32

33 **Abstract:**

34 Atmospheric CH₄ is the second largest anthropogenic contributor to global warming. However, its emissions,
35 components, spatial-temporal variations and projected changes still remain large uncertain from city to national
36 scales. CH₄ emissions from waste treatment (including solid waste landfills, solid waste incineration and sewage)
37 account for >50% of total anthropogenic CH₄ emissions at city scale, and considering the high temperature
38 sensitivity of CH₄ emission factors (EFs) for the biological processes-based sources such as waste treatment, large
39 bias will be caused when estimating future CH₄ emissions under different global warming scenarios. Furthermore,
40 the relationships between temperature and waste treatment CH₄ emissions have only been conducted in a few
41 site-specific studies and lack the representativity for whole city, which contains various biophysical conditions and
42 shows heterogeneous distribution. These above factors cause uncertainty in the evaluation of city scale CH₄
43 emissions (especially from waste treatments) and projected changes still remain unexplored. Here we conduct the
44 first tower-based CH₄ observation network with three sites in Hangzhou city, which is located in developed
45 Yangtze River Delta (YRD) area and ranks as one of the largest megacities in China. We found the *a priori* total
46 annual anthropogenic CH₄ emissions and those from waste treatment were overestimated by 36.0% and 47.1% in
47 Hangzhou city, respectively. In contrast, the total emissions in the larger region, such as Zhejiang province or the
48 YRD area, were slightly underestimated by 7.0%. Emissions from waste treatment showed obvious seasonal
49 patterns following air temperature. By using the linear relationship constructed between monthly waste treatment
50 CH₄ emissions and air temperature, we find the waste treatment EFs increase by 38%~50% with temperature
51 increases of 10°C. Together with projected temperature changes from four climate change scenarios, the global
52 warming induced EFs in Hangzhou city will increase at the rates of 2.2%, 1.2%, 0.7% and 0.5% per decade for
53 IPCC AR5 (International Peace Cooperation Center, the fifth assessment report) RCP (Representative
54 Concentration Pathway)8.5, RCP6.0, RCP4.5 and RCP2.6 scenarios, respectively. And the EFs will finally
55 increase by 17.6%, 9.6%, 5.6%, and 4.0% at the end of this century. Additionally, the derived relative changes in
56 China also show high heterogeneity and indicate large uncertainty in projecting future national total CH₄ emissions.
57 Hence, we strongly suggest the temperature-dependent EFs and the positive feedback between global warming and
58 CH₄ emissions should be considered in future CH₄ emission projections and climate change models.

59 **Keyword:** CH₄ emissions, waste treatment, observation network, global warming

60

61

62 1. Introduction

63 As the second largest anthropogenic greenhouse gas, the reduction of CH₄ emissions is considered
64 an effective way to mitigate future climate change on short timescales (Henne et al., 2016; Lin et
65 al., 2021). Accurate estimation of CH₄ emissions from its main sources is the basis of policy
66 making. However, recent studies find there still remain large uncertainties for its total emissions,
67 components, spatial-temporal variations and projected changes at city scale especially for
68 megacities in China (USPA 2013; Cai et al., 2018; Lin et al., 2021). CH₄ emission from waste
69 treatment (mainly including sewage and solid waste by landfills and incineration) ranked as the
70 world's third largest anthropogenic source after fuel exploitation and livestock, and was
71 responsible for ~13% of global anthropogenic CH₄ emissions of 371 (±26) Tg a⁻¹ (Lu et al., 2021).
72 It also ranked as the fourth largest anthropogenic source in China, the biggest anthropogenic CH₄
73 emitting country, and accounted for ~14% of national total anthropogenic emissions of 65 (±22)
74 Tg a⁻¹ (Saunio et al., 2020; Lu et al., 2021; Chen et al., 2022). Furthermore, its contribution is
75 even larger than 50% at city scale especially for megacities, where both active and closed
76 household waste (including landfills and waste water systems) are located and found as super
77 emitters (Williams et al., 2022; Maasakkers et al., 2022). A large number of Chinese landfills were
78 constructed in suburbs more than 5-10 years ago and most landfills have no gas collection systems,
79 with the urban area expanding in recent decades, the locations of many landfills are now within
80 the urban scope (Zhejiang Statistical Yearbook 2018-2019). In addition, the decreasing area of the
81 agricultural sector (rice paddies and husbandry) in megacities also makes their emissions
82 negligible when compared with waste treatment. Therefore, accurate quantification of CH₄
83 emissions from waste treatment in urban area becomes increasingly important.

