23

24 **Abstract.** Particulate nitrate ( $\text{NO}_3^-$ ) is one of the dominant components of fine particles  
25 in China, especially during pollution episodes, and has a significant impact on human  
26 health, air quality, and climate. Here a comprehensive field campaign that focuses on  
27 the atmospheric oxidation capacity and aerosol formation and their effects in the  
28 Yangtze River Delta (YRD) was conducted from May to June 2019 at a regional site in  
29 Changzhou, Jiangsu province in China. The concentration of  $\text{NO}_3^-$ , OH radical,  $\text{N}_2\text{O}_5$ ,  
30  $\text{NO}_2$ ,  $\text{O}_3$ , and relevant parameters were measured simultaneously. We showed a high  
31  $\text{NO}_3^-$  mass concentration with  $10.6 \pm 8.9 \mu\text{g m}^{-3}$  on average, which accounted for 38.3 %  
32 of total water-soluble particulate components and 32.0 % of total  $\text{PM}_{2.5}$ , followed by  
33 the proportion of sulfate, ammonium, and chloride by 26.0 %, 18.0 %, and 2.0 %,   
34 respectively. This result confirmed that the heavy nitrate pollution in eastern China not  
35 only happened in winter but also in the summertime. This study's high nitrate oxidation  
36 ratio (NOR) emphasizes the solid atmospheric oxidation and fast nitrate formation  
37 capacity in YRD. It is found that OH +  $\text{NO}_2$  during daytime dominates nitrate formation  
38 on clean days while  $\text{N}_2\text{O}_5$  hydrolysis vastly enhanced and became comparable with that  
39 of OH +  $\text{NO}_2$  during polluted days (67.2 % and 30.2 %, respectively). An updated  
40 observed-constrain Empirical Kinetic Modeling Approach (EKMA) was used to assess  
41 the kinetic controlling factors of both local  $\text{O}_3$  and  $\text{NO}_3^-$  productions, which indicated  
42 that the  $\text{O}_3$ -targeted scheme (VOCs:  $\text{NO}_x = 2: 1$ ) is adequate to mitigate the  $\text{O}_3$  and  
43 nitrate pollution coordinately during summertime in this region. Our results promote  
44 the understanding of nitrate pollution mechanisms and mitigation based on field  
45 observation and model simulation and call for more attention to nitrate pollution in the  
46 summertime.

## 49 **1 Introduction**

50 Chemical compositions of fine particles have been measured in China during the past  
51 twenty years, and secondary inorganic aerosol is regarded as one of the dominant  
52 species in aerosol (Cao et al., 2012; Hagler et al., 2006; Zhao et al., 2013; Andreae et  
53 al., 2008). Since the Air Pollution Prevention and Control Action Plan, there has been  
54 a significant decrease in SO<sub>2</sub>, NO<sub>2</sub>, and PM<sub>2.5</sub> concentration in China, while the  
55 inorganic nitrate ratio in PM<sub>2.5</sub> increased and became the considerable component in  
56 PM<sub>2.5</sub> (Shang et al., 2021; Zhang et al., 2022). Therefore, a comprehensive  
57 understanding of the particulate nitrate formation mechanism is essential and critical to  
58 mitigating haze pollution in China.

59 Massive research has been done in China to investigate nitrate formation  
60 mechanisms, and a basic framework has been established (Sun et al., 2006; Chang et  
61 al., 2018; Wu et al., 2019). In the daytime, NO<sub>2</sub> + OH radical oxidation (Reaction 1) is  
62 the major particulate nitrate formation pathway. The product (HNO<sub>3</sub>) reacts with  
63 alkaline substances in aerosol, generating particulate nitrate. This pathway is mainly  
64 controlled by precursors concentration as well as the gas-particle partition of gaseous  
65 nitric acid, and particulate nitrate depends on temperature, relative humidity (RH), NH<sub>3</sub>  
66 concentration, and aerosol acidity (Wang et al., 2009; Song and Carmichael, 2001;  
67 Meng et al., 2020; Zhang et al., 2021). At night, N<sub>2</sub>O<sub>5</sub> uptake is a vital nitrate formation  
68 pathway (Reaction 4)(Chen et al., 2020; Wang et al., 2022). N<sub>2</sub>O<sub>5</sub> is formed through  
69 NO<sub>2</sub> + NO<sub>3</sub> (Reaction 3) and there exists a quick thermal equilibrium balance ( $K_{eq} = 5.5$   
70  $\times 10^{-17}$  cm<sup>-3</sup> molecule<sup>-1</sup> s<sup>-1</sup>, 298 K). However, two problems remain ambiguous in  
71 quantifying the contribution of N<sub>2</sub>O<sub>5</sub> uptake to nitrate formation. The first is the N<sub>2</sub>O<sub>5</sub>  
72 heterogeneous uptake coefficient ( $\gamma$ ) on ambient aerosol is highly varied with the range  
73 from 10<sup>-4</sup> to 10<sup>-1</sup> based on previous lab and field measurements (Bertram and Thornton,  
74 2009; Brown et al., 2009; Wang et al., 2017c; Wang and Lu, 2016). The other one is  
75 ClNO<sub>2</sub> production yield which influences nitrate contribution due to the extensive  
76 variation range (Phillips et al., 2016; Staudt et al., 2019; Tham et al., 2018). Both two

77 parameters are complex to well-predicted by current schemes. NO<sub>2</sub> heterogeneous  
 78 uptake has been found nonnegligible for nitrate formation, which can be a vital pathway  
 79 during heavy haze events, according to recent study (Qiu et al., 2019; Chan et al., 2021).  
 80 The uptake coefficient and nitrate yield remain uncertain, as same as the N<sub>2</sub>O<sub>5</sub>  
 81 heterogeneous reaction. Besides, N<sub>2</sub>O<sub>5</sub> homogeneous hydrolysis and NO<sub>3</sub> radical  
 82 oxidation have a minor contribution to particulate nitrate under ambient conditions  
 83 (Brown et al., 2009; Seinfeld and Pandis, 2016).

