25 **Abstract.**

26 The effective density of black carbon (BC) is a crucial factor relevant to its aging
27 degree that would add uncertainty in evaluating its climate effect. Here, we have
28 developed a new method to retrieve the effective density of internally mixed BC in the
29 atmosphere combining field observations conducted on 15 November -14 December
30 2016 in urban Beijing with the Köhler theory. The uncertainty of the retrieval method
31 was evaluated within $\pm 30\%$, which is primarily caused by assumptions of the
32 hygroscopic parameter of organics and the fraction of primary organic aerosols in non-
33 hygroscopic or hygroscopic mode. Using the method, we obtain that the ambient
34 internally-mixed BC, accounting for $80\pm 20\%$ of total BC aerosol particles, is retrieved
35 with campaign mean density of $1.1\pm 0.6\text{ g cm}^{-3}$ during the observed periods. The
36 retrieved result is comparable with that reported in the literatures. By applying a lower
37 (0.14 g cm^{-3}) and upper (2.1 g cm^{-3}) limit of the retrieved BC density in cloud
38 condensation nuclei (CCN) number concentrations (N_{CCN}) estimation, we derived that
39 neglect of such variations in BC density led to an uncertainty of $-28\% \sim 11\%$ in
40 predicting N_{CCN} at supersaturations of 0.23% and 0.40% . We also find that the N_{CCN} is
41 more sensitive to the variations of BC density when it is $< 1.0\text{ g cm}^{-3}$. This illustrates a
42 necessity of accounting for the effect of BC density on CCN activity closer to source
43 regions where the BC particles are mostly freshly emitted. The CCN closure achieves
44 when introducing the retrieved real-time BC density and mixing state. This study
45 provides a unique way of utilizing field measurements to infer ambient BC density and

46 highlights the importance of applying variable BC density values in models when
47 predicting CCN and assessing its relevant climate effect.

48 **1 Introduction**

49 Black carbon (BC) aerosols, as the major absorber of solar radiation, play a vital
50 role in energy budget and climate of the earth-atmosphere system by affecting the
51 radiative forcing and cloud properties (Flanner et al., 2007; Ramanathan and
52 Carmichael, 2008). The light-absorbing capability induced by BC is related to its
53 density and morphology (Zhang et al., 2008; Rissler et al., 2014), which can be
54 modified after mixing with other atmospheric aerosol particles (Khalizov et al., 2009;
55 Xue et al., 2009). Changes in its physicochemical properties would also regulate its
56 ability to serve as cloud condensation nuclei (CCN) and further indirectly affect the
57 radiative balance by affecting the clouds process (Yuan et al., 2008; Wang et al., 2011).
58 Owing to the complex evolution of the mixing state, density and morphology of BC,
59 the contribution of BC particles to CCN budgets is still not well understood.

60 BC particles, with diesel vehicles, industrial and residential coal combustion as
61 major sources, are ubiquitous in urban environments (Bond et al., 2013; Dameto et al.,
62 2017; Li et al., 2017; Liu et al., 2019a). The mixing state of BC describes the
63 distribution of the bare BC and coating masteries among the aerosol population.
64 Typically, freshly generated BC exists in the form of chain aggregates and initially
65 uncoated, which is known as externally mixed BC (Ex-BC). When the BC particles
66 were emitted, they generally mix with other materials by condensation, coagulation,

67 and other processes (Riemer et al., 2004; Zhang et al., 2008; Liu et al., 2013; Zhang et
68 al., 2020a), forming the internally mixed BC (In-BC) particles consisting of BC core
69 and other chemical components (Cheng et al., 2006; Zhang et al., 2016). The BC
70 structure would be more compact with regular shapes (Pagels et al., 2009; Zhang et al.,
71 2008; Wang et al., 2017), and the effective density of internally mixed BC are changed
72 accordingly with the reconstruction (Liu et al., 2019b). The density and morphology of
73 BC particles are closely related to its sources, mobility size, coating thickness, coating
74 material and its chemical composition (Zhang et al., 2008; Pagels et al., 2009; Peng et
75 al., 2016; Zhang et al., 2022). A wide range of BC density has been reported in previous
76 studies (Lide 1992; McMurry et al., 2002; Park et al., 2004; Kiselev et al., 2010). Recent
77 field measurements have indicated that the average BC density is $\sim 1.2 \text{ g cm}^{-3}$ in the
78 ambient atmosphere (Zhang et al., 2016). Field measurements have also indicated that
79 a considerable fraction of externally mixed/uncoated BC exists (Clarke et al., 2004;
80 Cheng et al., 2012), although a higher proportion of internally mixed/aged BC particles
81 in the ambient atmosphere were observed (Schwarz et al., 2008; Massoli et al., 2015;
82 Chen et al., 2020). In climate models, the BC was generally assumed completely
83 internally-mixed and treated to have a void-free spherical structure and a density value
84 of 1.8 g cm^{-3} (Bond et al., 2013). This may lead to bias in estimating the climate effect
85 driven by BC.

86 Previous study based on a case study show that when the aging degree of ambient
87 particles is low, the BC density ($\sim 1.8 \text{ g cm}^{-3}$) under the spherical assumption will lead
88 to the overestimation of particle hygroscopicity by 40-50 % and the overestimation can

89 be explained almost 100 % using the effective density of fresh BC ($\sim 0.45 \text{ g cm}^{-3}$) (Fan
90 et al. 2020). This indicates the importance of using reasonable BC density values in the
91 calculation of particle hygroscopicity. In addition, when estimating the CCN number
92 concentration, a significant bias of $-35 \% \sim +20 \%$ was found due to the assumption of
93 particle mixing state (Ren et al., 2018). However, these studies have not yet accounted
94 for such impact of BC density and mixing state on CCN prediction due to lack of real
95 time measurement data.

96 The mixing state and the density of BC particles are usually directly measured by
97 several techniques, such as an integrated system of a volatility tandem differential
98 mobility analyzer and a single particle soot photometer (VTDMA-SP2) (Zhang et al.,
99 2016), or a differential mobility analyzer with a SP2 (DMA-SP2) (Olfert et al., 2007;
100 Rissler et al., 2014; Wu et al., 2019), and a differential mobility analyzer–centrifugal
101 particle analyzer–single-particle soot photometer (DMA–CPMA–SP2) system (Liu et
102 al., 2019b; Yu et al., 2020), etc. However, such techniques or measurements are not
103 available in many previously conducted field campaigns. In this study, we develop a
104 novel method for retrieving the mixing state and effective density of ambient BC
105 particles by combining field measured hygroscopic growth factor and aerosol chemical
106 composition and Köhler theory (Petters and Kreidenweis, 2007). The uncertainty of the
107 new retrieval method was evaluated. The retrieved results were also compared and
108 validated with existing observations. In addition, the effect of BC density and mixing
109 state on prediction of CCN number concentrations is further evaluated through a
110 sensitivity and closure test by accounting for the retrieved real-time variations of BC

111 density and mixing state.