84

85 Although some progress has been made in measuring site scale CH₄ emissions from waste
86 treatment, the estimated emissions still show large discrepancies due to many factors such as the
87 amount of waste and its composition, relative proportions of landfills and incineration, degradable
88 organic carbon ratio, CH₄ oxidation efficiency, and landfill gas collection, and meteorological
89 conditions including temperature, water content, atmospheric pressure (Masuda et al., 2018; Cai et
90 al., 2018; Zhao et al., 2019; Hua et al., 2022; Bian et al., 2022; Maasakkers et al., 2022; Kissas et

91 al., 2022).

92

93 Furthermore, CH₄ emissions from sewage and landfills **result from** microbial **processes** especially

94 from methanogens, **and their emission factors (EFs)** are highly sensitive to temperature. These

95 available studies were mainly conducted at some specific sites with measured EFs **varying widely**

96 (Du et al., 2017; 2018; Cai et al., 2014; 2018; Zhao et al., 2019; NBSC, 2015; Wang et al., 2015;

97 Florentino et al., 2010; Tolaymat et al., 2010; Hua et al., 2022). The lack and discrepancies of

98 detailed information for all the above factors and their uncertainties have led to considerable

99 **difficulty** in estimating CH₄ emissions for most-to-date inventories (Höglund-Isaksson, 2012;

100 USEPA et al., 2013; Cai et al., 2018; Lin et al., 2021; Maasakkers et al., 2022).

101

102 China, **the developing country with the** largest anthropogenic CH₄ emissions, is **expected** to

103 increase its emissions because of projected rapid economic development, urbanization and

104 generated waste (Cai et al., 2018). The increase of waste treatment emissions in **East** China was

105 also found as the second largest sector in driving national total anthropogenic CH₄ emissions since

106 2000 (Lin et al., 2021). **In addition**, the mitigation potential of waste treatment in developing

107 countries is thought **to be** four times **that** of developed countries (USEPA, 2013). Therefore,

108 mitigating CH₄ emissions from waste treatment in China is a robust and cost-effective way to

109 **reduce total national** anthropogenic greenhouse gas emissions.

110

111 Many previous studies have estimated the waste treatment CH₄ emissions for China by both

112 “bottom-up” and “top-down” approaches, with results varied by 2.5-fold from 4.3 to 10.4 Tg CH₄

113 yr⁻¹, and accounted for 8.1%~24.2% of national total anthropogenic CH₄ emissions (USEPA 2013;

114 Peng et al., 2016; Miller et al., 2019; Lin et al., 2021; Lu et al., 2021; Chen et al., 2022). For these

115 “bottom-up” **approaches**, the high uncertainties were directly attributed to omission of many small

116 point sources and discrepancies of observed site-specific EFs, which varied largely by climate and

117 management technology **such as the efficiency of gas collection systems** (Zhao et al., 2019; Hua et

118 al., 2022). **Previous studies most commonly used the** EDGAR (Emission Database for Global

119 Atmospheric Research) inventory, **using the** IPCC recommended default EF values **of** 15.0%

120 (Höglund-Isaksson, 2012; Lin et al., 2021; Bian et al., 2022), but this value is around 5-7 times of
121 EFs used in China by Zhang and Chen et al. (2014). A recent study comparing waste treatment
122 CH₄ emissions among different inventories also reported that the EDGAR v5.0 and CEDS
123 (Community Emissions Data System) inventories were 21~153% higher than other inventories,
124 and EDGAR v5.0 tended to assign more emissions in urban areas especially for provincial capitals.
125 In addition, emissions from wastewater were found to be overestimated by higher emission factors
126 or chemical oxygen demand (Peng et al., 2016; Lin et al., 2021).

127

128 And for the “top-down” atmospheric inversion approaches, a few studies constrained
129 anthropogenic sources including waste treatment, where the most widely used concentrations were
130 from satellite observations (Miller et al., 2019; Lu et al., 2021; Chen et al., 2022). The satellite
131 observations have the advantage of easy data access and global coverage. But as already noted, the
132 emissions constraint results are highly dependent on availability of observed concentrations,
133 which are largely influenced by weather conditions and cloud coverage. As was illustrated in a
134 recently published study by Chen et al. (2022), although the numbers of grid cell (0.25° × 0.3125°)
135 based year-round satellite observations were more than 1000 in north China, the available
136 numbers were less than 10 (even including grid cells without any observations) in most of central,
137 west, east and south of China. Such sparse distribution of available data may not provide robust
138 constraints on waste treatment emissions for some Chinese cities without enough observations,
139 especially considering waste treatment is co-located with high population density megacities in the
140 developed area of east and south of China. Furthermore, there should be large temperature induced
141 monthly variations for waste treatment CH₄ emissions (Börjesson et al., 1997), but almost all
142 satellite-based inversions were conducted at annual scale without seasonal variations. Besides,
143 given the strong influence from atmospheric pressure on landfill CH₄ emissions (Kissas et al.,
144 2022), satellite observations are too sparse to be up-scaled to estimate annual total because
145 satellite observations are mostly available only on clear-sky conditions and cannot represent
146 atmospheric pressure and CH₄ emissions on cloudy or rainy days. There was only one recent study
147 which focused on urban waste treatment CH₄ emissions, it found annual CH₄ emissions from four
148 cities were 1.4 to 2.6 times larger than inventories in India and Pakistan, where landfills