84 As a critical area of China's economy and industry, Yangtze River Delta (YRD)  
 85 has suffered severe air pollution during past decades, and fine particle pollution in YRD  
 86 has raised a widespread concern (Guo et al., 2014; Zhang et al., 2015; Zhang et al.,  
 87 2017; Ming et al., 2017; Xue et al., 2019). However, most research focuses on  
 88 wintertime PM<sub>2.5</sub> pollution and lacks measurements of critical intermediate species and  
 89 radicals to assess the importance of each nitrate formation pathway. In this study, with  
 90 the direct measurements of hydroxyl radical and the reactive nitrogen compounds and  
 91 chemical box model analysis, we explore the characteristics of nitrate and precursors in  
 92 YRD in the summer of 2019, the importance of particulate nitrate formation pathways  
 93 is quantified, and the controlling factors are explored. A further suggestion for summer  
 94 pollution prevention and control in the local area is proposed.

## 95 2 Site description and methods

### 96 2.1 The campaign site

97 This campaign took place at a suburban sanatorium from May 30<sup>th</sup> to June 18<sup>th</sup>, 2019,  
98 in Changzhou, China. Changzhou (119.95 °E, 31.79 °N) is located in Jiangsu province  
99 and about 150 km northwest of Shanghai. The sanatorium, located 420 m east of Lake  
100 Ge (one of the largest lakes in Jiangsu province, 164 square kilometers), is surrounded  
101 by farmland and fishponds. With the closest arterial traffic 1 km away, several industry  
102 zones are 4 km to the east. The prevailing wind was from the south and southeast sectors  
103 (about 30 % of the time) compared to 20 % from the west sector, of which only 15 %  
104 came from the east. The wind speed was usually lower than 5 m s<sup>-1</sup> with faster speed  
105 from the west. This site was influenced by anthropogenic and biological sources with  
106 occasional biomass burning.

107

108 **Figure 1** The location of the campaign site (red star), Changzhou, is 150 km on the  
109 northwest side of Shanghai.

### 110 2.2 The instrumentation

111 Multiple gaseous and particulate parameters were measured simultaneously during the

112 campaign to comprehensively interpret the nocturnal atmospheric capacity and aerosol  
113 formation. The related instruments are listed in Table 1.  $\text{N}_2\text{O}_5$  and Particle Number and  
114 Size Distribution (PNSD) were measured on the fourth floor of the sanatorium, which  
115 is the top of the building. Other instruments were placed in containers on the ground  
116 170 m northeast of the building and sampling inlets at circa 5 m above the ground  
117 through the containers' roof.

118  $\text{N}_2\text{O}_5$  was measured by Cavity Enhanced Absorption Spectrometer (CEAS) based  
119 on Lambert-Beer's law which was developed by (Wang et al., 2017b). Briefly, air  
120 samples were drawn through the window and reached out of the wall 30 cm to prevent  
121 influence from surface deposition. The aerosol membrane filter was deployed before  
122 the PFA sampling tube and changed every 2 hours at night to avoid a decrease in  $\text{N}_2\text{O}_5$   
123 transmission efficiency due to the increased loss of  $\text{N}_2\text{O}_5$  from the accumulated aerosols  
124 on the filter.  $\text{N}_2\text{O}_5$  was decomposed to  $\text{NO}_3$  and  $\text{NO}_2$  through preheating tube heat at  
125 130 °C and detected within a PFA-coated resonator cavity heated at 110 °C to prevent  
126 the formation of  $\text{N}_2\text{O}_5$  by reversible reaction subsequently. At the end of each sampling  
127 cycle (5 min), a 30 s injection of high concentration NO (10 ppm, 20 ml min<sup>-1</sup>) mixed  
128 with sample air was set to eliminate  $\text{NO}_3$ - $\text{N}_2\text{O}_5$  in the system. The NO titration  
129 spectrums were adopted as the dynamic background spectrum by assuming no  $\text{H}_2\text{O}$   
130 concentration variation in a single sampling cycle. The loss of  $\text{N}_2\text{O}_5$  in the sampling  
131 system and filter was also considered during data correction. The limit of detection  
132 (LOD) was estimated to be 2.7 pptv (1  $\sigma$ ) with an uncertainty of 19 %.

133 OH radical measurement was conducted by Fluorescence Assay by Gas Expansion  
134 Laser-Induced Fluorescence techniques (FAGE-LIF). Ambient air was expanded  
135 through a 0.4 mm nozzle to low pressure in a detection chamber, where the 308 nm  
136 laser pulse irradiated OH radical at a repetition rate of 8.5 kHz (Chen et al., 2018).  $\text{NO}_x$   
137 and  $\text{O}_3$  were monitored by commercial monitors (Thermo-Fisher 42i and 49i). Volatile  
138 organic compounds (VOCs) were measured by an automated Gas Chromatograph  
139 equipped with a Mass Spectrometer and flame ionization detector (GC-MS) with a time

140 resolution of 60 min. The photolysis frequencies were determined from the spectral  
141 actinic photon flux density measured by a spectroradiometer (Bohn et al., 2008).

142 PM<sub>2.5</sub> concentration was obtained by Tapered Element Oscillating Microbalance  
143 (TEOM 1405, Thermo Scientific Inc). Aerosol surface concentration (S<sub>a</sub>) was  
144 converted from particle number and size distribution, which was measured by Scanning  
145 Mobility Particle Sizer (SMPS, TSI 3936) and Aerosol Particle Sizer (APS, TSI 3321)  
146 and modified to the wet particle-state S<sub>a</sub> with a hygroscopic growth factor (Liu et al.,  
147 2013). The uncertainty of the wet S<sub>a</sub> was ~ 30 %. Meanwhile, water-soluble particulate  
148 components and their gaseous precursors were analyzed through the Monitor for  
149 AeRosols and GAses in ambient air (MARGA, Chen et al. (2017)). Meteorological data  
150 were also available, including the temperature, relative humidity (RH), pressure, wind  
151 speed, and wind direction.

