF_{POA-containing}$$

$$N_{bare-POA} = N_{POA-containing} \times NF_{bare-POA}$$

$$N_{Ex-BC} = N_{NH} - N_{bare-POA} \quad (3)$$

where $N_{POA-containing}$ and $NF_{POA-containing}$ are the number concentration and fraction of POA-containing particles, N_{total} is the total number concentration, $N_{bare-POA}$ and $NF_{bare-POA}$ are the number concentration and fraction of bare POA particles, and N_{NH} is the number of nearly- hydrophobic group ...”

2) A fixed effective density of 0.4 g cm⁻³ is assumed for hydrophobic BC to derive its mass, which is not correct. The effective density of BC obviously depends on the particle shape and it can't be fixed.

Re: Thanks for the comments. It's true that there is some bias in deriving the mass concentration by assuming a fixed value for ρ_{Ex-BC} . Generally, the ρ_{Ex-BC} would change as a function of the mobility diameter and its morphology (Park et al., 2003; Rissler et

al., 2014; Wu et al., 2019). By reviewing and summarizing the existing results about, we found that typical values of density for the freshly emitted or externally mixed BC observed in the winter of urban Beijing or North China Plain spans over 0.14-0.50 g cm⁻³, with mean of $\sim 0.40 \pm 0.10$ g cm⁻³ (Fig.R3 or Fig. S3), in the size range of 100 to 300 nm, where the mass concentration of externally mixed BC accounted for a large proportion in urban Beijing ((Peng et al., 2016, 2017; Wu et al., 2019; Liu et al., 2020; Zhao et al., 2022). Therefore, an average $\rho_{\text{Ex-BC}}$ of 0.4 g cm⁻³ was used for calculating the mass concentration of externally-mixed BC in our study. The uncertainty analysis exhibits that the variations of the $\rho_{\text{Ex-BC}}$ could lead to an average deviation of $\pm 10\%$ in the calculating In-BC density (Fig. 3e) by increasing the $\rho_{\text{Ex-BC}}$ from 0.1 to 0.6 g cm⁻³, showing a relatively small impact on the retrieved result. A summarized figure of the existing results about $\rho_{\text{Ex-BC}}$ and sensitivity test has been included in the revised paper.

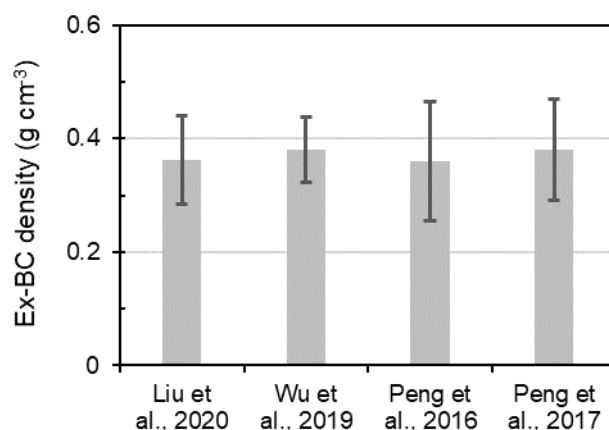

Fig. R3 Summary of the ambient externally mixed BC density particles in North China Plain from literatures.

3) By the following very complicated calculations, are you attempting to derive the BC density only for the hydrophilic mode? It is very confusing here as you have just used a fixed density of 0.4 but now why performing such calculation again.

Re: In this study, only when retrieving the density of internally-mixed BC, we assumed the density of the externally mixed BC is 0.4 g cm⁻³; when retrieving the bulk BC density, however, we didn't apply such assumption.