149 contributed to 6~50% of total emissions and indicated large bias of our understanding of waste
150 treatment CH₄ emissions (Maasackers et al., 2022).

151

152 The tower-based atmospheric inversion approach, which is based on hourly atmospheric
153 concentration observations within the planetary boundary layer, can be used independently to
154 constrain CH₄ emissions and its main components. Besides, compared with “bottom-up”
155 approaches, the “top-down” method can avoid using the factors that lead to large uncertainties in
156 CH₄ emissions especially from waste treatment. And to our best knowledge, there are few
157 tower-based observation inversion studies which focus on waste treatment emissions at city scale
158 or much larger regional scales especially in China. Only one study in Los Angeles, U.S.A. used
159 tower-based CH₄ concentration and found the influence of a landfill site closure on CH₄ emissions,
160 which was not included in *a priori* inventory (Yadav et al., 2019). In addition, the influences of
161 global warming on city scale (or higher regional scale) emissions are still unclear and have not
162 been considered in future emission projections (USEPA 2013; Cai et al., 2018). In general,
163 previous studies which predicted future waste treatment CH₄ emissions only used activity data
164 changes, without considering climate change on the EFs. Considering the potential high sensitivity
165 of waste treatment CH₄ emissions on the projected global warming, how these emissions will
166 change with increasing temperature is still unknown, especially within megacities where more
167 waste is generated and the urban heat island effect will lead to much stronger warming climate
168 (Zhang et al., 2022).

169

170 Here, we established three tower-based CH₄ concentration observation sites in Hangzhou city, one
171 of the largest megacities in China. To our best knowledge, it is the first city-scale tower-based CH₄
172 concentration observation network in China. We present our work on urban CH₄ emissions
173 inversion and aim to (1) constrain CH₄ emissions from waste treatment alongside total
174 anthropogenic emissions in Hangzhou city, (2) derive temperature sensitivity of waste treatment
175 CH₄ emissions at city scale and quantify the projected emission changes in future climate change
176 scenarios. One-year hourly CH₄ concentration observations from December 1st, 2020 to
177 November 30th, 2021 were combined with atmospheric transport model and Bayesian inversion

178 approach to constrain monthly CH₄ emission inventories. The constructed relationship between
179 monthly temperature and *posteriori* waste treatment CH₄ emissions will be used with future
180 temperature projection to quantify how the EFs will change in different global warming scenarios.

181

182 **2. Materials and Method**

183 **2.1 Tower-based CH₄ observation network and supplementary materials**

184 The city of Hangzhou, which has a population of 12.2 million and area of 1.7×10^4 km² (core
185 urban area of 8.3×10^3 km²), is the capital of Zhejiang province and located in the middle of East
186 China (Figure 1a). As displayed in Figures S1-S2, the East China accounts for the majority of the
187 national total population and waste treatment CH₄ emissions. Hangzhou city ranked in the top 10
188 megacities in China, with annual solid waste of around 5 million tons in 2021. The tower-based
189 CH₄ concentration observation network includes three observation sites (Figure 1a-d), as (1)
190 Hangzhou site (120.17° E, 30.23° N, 43.2 m a.s.l.), which is located in the core urban region; (2)
191 Linan site (119.72° E, 30.30° N, 138.6 m a.s.l.), regional background site with no obvious
192 emission sources within 10 km radius; (3) Damingshan site (119.00° E, 30.03° N, 1485.0 m a.s.l.),
193 which is built on the top of a 1500 m mountain and represents background from much more
194 diluted regional emission signals. The distance is around 50 km between Hangzhou site and Linan
195 site, and around 150 km between Hangzhou site and Damingshan site. These three sites represent
196 obvious gradients from east of densely populated area (Figure 1c-d) and anthropogenic emissions
197 to west of much weaker anthropogenic influence and background conditions. Based on the wind
198 direction for the three sites, there is not any obvious difference of seasonal wind direction patterns
199 among them. The prevailing wind direction from October to February was from the north, which
200 changed to east from February to May and then changed to south during the monsoon in summer.