152 **Table 1** The observed gas and particle parameters during the campaign.

Parameters	Detection of limit	Method	Accuracy
N <sub>2</sub> O <sub>5</sub>	2.7 pptv (1 σ, 1 min)	CEAS	± 19 %
OH	1.6 × 10 <sup>5</sup> cm <sup>-3</sup> (1 σ, 60 s)	LIF <sup>a</sup>	± 21 %
NO	60 pptv (2 σ, 1 min)	PC <sup>c</sup>	± 10 %
NO <sub>2</sub>	0.3 ppbv (2 σ, 1 min)	PC <sup>c</sup>	± 10 %
O <sub>3</sub>	0.5 ppbv (2 σ, 1 min)	UV photometry	± 5 %
VOCs	20-300 pptv (60 min)	GC-MS	± 15 %
PM <sub>2.5</sub>	0.1 μg m <sup>-3</sup> (1 min)	TEOM <sup>d</sup>	± 5 %
Photolysis frequencies	5 × 10 <sup>-5</sup> s <sup>-1</sup> (1 min)	SR <sup>e</sup>	± 10 %
PNSD	14 nm -700 nm (4 min)	SMPS, APS	± 10 %
HNO <sub>3</sub> , NO <sub>3</sub> , HCl	0.06 ppbv (30 min)	MARGA <sup>f</sup>	± 20 %
NH <sub>4</sub> <sup>+</sup> , NO <sub>3</sub> <sup>-</sup> , Cl <sup>-</sup> , SO <sub>4</sub> <sup>2-</sup>	0.05 μg m <sup>-3</sup> (30 min)	MARGA <sup>f</sup>	± 20 %

### 156 2.3 The empirical kinetic modeling approach

157 A box model coupled with the Regional Atmospheric Chemical Mechanism version 2  
158 (RACM2, Goliff, Stockwell & Lawson, 2013) is used to conduct the mitigation  
159 strategies studies. The model is operated in one-hour time resolution with measurement

160 results of temperature, relative humidity, pressure, CO, NO<sub>2</sub>, H<sub>2</sub>O, photolysis  
 161 frequencies, and aggregated VOCs input to constrain the model. It should be noted that  
 162 HONO concentration is calculated by NO<sub>2</sub> times 0.02, as suggested by Elshorbany et al.  
 163 (2012), and has been used in the box model before (Lou et al., 2022). Long-lived species  
 164 such as H<sub>2</sub> and CH<sub>4</sub> are assumed as constants (550 ppbv and 1900 ppbv, respectively).  
 165 Moreover, a 13-hour constant loss rate of unconstrained intermediate and secondary  
 166 products, the result of synthetic evaluating secondary simulation of secondary species,  
 167 is set for representing the multi-effects of deposition, transformation, and transportation.

168 The approaches to the chemical production of O<sub>3</sub> (P(O<sub>3</sub>)) and inorganic nitrate  
 169 (P(NO<sub>3</sub><sup>-</sup>)) are described in previous articles (Tan et al., 2021; Tan et al., 2018) and  
 170 expressed as Equation 1 and 4:

$$P(O_3) = F(O_3) - D(O_3) \quad \text{Eq1}$$

$$F(O_3) = k_{HO_2+NO}[NO][HO_2] + k_{(RO_2+NO)eff}[NO][RO_2] \quad \text{Eq2}$$

$$D(O_3) = k_{OH+NO_2}[OH][NO_2] + (k_{OH+O_3}[OH] + k_{HO_2+O_3}[HO_2] + k_{alkenes+O_3}[alkenes])[O_3] \quad \text{Eq3}$$

$$P(NO_3^-) = P(HNO_3) + P(pNO_3^-) \quad \text{Eq4}$$

$$P(HNO_3) = k_{OH+NO_2}[OH][NO_2] \quad \text{Eq5}$$

$$P(pNO_3^-) = 0.25(2 - \varphi) C \gamma S_a [N_2O_5] \quad \text{Eq6}$$

171 briefly, P(O<sub>3</sub>) is net ozone production, which is calculated by peroxy radical + NO  
 172 oxidation (Eq. 2) minus the chemical loss of O<sub>3</sub> and NO<sub>2</sub> (Eq. 3). P(NO<sub>3</sub><sup>-</sup>) is constituted  
 173 by reaction OH + NO<sub>2</sub> (Eq. 5) and N<sub>2</sub>O<sub>5</sub> heterogeneous uptake (Eq. 6). Here, rate  
 174 constants of reactions are obtained from NASA JPL Publication (Burkholder et al.,  
 175 2015) or RACM2 (Goliff et al., 2013).  $\gamma$  is the N<sub>2</sub>O<sub>5</sub> uptake coefficient calculated from  
 176 parameterization ( $\gamma_p$ , more details in chapter 3.3).  $\varphi$  represents ClNO<sub>2</sub> production yield  
 177 through N<sub>2</sub>O<sub>5</sub> hydrolysis, and the mean value reported by Xia et al. (2020) is used in  
 178 this work.

179 The empirical Kinetic Modeling Approach (EKMA) was innovated to study the  
 180 effects of precursors (VOCs and NO<sub>x</sub>) reactivity on the region's ozone pollution by  
 181 Kanaya et al., which helps recognize the region's susceptibility to precursors by weight  
 182 and become a prevalent tool to study the process of ozone formation (Tan et al., 2018;  
 183 Yu et al., 2020b; Kanaya et al., 2008). The prevention and control problem of pollutant  
 184 generation can be transformed through the EKMA curve to reduce its precursors'  
 185 emissions. Furthermore, the precursor reduction scheme needed for total pollutant  
 186 control is given qualitatively. P(NO<sub>3</sub><sup>-</sup>) can also be analyzed through EKMA for the

187 nonlinear secondary formation relationship with precursor reactivity. Here, an isopleth  
188 diagram of the net ozone production rate as functions of the reactivities of NO<sub>x</sub> and  
189 VOCs can be derived from EKMA. In detail, 0.01 to 1.2 emission reduction strategy  
190 assumptions are exponential interpolation into 20 kinds of emission situations of NO<sub>x</sub>  
191 and VOCs, respectively, which in total counts 400 scenarios.