112 **2 Field measurements and methodology**

113 **2.1 Field measurements**

114 Measurements in this study were conducted from 15 November to 14 December
115 2016 at a typical urban site of Beijing (39.97°N, 116.37°E, 49 m above sea level). The
116 site locates at the Institute of Atmospheric Physics, Chinese Academy of Sciences,
117 which is mainly influenced by the surrounding cooking, road traffic and residential coal
118 burning emissions during the home heating periods (Sun et al., 2016). The detailed
119 information about the sampling site was presented in previous studies (Sun et al., 2015;
120 Zhang et al., 2019). The number concentration of condensation nuclei (CN) at each size
121 was measured by a scanning mobility particle sizer, which is equipped with a
122 differential mobility analyzer (DMA; model 3081, TSI) and a condensation particle
123 counter (CPC; model 3772, TSI). Subsequently, the mono-dispersed particles were
124 introduced into a Droplet Measurement Technologies CCN counter (CCNc, DMT;
125 Lance et al., 2006) to measure CCN number concentration. A hygroscopic tandem
126 differential mobility analyzer (HTDMA) system was used to measure the hygroscopic
127 growth factor (Gf) (Tan et al., 2013). Here, four diameters of 40, 80, 110, 150, and 200
128 nm are selected in the campaign. Gf is defined as the ratio of the mobility diameter at
129 the given RH to the dry diameter (Petters and Kreidenweis, 2007). The nonrefractory
130 submicron aerosol chemical composition was measured by an Aerodyne high-
131 resolution time-of-flight aerosol mass spectrometer (HR-AMS; Xu et al., 2019),

132 including sulfate, nitrate, ammonium, chloride, and organics. Two factors, including a
 133 non-hygroscopic primary organic aerosol (POA) and hygroscopic secondary organic
 134 aerosol (SOA) were classified by positive matrix factorization (PMF) with PMF
 135 algorithm (v4.2) method (Paatero and Tapper, 1994) and followed the procedures
 136 reported in Ulbrich et al. (2009). The refractory black carbon mass loading was
 137 measured by an aethalometer (model AE33, Magee Scientific Corporation). Both the
 138 nonrefractory materials and BC mass concentration were measured with diameters <
 139 1.0 μm . The detailed description of the instrument operation and data process have been
 140 described in details elsewhere (Ren et al., 2018; Xu et al., 2019; Zhang et al., 2019; Fan
 141 et al., 2020).

142 **2.2 Retrieving the mixing state and density of BC**

143 2.2.1 Retrieving the mixing state of BC

144 The Gf probability distribution function (Gf-PDF) for a specified diameter can be
 145 retrieved firstly based on the TDMA_{inv} algorithm (Gysel et al., 2009). The κ -PDF can
 146 be further calculated based on the Gf-PDF (Fan et al., 2020). Size-resolved κ is derived
 147 using κ -Köhler theory based on hygroscopic growth factor (Gf) (Petters and
 148 Kreidenweis, 2007),

$$149 \quad \kappa_{gf} = (Gf^3 - 1) \cdot \left[\frac{1}{RH} \exp\left(\frac{4\sigma_{s/a}M_w}{RT\rho_w D_d Gf}\right) - 1 \right] \quad (1)$$

150 where Gf is hygroscopic growth factor, RH is the relative humidity in the HTDMA
 151 (90 %), D_d is the dry diameter, $\sigma_{s/a}$ is assumed to be the surface tension of pure water,

152 R is the universal gas constant, T is the temperature, M_w and ρ_w is the molecular mass,
 153 and the density of water, respectively.

154 The κ -PDF patterns of particles in different sizes always present two modes: nearly
 155 hydrophobic (NH) mode with $\kappa_{gf} \leq 0.1$ and more hygroscopic (MH) mode with $\kappa_{gf} > 0.1$
 156 (Fig. S1). Firstly, based on the κ -PDF patterns, the number fraction (NF) of the total
 157 nearly hydrophobic group with the boundary of $[0, 0.1]$ was calculated according to the
 158 following equation:

$$159 \quad NF = \int_0^{0.1} c(\kappa, D_p) d\kappa \quad (2)$$

160 here, the κ -PDF, represented by $c(\kappa, D_p)$, was normalized as $\int c(\kappa, D_p) d\kappa = 1$, where
 161 κ can be replaced by κ_{gf} , D_p is the selected electrical mobility diameter in the campaign.

162 The nearly hydrophobic mode consists of both externally mixed POA (Ex-POA or
 163 bare POA) and externally mixed BC (Ex-BC). Since the number fraction of the nearly-
 164 hydrophobic POA would change with the emission and aging processes, in this study,
 165 we have applied different values for the number fractions of hydrophobic POA (NH-
 166 POA) under clean (91 %), moderately polluted (70 %), and heavily polluted conditions
 167 (31 %) by referring the literature (Liu et al., 2021a), as shown in Fig. S2. The number
 168 concentration of Ex-BC was then calculated using the total number fraction of NH
 169 mode minus the number of NH-POA.

$$170 \quad N_{POA-containing} = N_{total} \times NF_{POA-containing}$$

$$171 \quad N_{bare-POA} = N_{POA-containing} \times NF_{bare-POA}$$

$$172 \quad N_{Ex-BC} = N_{NH} - N_{bare-POA} \quad (3)$$

173 where $N_{POA-containing}$ and $NF_{POA-containing}$ are the number concentration and fraction of

174 POA-containing particles, N_{total} is the total number concentration, $N_{\text{bare-POA}}$ and $NF_{\text{bare-}}$
175 POA are the number concentration and fraction of bare POA particles, and N_{NH} is the
176 number of nearly- hydrophobic group.

177 The number size distribution of the externally mixed BC ($n_{\text{Ex-BC}}(\log D_p)$) can be
178 calculated based on the particle number size distribution (PNSD) and the number
179 fraction of the hydrophobic mode of BC ($NF_{\text{Ex-BC}}$) as follows:

$$180 \quad n_{\text{Ex-BC}}(\log D_p) = NF_{\text{Ex-BC}} \times n(\log D_p) \quad (4)$$

181 where $n(\log D_p)$ is the function of the aerosol number size distribution, D_p is the
182 mobility diameter.

183 By assuming that the particles are spherical (Rader and McMurry, 1986), the mass
184 size distribution of Ex-BC ($M_{\text{Ex-BC}}$) was obtained as follows:

$$185 \quad M_{\text{Ex-BC}}(\log D_p) = \frac{\pi}{6} D_p^3 \rho n_{\text{Ex-BC}}(\log D_p) \quad (5)$$

186 where D_p is the mobility diameter, ρ is the effective density of Ex-BC, and $n_{\text{Ex-BC}}(\log$
187 $D_p)$ is the function of the number size distribution of Ex-BC, respectively. By reviewing
188 and summarizing the existing results about, we show that typical values of density for
189 the freshly emitted or externally mixed BC observed in the winter of urban Beijing or
190 North China Plain spans over 0.14-0.50 g cm⁻³, with mean of $\sim 0.40 \pm 0.10$ g cm⁻³ (Fig.
191 S3), in the size range of 100 to 300 nm, where the mass concentration of externally
192 mixed BC accounted for a large proportion in urban Beijing (Geller et al., 2006; Peng
193 et al., 2016, 2017; Wu et al., 2019; Liu et al., 2020; Zhao et al., 2022). Therefore, an
194 average $\rho_{\text{Ex-BC}}$ of 0.4 g cm⁻³ was used for calculating the mass concentration of
195 externally-mixed BC in our study. The uncertainty analysis exhibits that the variations

196 of the $\rho_{\text{Ex-BC}}$ could lead to an average deviation of $\pm 10\%$ in the calculating In-BC
 197 density (Fig. 3e) by increasing the $\rho_{\text{Ex-BC}}$ from 0.1 to 0.6 g cm⁻³, showing a small impact
 198 on the retrieved result. Uncertainty analyses due to the variations of $\rho_{\text{Ex-BC}}$ were given
 199 in section 2.3.

200 The mass size distribution of Ex-BC was fit using the log-normal distribution as
 201 shown in Fig. S4 (Wu et al., 2017; Liu et al., 2019a; Zhao et al., 2022). Thus, the bulk
 202 mass concentration of Ex-BC can be calculated from the integration of the mass size
 203 distribution:

$$204 \quad m_{\text{Ex-BC}} = \int_{D_{\text{start}}}^{D_{\text{end}}} M_{\text{Ex-BC}}(\log D_p) d \log(D_p) \quad (6)$$

$$205 \quad m_{\text{In-BC}} = m_{\text{BC}} - m_{\text{Ex-BC}} \quad (7)$$

206 where D_{start} and D_{end} are the lower and upper size limit, $M_{\text{Ex-BC}}(\log D_p)$ is the function
 207 of the Ex-BC mass size distribution. We then obtained the bulk mass concentration of
 208 internally mixed BC ($m_{\text{In-BC}}$) by subtracting $m_{\text{Ex-BC}}$ from the bulk BC mass
 209 concentration measured by AE33 in equation 7.