201

202 The air inlet heights are 25 m above ground for the Hangzhou site, 53 m at Linan and 10 m at
203 Damingshan, respectively. Atmospheric CH₄ concentrations at all three sites were continuously
204 measured by cavity ring-down spectroscopy analyzer (model G2301 for Hangzhou site and G2401
205 for Linan site and Damingshan site; Picarro Inc., Sunnyvale, CA). To obtain high precision
206 observations, two different standard gases were measured every 6 hours and a linear two-point fit

207 was used to calibrate observations, with the precision and accuracy of 2 ppb and 1 ppb. More
208 details of the observation and calibration systems were [described](#) in Fang et al., (2014; 2022).
209 Note [that](#) because of instrument issues at Damingshan site, there is [a](#) data gap in
210 September-October, 2021. In general, 99.4%, 99.0%, 79.3% of hourly CH₄ observations were
211 available in the whole year observation period for Hangzhou site, Linan site and Damingshan site,
212 respectively. Meteorological observations at Hangzhou meteorological station were used to
213 evaluate simulated meteorological fields, including air temperature at 2 m (T_{2m}), relative humidity
214 (RH), downward solar radiation (S↓), wind speed (WS) at 10 m height, and [planetary boundary](#)
215 [layer height \(PBLH\)](#).

216

217 Note some previous studies of city scale greenhouse gas concentration observation networks chose
218 sites at the edge of urban borders as background in emission inversion system (i.e. Indianapolis,
219 U.S.A., Miles et al., (2017); Los Angeles, U.S.A., Verhulst et al., (2017); Washington,
220 DC-Baltimore, U.S.A., Lopez-Coto et al., (2020); Paris, France, Lian et al., (2021)), but we chose
221 to use five [NOAA](#) CH₄ background sites as the potential background, [including](#) UUM, TAP, YRO,
222 YON and WLG site (Figure 1a), which were much further than the observations at Damingshan
223 site. This strategy is based on following three reasons: (1) our footprint domain is much larger
224 than Hangzhou city and these five sites are also located close to the edge of [the](#) model domain; (2)
225 CH₄ concentrations within Hangzhou city will be influenced by [seasonally varying](#) monsoon and
226 the monthly [varying](#) wind directions will lead to obvious changes of CH₄ background than only at
227 Damingshan site; (3) our model setups can partition CH₄ enhancements from within Hangzhou
228 city and other regions.

229

230 The projected climate data from four RCP (Representative Concentration Pathway) scenarios
231 (RCP8.5, RCP6.0, RCP4.5 and RCP2.6) by MRI-CGCM3 model were downloaded from World
232 Data Center for Climate (WDCC, <https://www.wdc-climate.de/ui/>), where annual air temperature
233 at 2m was used from years 2021 to 2100. The most recent population density data for Hangzhou
234 city is for the [year 2019](#) and was downloaded from Chinese national resource and environmental
235 science and data center.

236

237 2.2 WRF-STILT model setup

238 The WRF-STILT (WRF: Weather Research and Forecasting, version 4.2.2, and STILT: Stochastic
239 Time-Inverted Lagrangian Transport) model was used to simulate hourly footprint and CH₄
240 enhancement, see more details in Hu et al. (2019; 2021). Domain setups are displayed in Figure 1a,
241 with the outer nested domain (Domain-1, 27 km×27 km grid resolution) covering eastern and
242 central China, and the inner domain (Domain-2, 9 km×9 km grid resolution) covering the YRD
243 area. The physical schemes used in the WRF model are the same as in our previous studies for the
244 YRD domain (Hu et al., 2019; 2021). The simulated CH₄ concentration is the sum of background
245 and enhancement, where the enhancement is calculated by multiplying all CH₄ flux with hourly
246 footprint that represents the sensitivity of the concentration changes to its regional sources/sinks
247 with spatial resolution of 0.1°×0.1°. To better quantify CH₄ components at each site, CH₄
248 enhancements from different regions and sources are also tracked and separately simulated.
249 Besides, we should note the CH₄ background is important in simulating CH₄ concentrations and
250 atmospheric inversion. We will choose CH₄ background from the five background sites based on
251 monthly footprint as discussed in Section 3.1.