## 192 **2.4 The calculation of aerosol liquid water content**

193 Aerosol liquid water content (ALWC) is calculated through ISORROPIA II  
194 (Fountoukis and Nenes, 2007). Forward mode is applied in this study. Furthermore,  
195 water-soluble particulate components in PM<sub>2.5</sub> and gaseous species (NH<sub>3</sub> + HNO<sub>3</sub> + HCl)  
196 obtained from MARGA, along with RH and T, are input as initial input. In addition,  
197 metastable aerosol state is chosen due to high RH during this campaign.

## 198 **3 Result and discussion**

### 199 **3.1 Overview of measurements**

200 The time used in this study is China Standard Time (UTC + 8) and the local sunrise and  
201 sunset time during the campaign were around 5 am and 7 pm, respectively. The whole  
202 campaign period is divided into four PM<sub>2.5</sub> clean periods and four PM<sub>2.5</sub> polluted  
203 periods (9 out of 14 days, the latter polluted periods days refer to PM<sub>2.5</sub> pollution  
204 except specified description) according to the Chinese National Air Quality Standard  
205 (CNAAQs) Grade I of daily PM<sub>2.5</sub> concentrations (< 35.0 μg m<sup>-3</sup>). Figure 2 shows the  
206 meteorological parameters, and gas-phase and particulate species timeseries during the  
207 observation. During the campaign, the temperature was high; the maximum reached  
208 34.5 °C, with an average of 25.1 ± 3.7 °C. RH changed drastically from 21 % to 88 %,  
209 with a mean value of 58.9 ± 14.0 %. The mean NO<sub>2</sub> concentration was 14.8 ± 9.5 ppbv.  
210 Meanwhile, the O<sub>3</sub> average was 54.6 ± 28.8 ppbv, exceeding CNAAQs Grade II for a  
211 maximum daily average of 8 h ozone (160 μg m<sup>-3</sup>) on 14 out of 19 days and exceeding  
212 200 μg m<sup>-3</sup> on six days.

213

214 **Figure 2** Timeseries of NO<sub>2</sub>, O<sub>3</sub>, N<sub>2</sub>O<sub>5</sub>, OH radical, PM<sub>2.5</sub>, and water-soluble particulate  
 215 components, temperature, and RH. The vertical dotted line represents the zero clock.  
 216 The black horizontal solid line in O<sub>3</sub> and PM<sub>2.5</sub> panels represents Chinese national air  
 217 quality standards for O<sub>3</sub> and PM<sub>2.5</sub>, respectively. The top panel color blocks represent  
 218 the PM<sub>2.5</sub> clean day (light green) and PM<sub>2.5</sub> polluted day(salmon).

219

220 Daytime OH radical ranged from  $2 \times 10^6$  to  $8 \times 10^6$  molecular  $\text{cm}^{-3}$  with a daily  
 221 peak over  $3 \times 10^6$  molecular  $\text{cm}^{-3}$ . Maximum OH radical reached  $8.18 \times 10^6$  molecular  
 222  $\text{cm}^{-3}$  in this campaign. Compared with other summertime OH radical observed in China,  
 223 OH radical concentration in this site is relatively low but still on the same order of  
 224 magnitude (Lu et al., 2012; Lu et al., 2013; Ma et al., 2022; Tan et al., 2017; Woodward-  
 225 Massey et al., 2020; Yang et al., 2021). N<sub>2</sub>O<sub>5</sub> mean concentration was  $21.9 \pm 39.8$  pptv  
 226 with a nocturnal average of  $61.0 \pm 63.1$  pptv and a daily maximum of over 200 pptv at  
 227 eight nights. The maximum concentration of N<sub>2</sub>O<sub>5</sub> (477.2 pptv, 5 min resolution)  
 228 appeared at 20:47 on June 8<sup>th</sup>. The average NO<sub>3</sub> radical production rate P(NO<sub>3</sub>) is  $2.1$   
 229  $\pm 1.4$  ppbv  $\text{h}^{-1}$  with nocturnal average P(NO<sub>3</sub>)  $2.8 \pm 1.6$  ppbv  $\text{h}^{-1}$  and daytime P(NO<sub>3</sub>)  
 230  $2.2 \pm 1.4$  ppbv  $\text{h}^{-1}$ . P(NO<sub>3</sub>) is about twice of documented value in Taizhou and North  
 231 China Plain (Wang et al., 2017a; Wang et al., 2018b; Wang et al., 2020a), but close to

232 another result in YRD before (Chen et al., 2019). The average  $PM_{2.5}$  was  $34.6 \pm 17.8$   
233  $\mu\text{g m}^{-3}$  with a maximum reach of  $163.0 \mu\text{g m}^{-3}$ . The water-soluble particulate  
234 components of  $PM_{2.5}$  are displayed as well. The average  $\text{NO}_3^-$  concentration was  $10.6$   
235  $\mu\text{g m}^{-3}$ , which accounts for 38.3 % mass concentration of water-soluble particulate  
236 components and 32.0 % total  $PM_{2.5}$ , while the proportion of sulfate, ammonium, and  
237 chloride is 26.0 %, 18 %, and 2.0 % respectively. To sum up, during the campaign  
238 period, the pollution of  $PM_{2.5}$  would be generally exacerbated on high  $\text{O}_3$  and  $\text{NO}_2$  days.  
239 Precipitation occurred during four clean processes receded pollutant concentration;  
240 otherwise, the pollution condition remained severe.