210 2.2.2 Retrieving the density of BC

211 For retrieval of the density of BC, the principal idea is to use the measured κ_{gf} to
 212 calculate the density of BC based on the Zdanovskii–Stokes–Robinson (ZSR) mixing
 213 rule (Stokes and Robinson, 1966; Zdanovskii, 1948) with the chemical composition
 214 measured by AMS (Petters & Kreidenweis, 2007). In the retrieval, several aspects are
 215 concerned. First, since the ZSR rule is to assume the aerosol particles are internally
 216 mixed, the κ_{gf} value of the more MH mode ($\kappa_{\text{gf-MH}}$) is thus applied for retrieving the

217 density of internally mixed BC. Second, since the size distribution of BC number
 218 concentration is usually with peaks between 100 and 200 nm (Liu et al., 2019a; Yu et
 219 al., 2020; Zhao et al., 2022), the κ_{gf-MH} value of particles in accumulation mode was
 220 averaged and applied for the retrieval. Previous studies showed an independence of κ_{gf-}
 221 MH on particle size when the $D_p > 100$ nm during the campaign period (Fan et al., 2020).
 222 Therefore, the average of κ_{gf-MH} in accumulation mode is reasonable for the
 223 determination of the In-BC density. In addition, because the inversion including
 224 measurements from HTDMA and HR-AMS, a total mass closure of the measured
 225 aerosol particles was conducted between the two techniques by comparing the mass
 226 concentration of PM_{10} and the results are well consistent (Fig. S5). The density of
 227 internally mixed BC (In-BC), ρ_{In-BC} is then derived from the following equations:

$$228 \quad \kappa_{gf-MH} = \kappa_{chem} = \sum_i \varepsilon_i \kappa_i = \frac{v_{inorg}}{v_{total}} \kappa_{inorg} + \frac{v_{SOA}}{v_{total}} \kappa_{SOA} + \frac{v_{In-POA}}{v_{total}} \kappa_{POA} + \frac{v_{In-BC}}{v_{total}} \kappa_{BC} \quad (8)$$

229 where κ_{gf-MH} is the hygroscopic parameter of the more hygroscopic (MH) mode, κ_{chem}
 230 is the hygroscopic parameter of aerosol particles in the mixed composition and can be
 231 calculated based on chemical volume fractions using a simple rule (Stokes and
 232 Robinson, 1966; Petters & Kreidenweis, 2007), κ_i is the hygroscopic parameter of each
 233 pure composition and ε_i is the volume fraction of the individual components in the
 234 internal-mixed particle. v_{inorg} , v_{SOA} and v_{In-POA} are the volume of the inorganic, SOA
 235 and internally mixed POA species, and can be calculated as follows: $v_{inorg} = \frac{m_{inorg}}{\rho_{inorg}}$,
 236 $v_{SOA} = \frac{m_{SOA}}{\rho_{SOA}}$, and $v_{In-POA} = \frac{m_{In-POA}}{\rho_{POA}}$. v_{total} is the total volume of all the species and can be
 237 written as $v_{total} = \frac{m_{inorg}}{\rho_{inorg}} + \frac{m_{SOA}}{\rho_{SOA}} + \frac{m_{In-POA}}{\rho_{POA}} + \frac{m_{In-BC}}{\rho_{In-BC}}$. In equation (8), κ_{BC} and κ_{POA} are
 238 assumed to be 0. Then, the ρ_{In-BC} can be calculated based on its mass concentration and

239 volume as follows:

$$240 \quad \rho_{In-BC} = \frac{m_{In-BC}}{\left(\frac{\rho_{inorg} \kappa_{inorg} + \frac{m_{SOA} \kappa_{SOA}}{\rho_{SOA}}}{\kappa_{gf-MH}} + \frac{m_{inorg}}{\rho_{inorg}} + \frac{m_{SOA}}{\rho_{SOA}} + \frac{m_{In-POA}}{\rho_{POA}} \right)} \quad (9)$$

241 where, m_{In-BC} is the mass concentration of internally mixed BC, m_{inorg} and m_{SOA} are the
 242 mass concentrations of the inorganic species and SOA, which are measured by the AMS.

243 m_{In-POA} is the mass concentrations of internally mixed POA and can be calculated
 244 subtracting the mass fraction of NH-POA from the total mass concentrations of POA.

245 ρ_{inorg} , ρ_{SOA} and ρ_{POA} are the density of the inorganic species, SOA and POA. Since the
 246 AMS measures the concentrations of the organic and inorganic ions, including SO_4^{2-} ,

247 NO_3^- , NH_4^+ , Cl^- . Here inorganic species were derived by applying a simplified ion
 248 pairing scheme (Gysel et al., 2007) to convert mass concentrations of ions to the

249 inorganic salts as follows:

$$251 \quad n_{NH_4NO_3} = n_{NO_3^-}$$

$$252 \quad n_{NH_4HSO_4} = \min(2n_{SO_4^{2-}} - n_{NH_4^+} + n_{NO_3^-}, n_{NH_4^+} - n_{NO_3^-})$$

$$253 \quad n_{(NH_4)_2SO_4} = \max(n_{NH_4^+} - n_{NO_3^-} - n_{SO_4^{2-}}, 0)$$

$$250 \quad n_{H_2SO_4} = \max(0, n_{SO_4^{2-}} - n_{NH_4^+} + n_{NO_3^-}) \quad (10)$$

254 where n represents the number of moles, then the mass concentrations were obtained
 255 by the number of moles times the molar mass of each inorganic salts. Because the

256 maximum value of the $n_{H_2SO_4}$ was zero in this campaign. Three inorganic salts

257 including NH_4HSO_4 , $(NH_4)_2SO_4$, and NH_4NO_3 were applied in our study. The densities
 258 for inorganic salts were taken from previous studies (Gysel et al., 2007; Wu et al., 2016).

259 Here the densities for three inorganics are 1.78, 1.77 and 1.72 $g\ cm^{-3}$, respectively. By
 260 summarizing the previous studies (Gysel et al., 2007; Dinar et al., 2006), 1.4 $g\ cm^{-3}$ was

261 selected as the density of SOA (ρ_{SOA}). The density of POA (ρ_{POA}) is assumed to be 1.0
 262 g cm⁻³ for urban environments, which is similar to the lubricating oil (Wu et al., 2016).
 263 Considering the cooking organic aerosols represent a high contribution to POA in urban
 264 environments, a density of 0.85 g cm⁻³ chosen as the mean density for the rapeseed oil
 265 and oleic acid (Reyes-Villegas et al., 2018) was also used to evaluated the result as
 266 shown in section 2.3. The values of κ for inorganic components are 0.56 for NH₄HSO₄,
 267 0.48 for (NH₄)₂SO₄ and 0.58 for NH₄NO₃, along with the best-fit values for the three
 268 inorganic salts (Petters & Kreidenweis, 2007 and Gunthe et al., 2009). The κ_{SOA} is
 269 assumed to be 0.15 according to the field studies in urban areas (Chang et al., 2010;
 270 Kawana et al., 2016).

271 Note that, this method fails to retrieve the BC density when organics account for
 272 a large fraction (>60 %). This is because that a higher fraction of OA usually
 273 corresponds to lower total volume of all the species (Fig. S6), yielding negative values
 274 for v_{In-BC} introduced in equation 11. As a result, 61 % of the data observed during the
 275 campaign were valid for calculating the BC density.

$$276 \quad v_{In-BC} = \frac{v_{inorg}\kappa_{inorg} + v_{SOA}\kappa_{SOA}}{\kappa_{gf-MH}} - v_{inorg} - v_{SOA} - v_{In-POA} \quad (11)$$