252
253 The most recent inventory of Emission Database for Global Atmospheric Research (EDGAR v6.0),
254 which has 20 categories, and WetCHARTs ensemble mean were used as the *a priori*
255 anthropogenic and natural CH₄ emissions. We should note there are many CH₄ inventories for
256 some developed regions and countries (i.e. France, U.S.A., Germany) with high spatial resolutions.
257 The reasons to choose EDGAR as *a priori* anthropogenic emissions are: (1) for all available CH₄
258 inventories that covered China, the spatial resolution of EDGAR (0.1°×0.1°) is the highest, and it
259 provides the most up-to date results; (2) most previous studies that constrain emissions by
260 atmospheric inversion studies also chose EDGAR, and our results can be directly compared with
261 previous studies; (3) the preliminary simulation of CH₄ concentrations showed generally good
262 performance with observations, indicating its spatial distributions in Hangzhou city has relatively
263 small bias even with a potentially large bias for magnitude, which will be constrained by our
264 atmospheric inversion method.

265
266 The main sources of CH₄ emissions in Hangzhou city include SWD_LDF (solid waste landfills),

267 WWT (waste water handling), SWD_INC (solid waste incineration), PRO (all processes related to
 268 fuel exploitation from coal, oil, and natural gas, [including extraction, transportation, refining,](#)
 269 [distribution as list in IPCC database \(https://www.ipcc-nggip.iges.or.jp/EFDB/find_ef.php\)](#), RCO
 270 (energy for buildings, mainly containing nature gas [escaping](#) from household use) and AGS
 271 (agricultural soils). We found emissions from SWD_LDF, WWT and SWD_INC were simply
 272 assigned in the same locations in EDGAR inventory, and hence combined them as waste treatment.
 273 For the CH₄ emissions from wetland, we used WetCHARTs ensemble mean with spatial resolution
 274 of 0.5° at monthly average (Bloom et al., 2017). Considering WetCHARTs [treats](#) rice paddies
 275 (main source as AGS) as one wetland type, AGS in EDGAR was excluded and we assume
 276 WetCHARTs represent all wetland CH₄ emissions as natural wetland and rice paddies.

277

278 2.3 Bayesian inversion framework

279 The Scale Factor Bayesian inversion (SFBI) approach was applied to interpret the atmospheric
 280 CH₄ concentration (or enhancement) variations in terms of quantitative constraint on all CH₄
 281 sources. The relationship between observed and simulated CH₄ concentrations (or enhancement)
 282 can be expressed as follows in Equation 1:

$$283 \quad y = \mathbf{K}\Gamma + \varepsilon \quad (1)$$

284 Where y is the observed CH₄ concentration (or enhancement), \mathbf{K} corresponds to simulated
 285 enhancements from all categories, Γ is the state vector to be optimized and consists of *posteriori*
 286 SFs for corresponding categories in \mathbf{K} , and ε is the observing system error.

287

288 The optimal solution to derive *posteriori* SFs is to minimize a cost function $J(\Gamma)$, which represents
 289 the mismatch between CH₄ observations and simulations and the mismatch between *posteriori* and
 290 *a priori* SFs (Miller et al., 2008; Griffis et al., 2017). The cost function $J(\Gamma)$ can be expressed as:

$$291 \quad J(\Gamma) = \frac{1}{2} \left[(y - \mathbf{K}\Gamma)^T S_e^{-1} (y - \mathbf{K}\Gamma) + (\Gamma - \Gamma_a)^T S_a^{-1} (\Gamma - \Gamma_a) \right] \quad (2)$$

292 where S_e and S_a are the constructed error covariance matrices for observations and the *a priori*
 293 values, and S_e consists of measurement and model errors. Here each element in *a priori* SFs Γ_a
 294 is treated as 1. Therefore, the solution for obtaining the *posteriori* SFs is to solve $\nabla_{\Gamma} J(\Gamma) = 0$,
 295 and is given by,

296
$$\Gamma_{\text{post}} = (K^T S_e^{-1} K + S_a^{-1})^{-1} (K^T S_e^{-1} y + S_a^{-1} \Gamma_a) \quad (3)$$

297 In the Bayesian inversion framework, we first need to give an estimate of the error covariance
 298 matrices and the state vector for the *a priori* and observational data. And following our previous
 299 studies conducted in East China (Hu et al., 2019; 2022). **Uncertainties** of 10%, 13% and 20% were
 300 assigned to the measurement errors (S_{obs}), the finite number of particles (500) released in the
 301 STILT model ($S_{\text{particles}}$) and uncertainty in meteorological fields (S_{met}), respectively.