241 The mean diurnal variations (MDC) of temperature, RH,  $\text{NO}_2$ ,  $\text{O}_3$ ,  $\text{P}(\text{NO}_3)$ ,  $\text{N}_2\text{O}_5$ ,  
242 OH radical, and  $PM_{2.5}$  in different air quality are shown in Figure 3. The temperature,  
243 RH, and OH radical MDC show indistinctive differences between clean days (CD) and  
244 polluted days (PD). The MDC of  $\text{NO}_2$  has two concentration peaks that appear at 06:00  
245 and 21:00 on CD, while at PD, its peak appears at 20:00 and maintains a high level  
246 during the whole night.  $\text{O}_3$  diurnal pattern reflects a typical urban-influenced character  
247 with a maximum  $\text{O}_3$  peak that lasts four hours from 14:00 to 17:00, while polluted-day  
248  $\text{O}_3$  peak concentration is 1.2 higher than clean-day.  $\text{P}(\text{NO}_3)$  grows after the  $\text{O}_3$  peak and  
249 maximum  $\text{P}(\text{NO}_3)$  shows at 19:00 with an average value of  $1.7 \text{ ppbv h}^{-1}$  on CD. By  
250 contrast, the mean polluted-day  $\text{P}(\text{NO}_3)$  is  $2.6 \text{ ppbv h}^{-1}$ , and the maximum value  
251 reaches  $4.7 \text{ ppbv h}^{-1}$ . In contrast, the clean-day  $\text{N}_2\text{O}_5$  has a higher average and maximum  
252 concentration than PD, which suggests a faster removal process during PD.  $PM_{2.5}$  has  
253 a similar trend with  $\text{P}(\text{NO}_3)$  and has a higher concentration during nighttime.

254

255  
 256 **Figure 3** The mean diurnal variations of temperature, RH, NO<sub>2</sub> (Salmon), O<sub>3</sub>, P(NO<sub>3</sub>),  
 257 N<sub>2</sub>O<sub>5</sub>, OH radical(orange), and PM<sub>2.5</sub> of clean day and polluted day.

258 **3.2 The evolution of nitrate pollution**

259 Figure 4 (a) shows the relationship between nitrate and sulfate with water-soluble  
 260 particulate components. Nitrate positively correlates with total water-soluble  
 261 particulate components, while the sulfate ratio has an inverse correlation. With PM<sub>2.5</sub>  
 262 concentration increasing, nitrate proportion increases rapidly and keeps high weight at  
 263 heavy PM<sub>2.5</sub> period while sulfate ratio peers opposite phenomenon. Once the mass  
 264 concentration of total water-soluble particulate component is over 30 μg m<sup>-3</sup>, the mass  
 265 fraction of nitrate in total water-soluble particulate components is up to 50 % on average.  
 266 This result illustrates that particulate nitrate is one of the vital sources of explosive  
 267 growth particulate matter.

268  
 269 **Figure 4** (a) Particulate ion mass concentration ratio of nitrate and sulfate to water  
 270 soluble ion. (b) NOR against RH, colored with temperature. (c) SOR against RH,  
 271 colored with temperature.

272

273 To further assess the conversion capacity of nitrate and sulfate in this site, the sulfur  
274 oxidation ratio (SOR) and the nitrogen oxidation ratio (NOR) are used to indicate the  
275 secondary transformation ratio of SO<sub>2</sub> and NO<sub>2</sub>, respectively (Sun et al., 2006). SOR  
276 and NOR are estimated using the formulae below:

277

$$\text{SOR} = \frac{n\text{SO}_4^{2-}}{n\text{SO}_4^{2-} + n\text{SO}_2} \quad \text{Eq7}$$

$$\text{NOR} = \frac{n\text{NO}_3^-}{n\text{NO}_3^- + n\text{NO}_2} \quad \text{Eq8}$$

278 Where n refers to the molar concentration, the higher SOR and NOR represent more  
279 oxidation of gaseous species into a secondary aerosol. As depicted in Figure 4 (b-c),  
280 NOR rapidly increases at RH < 45 %, remains constant at 45 % < RH < 75 %, and ends  
281 with a sharp increase at RH > 75 %. During the study period, not only is the average  
282 concentration of NO<sub>2</sub> higher among PD but there is also a significant difference  
283 between PD and CD NOR. The average values of NOR are 0.32 in PD and 0.25 in CD,  
284 respectively, which manifests the more secondary transformation and pollution  
285 potential in PD. In contrast, the SOR stays constant at a high value (~ 0.5) during the  
286 whole RH scale, which shows a different pattern from previous research (Li et al., 2017;  
287 Zheng et al., 2015). One possible explanation is that SO<sub>2</sub> concentration stays low during  
288 the whole campaign (4.4 ± 2.4 ppbv on average), and SO<sub>2</sub> oxidation depends on the  
289 limit of SO<sub>2</sub> instead of oxidation capability. Meanwhile, the mean SOR in both  
290 situations is over 0.5 (0.52 in CD and 0.56 in PD), further supporting the SO<sub>2</sub> limited  
291 hypothesis. Besides, Table 2 summarizes NOR and SOR values in YRD. NOR and  
292 SOR in this study are similar to values reported in other YRD research (Shu et al., 2019;  
293 Zhang et al., 2020b; Qin et al., 2021; Zhao et al., 2022), except values in 2013 (Wang  
294 et al., 2016), but higher than north China study (Cao et al., 2017) which emphasize the  
295 solid atmospheric oxidation capacity in YRD region.