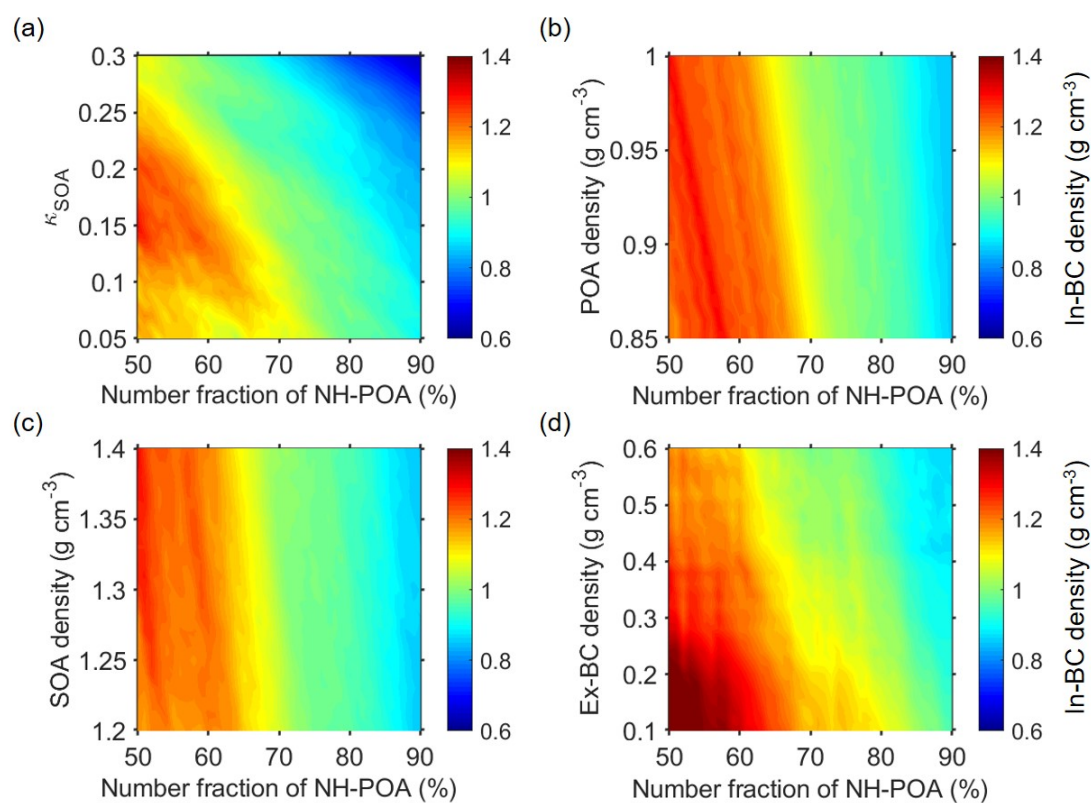

277 Similarly, the bulk density of BC ($\rho_{bulk-BC}$) is calculated with the same method as
 278 that for calculating the ρ_{In-BC} . When calculating the $\rho_{bulk-BC}$, the bulk κ_{gf} value measured
 279 by HTDMA is applied with the assumption of all the aerosol particles are internally
 280 mixed.

281 **2.3 Uncertainties and limitations**

282 For the retrieval, the assumptions on the values of κ_{SOA} , ρ_{POA} , ρ_{SOA} and $\rho_{\text{Ex-BC}}$ as
283 well as the fraction of primary organic aerosols in non-hygroscopic or hygroscopic
284 mode would add uncertainty in the inferred values of ambient internally mixed BC
285 density. For example, the freshly emitted POA particles might consistently be coated
286 with the secondary particles during the aging process, resulting in changes of the $NF_{\text{NH-}}$
287 POA . However, a real-time variation of the $NF_{\text{NH-POA}}$ is not yet available due to the lack
288 of such measurements data. Applying the rough fractions of hydrophobic POA only
289 under three different atmospheric conditions could still cause uncertainties. Also, the
290 densities of POA and SOA may differ due to their precursors, emission sources and the
291 formation mechanisms in ambient atmosphere (Alfarra et al., 2006; Reyes-Villegas et
292 al., 2018). And the density of Ex-BC is generally characterized by the morphology and
293 size (Wu et al., 2019). In addition, the value of κ_{SOA} spans largely due to the variability
294 in the emissions of gas precursors and formation processes under different atmospheric
295 conditions (Zhang et al., 2015; Liu et al., 2021b). Therefore, we examined the
296 sensitivities of In-BC density to the variations of these factors, as exhibited in Fig. 1
297 and Fig.2.

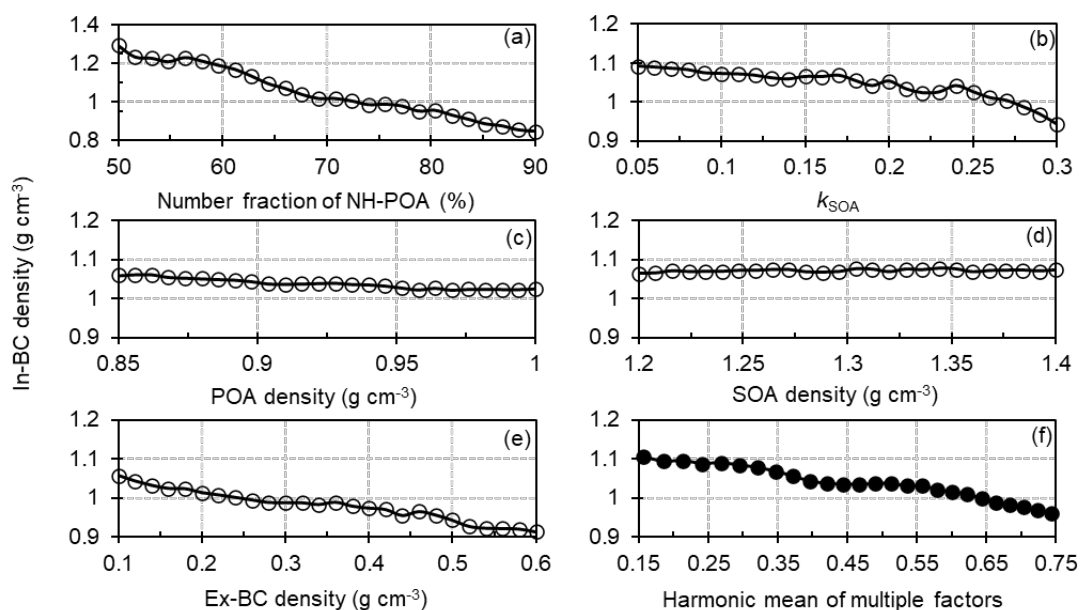

298 The figures show that the In-BC density gradually decreases with the increment of
299 the $NF_{\text{NH-POA}}$, implying the higher fraction of bare POA particles correspond to the early
300 aging stage of aerosol particles. With increase of κ_{SOA} , the In-BC density is generally
301 reduced, but with small fluctuations (Fig.1a, Fig. 2b). This suggests a complex impact
302 of assumptions of κ_{SOA} on the retrieved BC density. In addition, the In-BC density

303 decreases very slightly as $\rho_{\text{Ex-BC}}$ increases (Fig. 2e), suggesting applying a larger $\rho_{\text{Ex-BC}}$
 304 would derive smaller values for In-BC density. The In-BC density is insensitive to the
 305 changes of the density of POA and SOA, showing an almost negligible effect on the
 306 retrieved results (Fig. 2c and d).

307

308 **Figure 1.** Sensitivities of In-BC density to the variations in the number fraction of
 309 nearly hydrophobic (NH) POA and hygroscopic parameter of OA (k_{SOA}) (a), POA
 310 density (b), SOA density (c) and the externally mixed BC density (d).