302

303 A previous study derived **uncertainties** of CH₄ from waste treatment and other categories, which
 304 varied between 30% and 50%, these uncertainties were calculated mainly from activity data and
 305 EFs at the country scale on annual **averages** (Solazzo et al. 2021). We should also note CH₄
 306 **emissions** uncertainty will largely increase **as the** study region size **decreases, and**, as stated above,
 307 the relative difference among different inventories can reach 150%. Considering the
 308 disaggregation of spatial distributions and temporal variations, CH₄ emission uncertainties can be
 309 much larger at urban and monthly scales. To provide robust **constraints** on CH₄ emissions in our
 310 study, we used three cases of *a priori uncertainty* combinations for different emissions in Bayesian
 311 inversion:

312 (1) the first case use three elements as wetland, waste treatment and **all other** anthropogenic
 313 sources, considering the larger seasonality of waste treatment, the uncertainties of 300% was used
 314 for waste treatment and 200% for other categories, (2) the second case have more detailed
 315 categories as wetland, waste treatment, fuel exploitation, energy for building, and the **other**
 316 anthropogenic sources, where the *a priori* uncertainty of 200% was used for each **category**, (3) the
 317 third case has the same categories as case 1 but **uses** a different *a priori* uncertainty for waste
 318 treatment of 200%. The averages of all three cases are used as final *posteriori* SFs and the largest
 319 difference between each of three cases **is used as the final** uncertainty.

320

321 **3. Results**

322 **3.1 Atmospheric CH₄ observations**

323 We first display the hourly CH₄ concentrations from our three tower-based sites and smoothed
 324 background at five sites by CCGCRV fitting method (Thoning et al., 1989) in Figure 2a. **The**

325 hourly observations at three towers show similar temporal variations but with different amplitudes.
326 Observations at Hangzhou site vary between 2000 ppb and 2800 ppb, and were much larger than
327 both Linan site and Damingshan site. Their monthly averages are also compared in Figure 2b, and
328 results show the monthly CH₄ vary between lowest 2106.3 ppb in July and highest 2225.0 ppb in
329 September (annual mean of 2159.9 ppb) at Hangzhou site, lowest 2023.3 ppb in July and highest
330 2132.0 ppb in September (annual mean of 2086.7 ppb) at Linan site, the lowest 1955.5 ppb in July
331 and without observations in September at Damingshan site (annual mean of 2013.4±(3) ppb,
332 where the uncertainty was calculated based on the assumption that monthly CH₄ concentration in
333 September and October varies between August and November), respectively. The similar trends
334 among the three sites can be explained by all three sites being dominated by similar atmospheric
335 transport processes, such as synoptic process (i.e. monsoon) and seasonally changing wind
336 directions as summarized above. But their surrounding emission sources are highly different,
337 implying the emissions of Hangzhou site should be much larger than Linan and Damingshan sites.

338

339 Because the CH₄ background is important in concentration simulation and emission inversion, we
340 also compare CH₄ background between five sites, where the annual averages at TAP, YON, RYO,
341 WLG and UUM were 1989.8 ppb, 1850.1 ppb, 1982.7 ppb, 1973.4 ppb and 1984.2 ppb,
342 respectively. We found the differences were generally within 20 ppb among TAP, RYO, WLG and
343 UUM sites (Figure 2), but there was large difference between YON site and other four sites from
344 May to August, which can reach to around 100 ppb. Note YON site is located in the south of East
345 China Sea (Figure 1a), it can be influenced by monsoon with clean air flows from the South China
346 Sea, which has many fewer CH₄ sources compared to air flows from East Asia. The CH₄
347 background at TAP site appeared slightly higher than other four sites because TAP site is located
348 in the coast of South Korea and can be more easily polluted by anthropogenic emissions.
349 Considering the large spatial difference between the CH₄ background sites, monthly air flows and
350 source footprint will be used to identify backgrounds for our observation network, with details
351 discussed in Supplementary Material (Section S1, Figure S3 and Table S1).

352

353

354 3.2 Concentration footprint and *the a priori* emissions

355 To illustrate the potential source regions of *the* three sites, annual averages of simulated footprints
356 for each site are displayed in Figure 3a-c. *The* results *show* their footprint distributions *were* quite
357 similar because of close distance, but we also *notice* there *were* obvious *differences in the*
358 *footprint strengths* (i.e. the area covered by red color) with Hangzhou site > Linan site >
359 Damingshan site. The reason why *the* footprint at *the* Damingshan site is the lowest *can be*
360 *explained* that *the* observations *were collected* at 1500 m height, *and it* was not easy to receive
361 *emissions* signals within boundary layer *at that height*. Besides, the Hangzhou site is located in the
362 core urban area of Hangzhou city, and it will show significant diurnal variation in PBLH,
363 especially *since it has* higher nighttime PBLH caused by anthropogenic heat and high buildings
364 than grassland/farmland, *which dominate* Linan site and Damingshan site. Hence more air
365 particles can *remain* within PBLH and *generate* stronger footprint.