**Table 2** Statistical result of NOR and SOR in YRD

### 297 3.3 The derivation of N<sub>2</sub>O<sub>5</sub> uptake coefficient

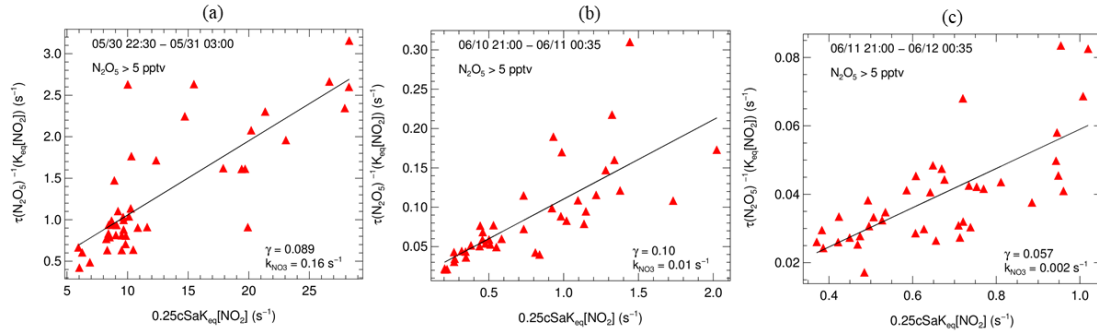

298 Statistical analysis of the observation above highlights the rapid formation of  
 299 particulate nitrate. To assess the contribution of N<sub>2</sub>O<sub>5</sub> hydrolysis to particular nitrate  
 300 formation, two methods are applied to calculate the N<sub>2</sub>O<sub>5</sub> uptake coefficient. The first  
 301 method is a stationary-state approximation (Brown et al., 2003). By assuming that the  
 302 rates of production and loss of N<sub>2</sub>O<sub>5</sub> are approximately in balance, the total loss rate of  
 303 N<sub>2</sub>O<sub>5</sub> ( $k_{N_2O_5}$ ) can be calculated through equation 9. The  $k_{N_2O_5}$  is main dominated by  
 304 N<sub>2</sub>O<sub>5</sub> heterogeneous uptake, since homogeneous hydrolysis of N<sub>2</sub>O<sub>5</sub> contribute tiny  
 305 (Brown and Stutz, 2012). N<sub>2</sub>O<sub>5</sub> uptake coefficient through steady-state (note as  $\gamma_s$ ) is  
 306 derived as equation 10. Here C is the mean molecule speed of N<sub>2</sub>O<sub>5</sub>, and S<sub>a</sub> is the aerosol  
 307 surface concentration.

$$\tau_{ss}(N_2O_5) = \frac{[N_2O_5]}{k_{R3.1}[NO_2][O_3]} = \left( k_{N_2O_5} + \frac{k_{NO_3}}{K_{eq}[NO_2]} \right)^{-1} \quad \text{Eq9}$$

$$k_{N_2O_5} = 0.25 C \gamma_s S_a \quad \text{Eq10}$$

308 Due to the fast variety of NO<sub>3</sub> loss rates from VOCs, the steady-state method has been  
 309 unattainable in conditions affected by emission interferences. During the whole  
 310 campaign, we only retrieve three valid fitting results. As shown in Figure 5, the fitted

311  $\gamma_s$  ranged from 0.057 to 0.123, which is comparable with Taizhou (0.041, Wang et al.  
 312 (2020a)) and much higher than other results in China (Yu et al., 2020a; Wang et al.,  
 313 2018a; Wang et al., 2020b; Wang et al., 2017a). The calculated  $k_{\text{NO}_3}$  ranged from 0.002  
 314 to  $0.16 \text{ s}^{-1}$ , represents drastic VOCs change during this campaign.

315  
 316 **Figure 5** Derived  $\text{N}_2\text{O}_5$  uptake coefficients from  $\text{N}_2\text{O}_5$  steady lifetime ( $\gamma_s$ ) with  $\text{NO}_2$   
 317 and  $S_a$ , plots (a-c) represent the linear fitting results on the nights of 05/30, 06/10, and  
 318 06/11, respectively.

319 The other approach is the parameterization by (Yu et al., 2020a) which is depicted  
 320 as follows:

$$\gamma_{\text{P}} = \frac{4 V_a}{c S_a} K_{\text{H}} \times 3.0 \times 10^4 \times [\text{H}_2\text{O}] \left( 1 - \frac{1}{\left( 0.033 \times \frac{[\text{H}_2\text{O}]}{[\text{NO}_3^-]} \right) + 1 + \left( 3.4 \times \frac{[\text{Cl}^-]}{[\text{NO}_3^-]} \right)} \right) \quad \text{Eq11}$$

321  
 322 Where  $V_a/S_a$  is the measured aerosol volume to surface area ratio by SMPS;  $K_{\text{H}}$  is  
 323 Henry's law coefficient which is set as 51 as recommended;  $[\text{NO}_3^-]$  and  $[\text{Cl}^-]$  are aerosol  
 324 inorganic concentration measured by Marga;  $[\text{H}_2\text{O}]$  is aerosol water content calculated  
 325 through ISORROPIA II. The valid parameterization calculated  $\text{N}_2\text{O}_5$  uptake coefficient  
 326 (note as  $\gamma_{\text{P}}$ ) from May 30<sup>th</sup> to June 08<sup>th</sup>, 2019, shows in Figure 6 a good consistency  
 327 between the trends of  $\gamma_{\text{P}}$  and aerosol water content. Nighttime  $\gamma_{\text{P}}$  varies from 0.001 to  
 328  $0.024$  with an average of  $0.069 \pm 0.0050$  in polluted condition and  $0.0036 \pm 0.0026$  in  
 329 clean condition. The  $\text{N}_2\text{O}_5$  uptake coefficient shows a good correlation between RH and  
 330 aerosol water content. For the  $\text{N}_2\text{O}_5$  uptake coefficient, although particulate nitrate mass  
 331 concentration increased during the pollution event, an antagonistic effect on the  $\text{N}_2\text{O}_5$   
 332 uptake coefficient was not obvious for the nitrate molarity decreasing.

333 Furthermore, we compare the difference between  $\gamma_{_S}$  and  $\gamma_{_P}^h$ . Taking the night of  
 334 May 30<sup>th</sup> as an example, the  $\gamma_{_S}$  is 0.089 while  $\gamma_{_P}$  ranges from 0.024 to 0.057 with an  
 335 average value of  $0.013 \pm 0.0051$ . The difference between steady-state and  
 336 parameterization is significant; one possible explanation is uncertainty for stationary-  
 337 state approximation caused by local NO or VOCs emission (Brown et al., 2009; Chen  
 338 et al., 2022). Another reason is that parameterization by Yu et al. ignores the impact of  
 339 organic matter on the fine particle. The difference in aerosol composition between this  
 340 work and Yu et al may also bring uncertainty. Overall consideration,  $\gamma_{_P}$  will be chosen  
 341 for the N<sub>2</sub>O<sub>5</sub> heterogeneous uptake coefficient in later analysis and discussion.