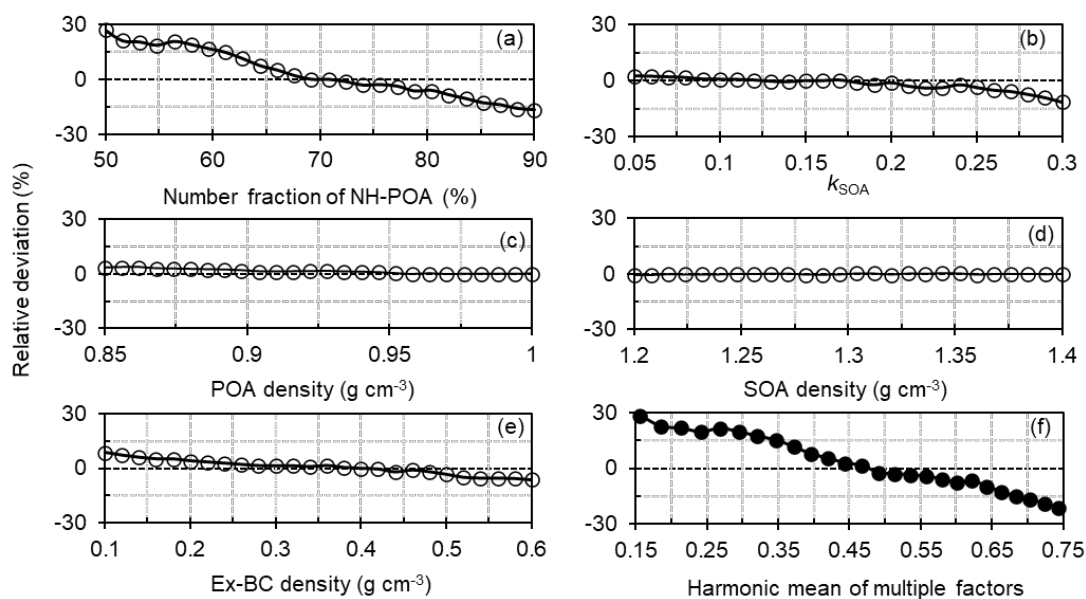

311

312 **Figure 2.** Sensitivity of the In-BC density to variations in the number fraction of nearly
 313 hydrophobic (NH) POA (a), the hygroscopic parameter of SOA (b), the POA density
 314 (c), the SOA density (d), the externally mixed BC density (e) and the harmonic mean
 315 of multiple factors (f).

316 The uncertainty analysis shows that, by comparing the results based on the mean
 317 fractions of the NF_{NH-POA} with a typical atmospheric observed range of 50-90 % for the
 318 NF_{NH-POA} (Liu et al., 2021a), we show that the assumption on NF_{NH-POA} can lead to
 319 relative deviations (uncertainty) of -17 %–+27 % for the retrieved BC density (Fig.3a).

320 In addition, unlike inorganics (eg., NH_4HSO_4 , $(NH_4)_2SO_4$ and NH_4NO_3), which
 321 the hygroscopicity has been already well-understood (Petters and Kreidenweis, 2007),
 322 the hygroscopicity of organic species varies largely due to the complexity in organic
 323 aerosol constituents. Therefore, the assumption of the values of κ_{SOA} will add the
 324 uncertainty in the calculation of BC density. Previous studies have suggested that the
 325 organics has a wide range of κ values ranging from 0.05 to 0.3 (Jimenez et al., 2009;

326 Mei et al., 2013). Thus, the sensitivity test has also been done to examine the effect due
 327 to changes in κ_{SOA} on calculating the density of BC (Fig. 1a). The result shows that the
 328 assumption of κ_{SOA} value can cause an average relative deviation of -10 % - +3 % in
 329 calculating the density of In-BC (Fig. 3b).

330
 331 **Figure 3.** Relative deviations of the number fraction of nearly hydrophobic (NH) POA
 332 to the In-BC density (a), the hygroscopic parameter of OA to the In-BC density (b), the
 333 POA density to the In-BC density (c), the SOA density to the In-BC density (d), the
 334 externally-mixed BC density to In-BC density (e) and the combined deviations based
 335 on multiple factors mentioned above (f).

336 However, the sensitivity test shows that the impact of both the ρ_{POA} and ρ_{SOA}
 337 variations on the BC density estimation is very small or even negligible (Fig. 1b, c). By
 338 varying the ρ_{POA} from 0.85 to 1.0 g cm^{-3} and the ρ_{SOA} from 1.2 to 1.4 g cm^{-3} according
 339 to the literatures (Noureddini et al., 1992; Alfarrar et al., 2006; Reyes-Villegas et al.,
 340 2018), the retrieval uncertainties in the BC density are within $\pm 5\%$ and $\pm 1\%$
 341 respectively (Fig. 3c, d). For $\rho_{\text{Ex-BC}}$, it exhibits that the evolution of the $\rho_{\text{Ex-BC}}$ could lead

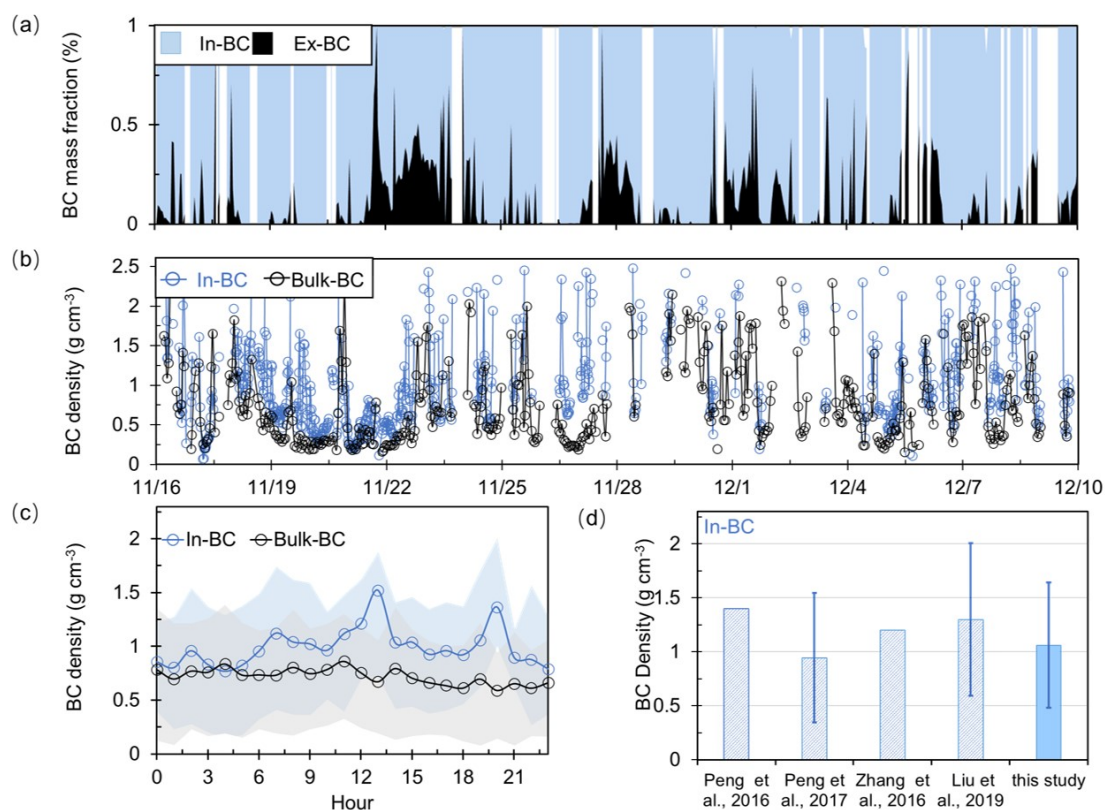

342 to an average deviation of ± 10 % in calculating In-BC density (Fig. 3e) when
343 increasing the values of $\rho_{\text{EX-BC}}$ from 0.1 to 0.6 g cm⁻³, which represents a typical range
344 in ambient atmosphere (Wu et al., 2019; Liu et al., 2020). A combined uncertainty (δ)
345 caused by the multiple factors (δ_i), which is calculated by equation 12, is -21 % - +29 %
346 as shown in Fig. 3f.

$$347 \quad \delta = \sqrt{\sum_{i=1}^n \delta_i^2} \quad (12)$$

348 **3 Results and Discussion**

349 **3.1 Retrieved mixing state and density of BC: comparison and validation**

350 Figure 4a shows retrieved time series of the mixing state of ambient BC during the
351 campaign. Large temporal variations of the mass fraction of internally and externally
352 mixed BC are presented during the observed period at the sites. The temporal changes
353 should be related to the atmospheric aging process or diurnal variations of emissions
354 (Liu et al., 2019a; Fan et al., 2020). Statistically, the average mass fraction of externally
355 and internally mixed BC is 20 \pm 18 % and 80 \pm 20 % respectively, showing that most of
356 the BC particles were aged and internally mixed with other components. Previous
357 studies at urban sites have shown that the co-existence of the externally mixed BC in
358 the ambient atmosphere (Schwarz et al., 2008; Cheng et al., 2012; Chen et al., 2020)
359 due to continuous combustion processes (e.g., vehicle exhaust and residential sector)
360 (Wang et al., 2017; Liu et al., 2019a). Our results are basically comparable with those