Since the Gf-PDF measured by the HTDMA can reflect the mixing state of aerosol particles (Tan et al., 2013; Hong et al., 2018; Chen et al., 2022), and the hydrophobic mode generally refers to components like freshly emitted BC or POA, which are externally-mixed with the aerosol particles populations; while the hydrophilic mode is those secondary inorganic or organic salts and aged BC. In this study, we think the aged

BC is hydrophilic and should be internally mixed with the secondary inorganic or organic salts, so defined as internally mixed BC. To retrieve the density of internally-mixed BC density, we assumed the density of the externally-mixed BC, $\rho_{\text{Ex-BC}}$, is 0.4 g cm^{-3} ; As described in Section 2.2.1, we first retrieved the mixing state of BC based on the Gf-PDF. After obtaining the number fraction of the externally mixed BC from measured Gf-PDF, the $\rho_{\text{Ex-BC}}$ was used to calculate the mass concentration of the externally mixed BC ($m_{\text{Ex-BC}}$). Then, the mass concentration of the internally mixed BC ($m_{\text{In-BC}}$) was calculated by subtracting $m_{\text{Ex-BC}}$ from the bulk BC mass concentration measured by AE33, and finally, the $m_{\text{In-BC}}$ was used for retrieving the density of internally-mixed BC as described in Section 2.2.2.

Scientific significance to retrieve the density of internally-mixed BC: since the BC particles experience rapid aging once they were emitted to the atmosphere, particularly, in the polluted urban regions, the BC could undergo more rapidly aging to internally mixed with other components compared to that in relative clean atmosphere (Peng et al., 2016). It has been observed that more than 80 % BC are internally-mixed with other components in the atmosphere (Chen et al., 2020). During aging, the physiochemical properties (morphology, density, hygroscopicity and CCN activity, etc.) of BC could be very different depending on its aging degree (Zhang R et al., 2008; Zhang F et al., 2022). however, in the current models, the internally-mixed BC density was treated as a void-free sphere throughout its atmospheric lifetime, which caused biases in the calculation of the BC absorption enhancement and CCN activity of In-BC particles. Therefore, it is with great scientific significance of understanding the density of the internally-mixed BC particles.

The effective density of BC can be obtained through combing the SMPS and mass measurement as many people did (as the authors are aware), I can't really understand why the authors have spent such efforts using an HTDMA measurement to perform such analysis (but this instrument is not intrinsically designed for such application).

Re: Yes, although various techniques have been developed to quantify the mixing state and density of BC in recent years, as we addressed in the Introduction section. However, such techniques or measurements are not available in many previously conducted filed campaigns. To obtain insights on the real-time variations of BC density in the polluted urban atmosphere, and to further study the effects of BC density variations on CCN activity and prediction, in this study, we attempt to retrieve the mixing state and effective density of ambient BC particles by combining field measured hygroscopic

growth factor and aerosol chemical composition and Köhler theory (Petters and Kreidenweis, 2007). We think that the current work is with scientific significance for that the effective density of BC is a crucial factor relevant to its aging degree that would add uncertainty in evaluating its climate effect. As the reviewer #1 commented, "... Since the BC density is difficult to measure, it is worth trying to develop new methods for retrieving accurate BC density from available measured data. It is quite interesting ..."

Actually, the reviewer #2 also commented that "... This is indeed challenging from a bulk HTDMA measurement to derive BC information, as the BC only constitutes of a small fraction of ambient atmospheric particles. However, the current method is still not convincing...". We are greatly appreciated for these insightful comments, which has let us think this work more deeply and revise it more carefully. Especially, for the methods, we have conducted more analyses and evaluations of the assumed parameters which may lead to uncertainties in the retrieved results in the Section 2.3. The overall uncertainty of the retrieval method was evaluated within $\pm 25\%$. Regarding to the small fraction of ambient BC particles as the reviewer #2 commented, we have noted that, this method fails to retrieve the BC density when organics account for a large fraction ($>60\%$). This is because that a higher fraction of OA usually corresponds to lower total volume of all the other species like BC, yielding negative values for v_{In-BC} introduced in equation 11. As a result, 39 % of the data observed during the campaign were excluded when calculating the BC density.

In addition, according to the reviewer's comments, in the revise version, instead of using a fixed fraction of 70%, we just have applied different values for fractions of hydrophobic POA under clean, moderately polluted, and heavily polluted conditions by referring the literature (Liu et al., 2021a). Updated results have been given in the revised manuscript. Also, we compared our results with the laboratory and field measurements reported in the literature. It shows generally good agreement with the previously reported values, indicating that the method is feasible.