366

367 *The a priori* EDGAR CH₄ emissions for total anthropogenic categories, waste treatment and its
368 proportions are *given* in Figure 3d-f. *Significant* gradients *are observed* from higher emissions in
369 *the* east to lower emissions in the west, which is consistent with our three tower-based *sets of*
370 observations. And the CH₄ emissions for waste treatment *indicated* similar spatial distributions
371 with urban land use and population density (Figure 1c-d). *Moreover*, waste treatment seems *to*
372 *emit* CH₄ *as* area sources instead of point sources *from* waste treatment super plants. Although a
373 few previous studies found limitations of EDGAR inventory to capture CH₄ emission patterns in
374 some urban areas (Pak et al., 2021), here considering the fact that locations of landfills (*Figure*
375 *1b-d*), which is the largest anthropogenic CH₄ emitter in Hangzhou city, are very close to the core
376 urban area and in high *consistency* with EDGAR, hence we believe the spatial patterns of EDGAR
377 in study region *to* be reliable. We should note the Chinese government constructed waste
378 separation *stations* in each city with density of one station for per 150~200 households (around
379 450~800 people), *usually these waste separation stations are full with waste because domestic*
380 *garbage can be generated every day, they do not have gas collection systems and can emit large*
381 *quantity of CH₄ emissions* caused by daily biomass waste as area sources (Tian et al., 2022).
382 *Besides, there is only one landfill that has gas collection systems, the reported gas collection*

383 efficiency was less than 80%, which also indicates large quantity of CH₄ emissions will be directly
384 emitted into the atmosphere and the emissions will be influenced by climate change. These above
385 analyses also imply Hangzhou site can observe higher emissions from both waste treatment and
386 total anthropogenic emissions, which will be discussed and quantified later.

387

388 **3.3 Simulation of CH₄ concentrations and its components for three sites**

389 Comparisons between observed and simulated daily CH₄ concentration averages are displayed in
390 Figure 4a-c and hourly concentrations in Figure S4 for three sites. First, the hourly simulations in
391 Figure S4 show high consistency when only comparing the temporal patterns with observations,
392 indicating good performance of model transport simulations as confirmed in Figure S5 for
393 evaluating meteorological fields. But the relative variations display obvious differences among the
394 three sites for daily averages in Figure 4a-c. The mean bias (MB), root mean squared error
395 (RMSE), and correlation coefficient (R) between daily observations and *a priori* simulations were
396 64.1 ppb, 129.2 ppb and 0.44, respectively, for Hangzhou site; and were -6.0 ppb, 57.1 ppb, 0.50
397 for Linan site, 36.2 ppb, 55.6 ppb, 0.54 for Damingshan site. As for the Hangzhou site, simulated
398 CH₄ concentrations show obvious overestimation from October to April, and the overestimation is
399 also found at Damingshan site. We found the simulations at the Linan site showed overall good
400 agreement with observation, but still with slight overestimation from January to April and
401 underestimation from May to September. Considering the source area contributions for the three
402 sites are different, these differences among the three sites indicated the bias in CH₄ emission
403 largely varied from Hangzhou city to larger regional scale.

404

405 To further quantify detailed contributions from different regions and categories to each tower site,
406 CH₄ enhancements from different categories and source areas were also simulated separately for
407 the three sites. As displayed in Figure 4d-e, the simulated *a priori* total enhancements at Hangzhou
408 site, Linan site, and Damingshan site were 244.3 ppb, 100.8, and 69.0 ppb, respectively. We also
409 found contributions by waste treatments dominated the total enhancements but with obvious
410 differences among the three sites, which varied from the highest 64.2% at Hangzhou site to the
411 lowest 41.4% at Damingshan site. We further calculated anthropogenic contributions from