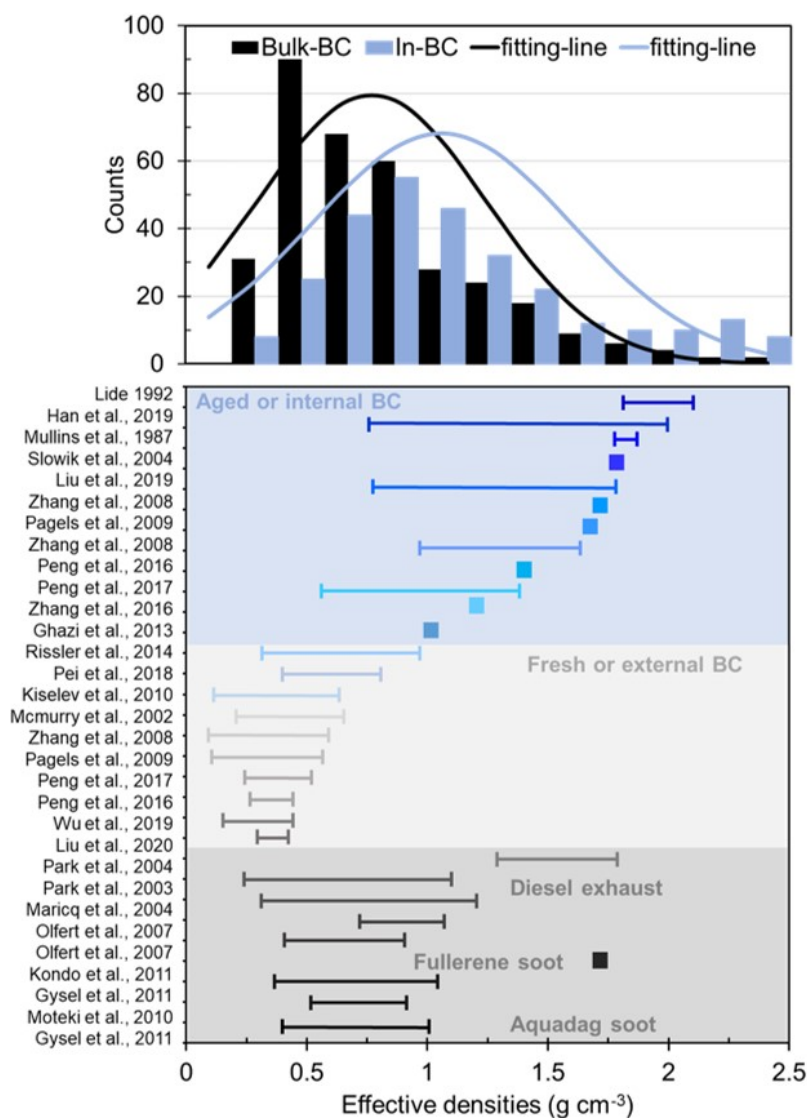

361

362 **Figure 4.** (a) Time series of the mass fraction of the retrieved internal- and external-
 363 mixed BC; (b) Time series of the retrieved density of the bulk and internal- mixed BC
 364 (In-BC); (c) Diurnal variation of the retrieved density of bulk and In-BC; (d)
 365 Comparison of the results of the derived In-BC density in this study with that reported
 366 in literatures.

367 directly measured or indirectly retrieved previously reported results. For example, Chen
 368 et al., 2020 found that the mass fraction of internally mixed BC particles was nearly to
 369 be ~80–90 % in summer of Beijing based on VTDMA measurements. Liu et al. (2020),
 370 using a tandem system with an aerodynamic aerosol classifier and SP2, reported that
 371 the mass fraction of internally BC-containing particles would increase with increasing
 372 size and reach ~70 % in Beijing. Overall, the mass fraction obtained in our study is
 373 comparable with those reported in urban Beijing. Previous studies also displayed that

374 the significant diversity of the BC mixing state among emission conditions and coating
375 process (Shiraiwa et al., 2008; Pan et al., 2017; Zhang et al., 2020b). Accordingly, the
376 densities of the bulk and internally mixed BC present apparent fluctuations as shown in
377 Fig. 4b, which is significantly affected by the variations of BC emission sources and its
378 rapid aging process. The density of the In-BC during daytime was generally higher than
379 that at night (Fig. 4c). The elevated BC density during daytime is likely due to that the
380 strong photochemical processes promote the aging of BC particles, which resulted in a
381 conversion from uncompacted structure to compact and regular spherical shapes of BC
382 (Qiao et al., 2018; Liu et al., 2019b; Zhou et al., 2022). The lift in BC density around
383 20:00 LT might indicate that the BC particles would be rapidly coated with the SIA
384 particles and continuously aged in the polluted period due to the heterogeneous
385 reactions of SIA in urban regions (Zhang et al., 2016; Peng et al., 2017). Actually,
386 following the haze evolution, the fraction of nearly hydrophobic group reduced rapidly
387 (Fig. S7). Consequently, the average density of In-BC increased obviously from the
388 clean conditions to the polluted periods (Fig. S8). A slight decrease was observed in the
389 bulk BC density during traffic hours. This is likely associated with the continues
390 emissions (e.g., vehicle exhaust) that lead to uncoated or uncompacted BC particles in
391 this period. The diurnal cycle in In-BC density is consistent with the coating thickness
392 measured by a tandem CPMA-SP2-DMA-SP2 (Liu et al., 2020), demonstrating that the
393 new method can derive the density of ambient BC particles reasonably. Averagely, the
394 bulk and internally mixed BC densities are with campaign averaged values of 0.7 ± 0.5
395 and $1.1\pm 0.6 \text{ g cm}^{-3}$ respectively, which are much less than 1.8 g cm^{-3} , implying that the

396 BC particles is not a void-free spheres in the urban atmosphere. The results of In-BC
 397 density are comparable with that observed at the other sites in North China Plain (NCP)
 398 as shown in Fig. 4d, illustrating that the BC effective density retrieved by this method
 399 is within the range of field measurements.

400
 401 **Figure 5.** The probability distribution function (PDF) of the retrieved density of bulk
 402 and In-BC and the measured density distribution spectrum of BC from different sources
 403 reported in literatures.