342 **Figure 6** Results of N<sub>2</sub>O<sub>5</sub> uptake coefficients through parameterization ( $\gamma_{_P}$ ). (a) shows  
 343 timeseries of  $\gamma_{_P}$  and ISORROPIA II results of aerosol water content (AWC). (b) is the  
 344 box-plot of  $\gamma_{_P}$  on the polluted day and clean day, the hollow square represents the mean  
 345 value, and the solid line across the box shows the median score for the data set, while  
 346 the top and bottom whiskers represent 90 % and 10 % value of  $\gamma_{_P}$ , respectively.  
 347

### 348 3.4 Quantifying the contribution of nitrate formation pathways

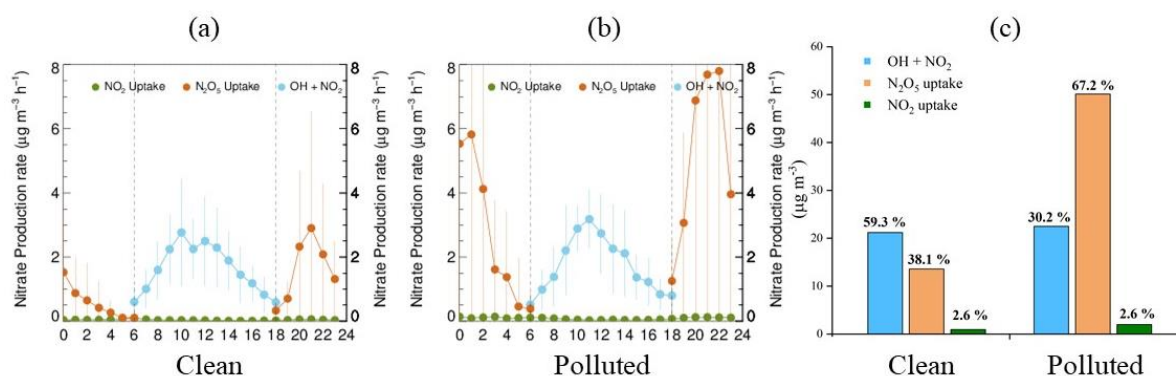

349 After the N<sub>2</sub>O<sub>5</sub> uptake coefficient is counted, nitrate production potential (P(NO<sub>3</sub><sup>-</sup>)) can  
 350 be calculated. Here N<sub>2</sub>O<sub>5</sub> uptake coefficient is set as 0.036 on clean day and 0.069 on  
 351 polluted day, respectively, which are the average value derived from parameterization.  
 352 The production ratio of NO<sub>3</sub><sup>-</sup> (by considering ClNO<sub>2</sub> yield of 0.54) is set as 1.46 in the  
 353 former study (Xia et al., 2020). Gas particle distribution is considered by the result of  
 354 particular nitrate and gas-phase nitrate by MARGA (input HNO<sub>3</sub>/NO<sub>3</sub><sup>-</sup> ratio to the  
 355 model as OH + NO<sub>2</sub> nitrate production rate). NO<sub>2</sub> heterogeneous uptake coefficient is set

356 as  $5.8 \times 10^{-6}$  depending on the report by Yu et al. (2021) which is the result of 70% RH  
 357 on urban grime.

358 The mean diurnal variations of the nitrate production potential of clean and polluted  
 359 day are depicted in Figure 7. The OH + NO<sub>2</sub> pathway shows no significant difference  
 360 between clean and polluted day and dominates clean day nitrate formation potential.  
 361 Since the level of OH and NO<sub>2</sub> is less affected by the fine particle level. However, the  
 362 rapid increase of the N<sub>2</sub>O<sub>5</sub> heterogeneous uptake pathway on polluted day is fatal, and  
 363 its peak formation rate at night over the OH + NO<sub>2</sub> pathway can be used to explain  
 364 nighttime nitrate explosive growth.