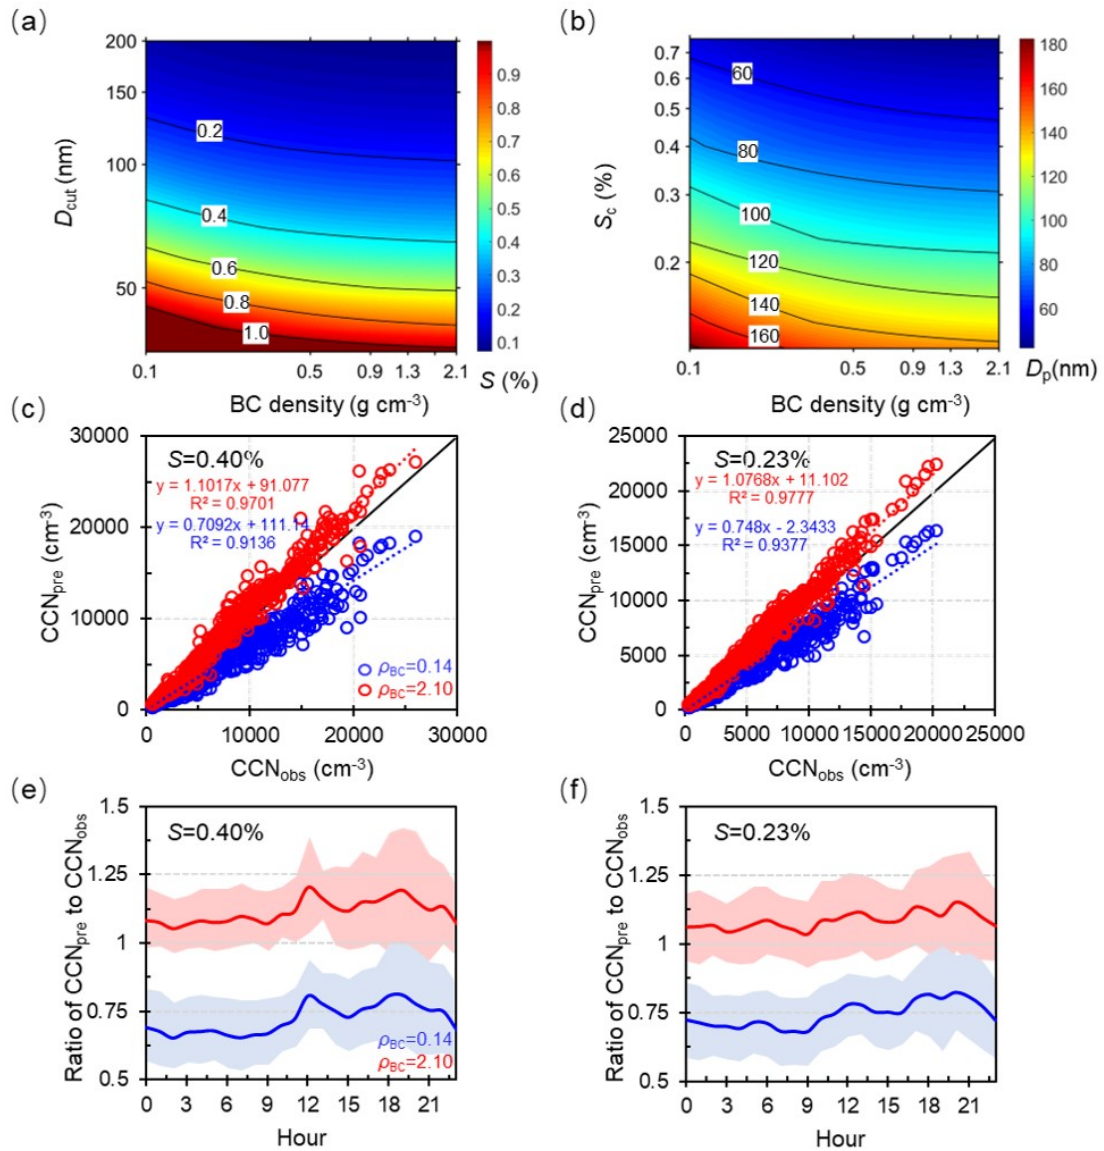

404 Based on both field measurements (e.g. Lide 1992; Zhang et al., 2016; Wu et al.,
 405 2019; Liu et al., 2019b) and laboratory studies (e.g. McMurry et al., 2002; Park et al.,

2003, 2004; Olfert et al., 2007; Kiselev et al., 2010; Gysel et al., 2011, 2012), the BC density from diverse combustion sources or representing different aging degree has been obtained and ranges widely from 0.14 to 2.1 g cm⁻³, as has been summarized and shown in Fig. 5. Mean probability distribution function (PDF) of the density of bulk and In-BC retrieved by this study is also presented in Fig. 5. It shows that the retrieved density of bulk BC exhibits a dominant mode with a peak value of 0.7 g cm⁻³, which is situated between the typical density range of those externally mixed and internally mixed BC measured previously. For the In-BC, the PDF is with a peak value at 1.1 g cm⁻³, but ranges widely from ~0.5 to 2.5 g cm⁻³, which indicates various morphologies, different aging degree and compositions of ambient BC particles due to the complex impact of multiple local sources and aging processes during the observed period in urban Beijing. Overall, the retrieved values for In-BC fall within the range of typical internal mixed BC reported in the literatures, verifying the reliability of our inversion results.

3.2 Sensitivity of predicted N_{CCN} to changes of BC density

A previous study showed that the use of an inaccurate density value of BC particles would result in large bias in estimating κ of ambient aerosol particles with the ZSR mixing rule (Fan et al., 2020), as would further lead to uncertainties in prediction of N_{CCN} and relevant climate effects. Considering the large variation range of BC density during the campaign, which is closely associated with its morphology or degree of its aging, we further examine the sensitivity of critical supersaturation (S_c), critical

427 diameter (D_{cut}) and predicted N_{CCN} to variations of BC density (Fig. 6). Here, we use
 428 the critical diameter and particle number size distribution to calculate N_{CCN} . The method
 429 to derive the critical diameter is based on Köhler theory and ZSR rule.

430
 431 **Figure 6.** Sensitivity of critical supersaturation (S_c) (a) and diameter (D_{cut}) (b) to the
 432 variations in BC density; Predicted N_{CCN} as a function of measured N_{CCN} by varying the
 433 density from 0.14 to 2.1 g cm^{-3} at $S = 0.40\%$ (c) and $S = 0.23\%$ (d), the black solid line
 434 is the 1:1 line; Diurnal variations in the ratio of predicted-to-measured N_{CCN} at $S = 0.40\%$
 435 (e) and $S = 0.23\%$ (f).

436 The results show that, by varying the value of density from 0.14 to 2.1 g cm⁻³ that
437 represents the lower and upper limit of BC density in the atmosphere, the D_{cut} reduces
438 apparently at a given supersaturation (S) (Fig. 6a), or similarly, the S_c decreases rapidly
439 for a given particle size (Fig. 6b). The results show that the changes of the D_{cut} and S_c
440 are more sensitive when the BC density is below 1.0 g cm⁻³. And the effects on the D_{cut}
441 and S_c both gradually weakened with the increase of BC density. This shows that it is
442 critical to apply more accurate BC density for the aerosol particles with low aging
443 degree in predicting CCN and its climate effect. Accordingly, the ratios of predicted-
444 to-measured N_{CCN} ranged from 0.72 to 1.11 by varying the BC density from 0.14 to 2.1
445 g cm⁻³ at the typical S of 0.23 % and 0.40 % (Fig. 6c, 6d), showing an estimation
446 uncertainty of -28 %–11 % in N_{CCN} prediction.

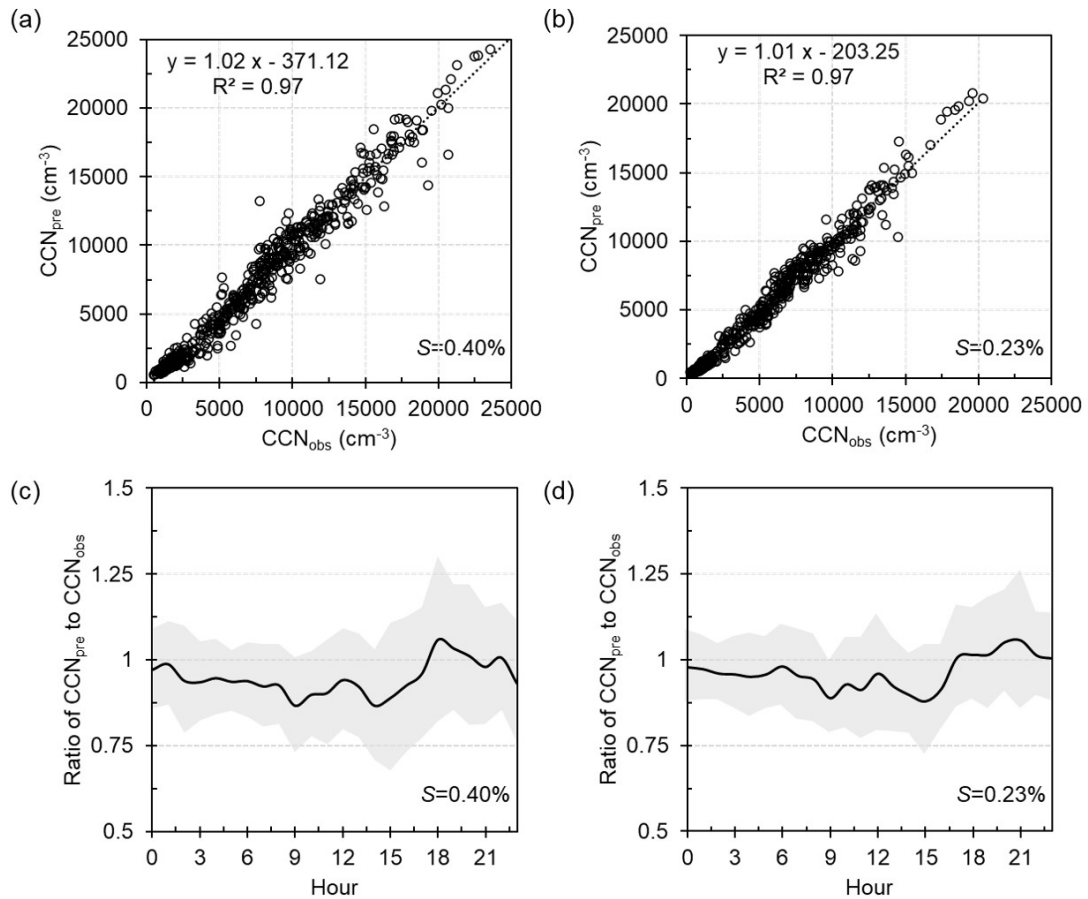

447 The diurnal variations in the ratio of predicted-to-measured N_{CCN} at $S=0.40$ % and
448 0.23 % are shown to examine the response of the BC density on N_{CCN} prediction at
449 different time periods (Fig. 6e, 6f). By applying the lower limit of density value of 0.14
450 g cm⁻³, the prediction is much worse compared to the use of the density of 2.1 g cm⁻³ at
451 nighttime (00:00-06:00 LT), when the latter is much closer to the real density of ambient
452 BC (Fig. 4c). The prediction is improved substantially by applying the value of 0.14 g
453 cm⁻³ during evening rush hours (18:00-20:00 LT), during which the ambient BC
454 particles is disturbed by the traffic emissions (Fig. 4c). And now, the prediction becomes
455 worse by applying the value of 2.1 g cm⁻³, and an obvious overestimation by up to ~40 %
456 is shown. The results further illustrate that it is critical to account for the real-time
457 mixing state and density of BC particles in N_{CCN} prediction, particularly in those regions

458 with heavy traffic and residential coal emissions.

459 It should be noted that the assumption of the surface tension of water would
460 overestimate the critical diameter and underpredict CCN number concentration. While
461 the surface tension depression might be more obvious for the small size particles (<60
462 nm), as the fraction of organics are higher at small particles size (Meng et al., 2014; Cai
463 et al., 2018). Here, in this study, we calculated the critical diameters at supersaturations
464 of 0.40 % and 0.23 %, typical values in cloud, corresponding to larger sizes (> 70 nm
465 and 90 nm) of aerosols. Therefore, the uncertainties from the application of the surface
466 tension of pure water should be negligible (< 10 %). Here, three schemes were assumed
467 to evaluate the effect of BC density and mixing state on prediction of CCN number
468 concentrations. The detailed calculation methods are presented in the supporting
469 information (SI: Methods) or referenced from Ren et al., 2018.

470 **3.3 Using the real-time variations of BC density and mixing state to predict N_{CCN}**

471 Figure 7 exhibits the comparisons between predicted and measured N_{CCN} at S of
472 0.23 % and 0.40 % by accounting for the retrieved real-time variations of BC density
473 and mixing state. It shows that the N_{CCN} can be well predicted with a slope of 1.01 and
474 1.02 at S of 0.23 % and 0.40 % respectively (Fig. 7a, 7b), only presenting a slight
475 deviation. The slight deviation is primarily due to the fixed value of the density for the
476 externally mixed BC caused by the retrieved method, especially during noontime and
477 evening rush periods (Fig. 7c and 7d).

478

479 **Figure 7.** Prediction CCN number concentration using the mixing state and In-BC
 480 density derived from HTDMAs at $S=0.40\%$ (a) and $S=0.23\%$ (b). Diurnal variations
 481 in the ratio of predicted-to-measured N_{CCN} at $S=0.40\%$ (c) and $S=0.23\%$ (d).

482 The diurnal variations in the ratio of predicted-to-measured N_{CCN} shows the N_{CCN}
 483 can be underestimated by up to 15% at $S=0.40\%$ during those periods. While, a slightly
 484 overrated during the evening traffic hours and nighttime may be due to the
 485 underestimation of the number fraction of Ex-BC. Overall, the dependence of the CCN
 486 prediction on S is due to the size dependence of κ and mixing state (Zhang et al., 2017;
 487 Liu et al., 2020; Xu et al., 2021). The better closure at $S=0.23\%$ is because that the bulk
 488 κ of particles is closer to that the critical diameter corresponding to $S=0.23\%$, with D_p
 489 of 100-150 nm. Similarly, the effect on CCN prediction induced by the bulk mixing

490 state would be more critical for smaller particles, corresponding to the critical diameter
491 at high S .

492 Overall, when considering the effective density of BC relevant to its mixing state,
493 the CCN closure achieves. Previous studies have shown that the fresh emitted BC
494 particles may convert from fractal-like aggregates to a compact structure and its density
495 would increase with the aging process (Pagels et al., 2009; Rissler et al., 2014; Peng et
496 al., 2016; Liu et al., 2019b; Zhang et al., 2020a, 2022), but the actual density of In-BC
497 may be lower than 1.8 g cm^{-3} in the ambient atmosphere according to this study.
498 Therefore, the currently applied value represents a density of the void-free structure of
499 BC particles may cause an overestimation in CCN prediction.

500 **4 Conclusions**

501 The mixing state and effective density of BC changed through heterogenous
502 chemistry process and thus would cause uncertainty in evaluating its CCN activity. In
503 this study, we develop a new method to retrieve the mixing state and effective density
504 of ambient BC using field measurements and the Köhler theory. The uncertainty of the
505 new retrieval method was evaluated within $\pm 30 \%$, which is primarily caused to
506 assuming the κ_{SOA} and the fraction of primary organic aerosols in non-hygroscopic or
507 hygroscopic mode. The retrieved results show that most of the BC particles were aged
508 and internally mixed with other components, with mean mass fraction of $80 \pm 20 \%$.
509 Averagely, the retrieved densities of the bulk and internal-mixed BC are 0.7 ± 0.5 and
510 $1.1 \pm 0.6 \text{ g cm}^{-3}$ respectively, but ranges widely from ~ 0.1 to 2.5 g cm^{-3} , indicating

511 various morphologies, different aging degree and compositions of ambient BC particles
512 due to the complex impact of multiple local sources and aging processes during the
513 observed period. The retrieved results are basically comparable with the previous
514 observations in North China Plain.

515 Further examination shows the N_{CCN} prediction is with uncertainties of -28 %–11 %
516 at the typical S of 0.23 % and 0.40 % by varying the BC density from 0.14 to 2.1 g cm⁻³
517 ³ that represents the lower and upper limit of ambient BC particles. Moreover, the
518 prediction is found more sensitive to the variability of BC density when it is <1.0 g cm⁻³
519 ³, suggesting a great significance to account for the effect of BC density for the aerosol
520 particles with low aging degree when evaluating the climate effect. The CCN closure
521 achieves when introducing the retrieved real-time BC density relevant to its mixing
522 state. This work provides a unique way of utilizing field observations to infer ambient
523 BC density and highlights the current assumption of a void-free structure of BC
524 particles in models would cause large uncertainties in CCN prediction and in the
525 relevant climate effect evaluation.

526 **Data availability.**

527 All data needed to evaluate the conclusions in the paper are present in the paper and/or
528 the Supplement. All data used in the study are also available from the corresponding
529 author upon request (zhangfang2021@hit.edu.cn).

530 **Author contributions.**

531 FZ and JR conceived the conceptual development of the manuscript. JR directed and
532 performed of the experiments with JL, LC, and FZ. JR conducted the data analysis and
533 wrote the draft of the manuscript. All authors edited and commented on the various
534 sections of the manuscript.

535 **Acknowledgments.**