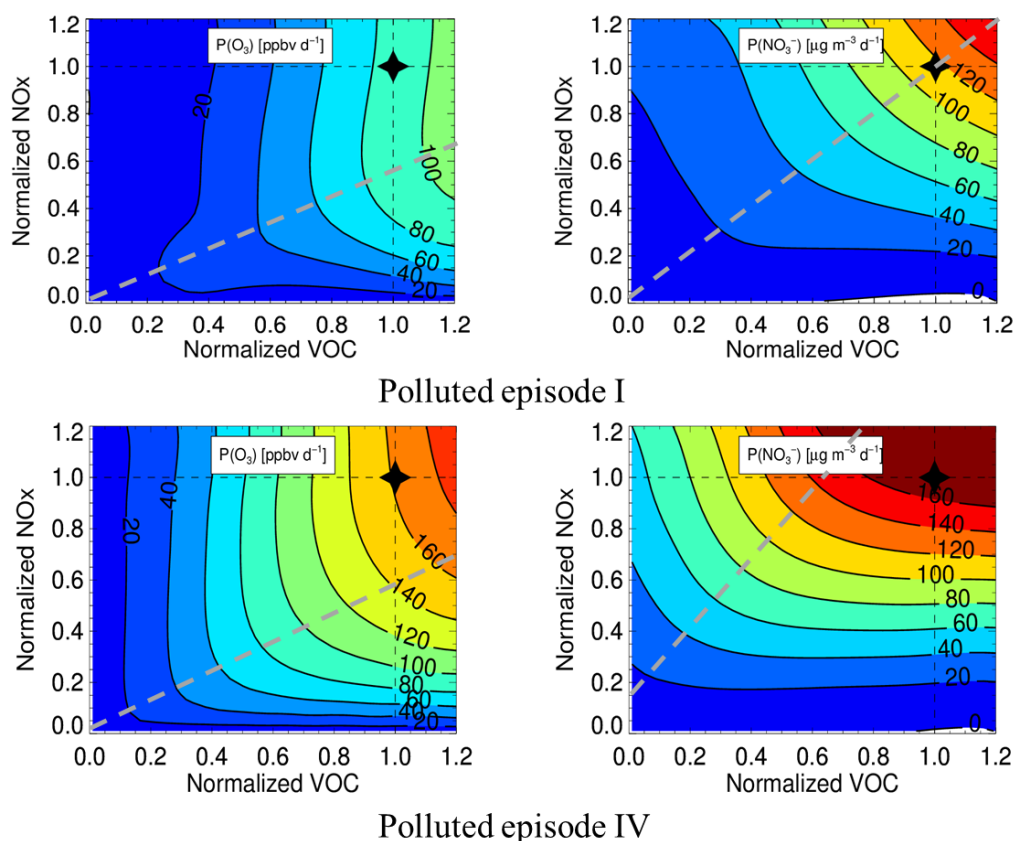

365 As shown in Figure 7c, OH + NO<sub>2</sub> dominates nitrate production on clean day, while  
 366 the N<sub>2</sub>O<sub>5</sub> uptake pathway only contributes 13.6  $\mu\text{g m}^{-3}$ . On polluted days, the ability of  
 367 N<sub>2</sub>O<sub>5</sub> uptake grows fast, reaching 50.1  $\mu\text{g m}^{-3}$ , while the OH pathway doesn't change  
 368 much. There is no distinct difference in the daytime pathway (OH + NO<sub>2</sub>) between clean  
 369 day and polluted day, while the nighttime pathway ratio rises from 38.1 % on clean day  
 370 to 67.2 % on polluted day. NO<sub>2</sub> heterogeneous uptake increases from 0.93  $\mu\text{g m}^{-3}$  on  
 371 clean day to 2.0  $\mu\text{g m}^{-3}$  on polluted day, but the contribution proportion does not change  
 372 obviously. Both the higher N<sub>2</sub>O<sub>5</sub> uptake coefficient and higher S<sub>a</sub> on polluted day  
 373 increase the contribution of N<sub>2</sub>O<sub>5</sub> hydrolysis on particular nitrate at pollution condition.  
 374

375  
 376 **Figure 7** The mean diurnal variations of the nitrate production potential of clean day(a)  
 377 and polluted day (b) and the P(NO<sub>3</sub><sup>-</sup>) distribution of clean and polluted day (c).

### 378 3.5 Mitigation strategies of particulate nitrate and ozone productions

379 We selected two pollution episodes (Episode I (2019.05.30 00:00 - 2019.06.02 00:00)  
380 and IV (2019.06.14 17:30 - 2019.06.17 12:00)) to explore the mitigation way of ozone  
381 and nitrate pollution. Figure 8 shows the EKMA of  $P(O_3)$  and  $P(NO_3^-)$  of these two  
382 periods,  $O_3$  located at VOCs controlling area in the two pollution episodes, which  
383 consist with previous YRD urban ozone sensitivity study (Jiang et al., 2018; Zhang et  
384 al., 2020a; Xu et al., 2021). The best precursor reduction for  $O_3$  is VOCs:  $NO_x = 2:1$   
385 while nitrate is located at the transition area, which means either of the precursors  
386 reduction will mitigate nitrate pollution. For the regional and complex air pollution  
387 characteristics in this region, a fine particle-targeting reduction scheme will aggravate  
388  $O_3$  pollution. In contrast, the  $O_3$ -targeting scheme can mitigate  $O_3$  and fine particle  
389 simultaneously.

390  
391 **Figure 8** Isogram of  $P(O_3)$  and  $P(NO_3^-)$  of polluted episode I (2019.05.30 00:00 -  
392 2019.06.02 00:00) and IV (2019.06.14 17:30 - 2019.06.17 12:00) with different  $NO_x$   
393 and VOC reduction degree. The grey dash line represents the ridge line.

## 394 **4 Conclusion**

395 A comprehensive campaign was conducted to interpret the atmospheric oxidation  
396 capacity and aerosol formation from May 30<sup>th</sup> to June 18<sup>th</sup>, 2019, in Changzhou, China.  
397 The high O<sub>3</sub> and PM<sub>2.5</sub> concentrations confirm complex air pollution characteristics in  
398 Changzhou, and nitrate accounts for 38.3 % mass concentration of total water-soluble  
399 particulate components and 32.0 % of total PM<sub>2.5</sub>. In addition, the average values of  
400 NOR are 0.32 in PD and 0.25 in CD. The positive correlation between NOR and RH  
401 and inverse correlation refer to the contribution of N<sub>2</sub>O<sub>5</sub> heterogeneous uptake to nitrate  
402 formation.

403 Based on field observations of OH and related parameters, we show OH oxidation  
404 of the NO<sub>2</sub> pathway steadily contributes to nitrate formation no matter the clean or  
405 polluted period and domination clean day nitrate production (about 22 μg m<sup>-3</sup>). N<sub>2</sub>O<sub>5</sub>  
406 heterogeneous uptake contribution proliferated on polluted day, from 13.6 μg m<sup>-3</sup>  
407 (38.1 %) on clean days to 50.1 μg m<sup>-3</sup> (67.2 %) on polluted days. NO<sub>2</sub> heterogeneous  
408 uptake contributes minor to nitrate formation (2.6 %).

409 The precursor reduction simulation suggests the reduction ratio of VOCs: NO<sub>x</sub>  
410 equals 2:1 can simultaneously and effectively mitigate O<sub>3</sub> and fine particle pollution  
411 during the summertime complex pollution period in Changzhou. To more precisely and  
412 delicately establish a cooperative control scheme for regional O<sub>3</sub> and nitrate, the  
413 regional and long-time field campaigns are needed in the future to analyze the seasonal  
414 and interannual variation of O<sub>3</sub> and nitrate and relevant parameters.