412 Hangzhou city (excluding wetlands because of coarser spatial resolution for Hangzhou city) and
413 other provinces, which were 158.4 ppb at Hangzhou site, 30.7 ppb at Linan site, and 10.1 ppb at
414 Damingshan site, respectively. And they accounted for 69.3%, 34.0%, and 16.9% of total
415 anthropogenic enhancements at corresponding sites. These results indicate the CH₄ observations at
416 Hangzhou site, which is located at the core urban region, are more influenced by local emissions
417 (mainly for waste treatment which will be discussed later) and contain much higher enhancements
418 than the other two sites. The relative contributions from Hangzhou city to observations at the
419 Hangzhou site, Linan site and Damingshan site were 158.4 ppb (69.3% to total CH₄ enhancement),
420 30.7 ppb (34.0% to total CH₄ enhancement), and 10.1 ppb (16.9% total CH₄ enhancement),
421 respectively. The relative contributions from Zhejiang province to observations at the Hangzhou
422 site, Linan site and Damingshan site were 181.7 ppb (79.5% to total CH₄ enhancement), 44.3 ppb
423 (49.0% to total CH₄ enhancement), and 17.9 ppb (29.9% total CH₄ enhancement), respectively.
424 These different values also imply that the observations at Linan and Damingshan sites can
425 represent CH₄ emissions of much larger region as Zhejiang province or YRD area than Hangzhou
426 city (Figure 4e), and Damingshan site.

427

428 The seasonally averaged diurnal variations for both observations and simulations are also
429 displayed in Figure 5 for the three sites. Although many previous studies only used daytime
430 observations and simulations to evaluate *a priori* emissions bias and constrain emissions (Sargent
431 et al., 2018; Hu et al., 2022), these studies were based on the assumption that the diurnal scaling
432 factors used for the *a priori* emissions are right (i.e. for anthropogenic CO₂), or the emissions do
433 not have obvious diurnal variations (i.e. emissions from industries or manufacturing). As
434 concluded above, the main CH₄ component in Hangzhou city was waste treatment (Figure 3f),
435 which should be highly sensitive to temperature and indicates obvious diurnal and seasonal
436 patterns (Mønster et al., 2019; Kumar et al., 2022). And total CH₄ emissions will be overestimated
437 when using daytime emissions to represent all-day averages. Further, we found strong similarities
438 of the diurnal variations between observations and simulations for the three sites, but there are still
439 some discrepancies especially that the observations at Linan site were generally higher than
440 simulations from spring to autumn for both all-day and midday averages.

441 Hence, our preliminary conclusions were that the *a priori* CH₄ emissions were generally
442 overestimated for Hangzhou city but underestimated in the larger region of Zhejiang or YRD area.
443 We also found simulations were higher than observations for all seasons at Damingshan site, and it
444 can be explained by the complex topography around the Damingshan site, where elevations
445 changed from 0 m to 1600 m within the site's grid cell of 9 km (~ 0.1°) as displayed in Figure 1b,
446 and the mountain-valley wind patterns, PBLH changes can only be resolved with much higher
447 spatial resolutions of < 1km. Hence the use of coarse resolutions (i.e. 9 km in this study) at the
448 mountainous regions introduces large bias in simulating concentration and emission inversion, as
449 also recently found in China for CO₂ as “aggregation error” (Agustí-Panareda et al., 2019; Wang et
450 al., 2022), so observations at Damingshan site will not be used in emissions inversions in this
451 study.

452

453 **3.4 Constraints on anthropogenic CH₄ emissions**

454 As displayed in Figures 3f, 5a and concluded in Section 3.3, simulations using *a priori* CH₄
455 emissions show obvious overestimation especially from October to April at Hangzhou site, and
456 emissions were also overestimated in winter and underestimated from spring to autumn at Linan
457 site. Note this bias can be attributed to *a priori* emissions or meteorological simulations. Our
458 previous studies in YRD have evaluated the meteorological simulations by using the same
459 physical parameterization schemes, which showed high consistency with observations (Hu et al.,
460 2019; 2021; 2022; Huang et al., 2021). We also evaluated the meteorological simulations with
461 observations and confirmed with good model performance (Figure S5). Note PBLH simulations
462 are important in evaluating model performance, we only have four months of PBLH observations
463 (one month in each season), these hourly PBLH observations were used to evaluate the general
464 performance of WRF model. As displayed in Figure S6, it shows overall good performance for
465 both daytime and nighttime PBLH variations. Furthermore, we found there no monthly variations
466 in EDGAR v6.0 CH₄ emissions for waste treatment, which contributed 64.2% to annual CH₄
467 enhancement average and much higher in winter (Figure S7-S8). The CH₄ emissions from waste
468 treatment are produced by the microbial process, which should be affected by meteorological
469 conditions especially by seasonal temperature changes. Hence our assumption is that the bias in

470 both its seasonality and annual average lead to large overestimation/underestimation in the
471 simulated CH₄ concentration. Besides, bias in other anthropogenic emissions and [wetlands](#) can
472 also partly [contribute](#) to the bias of [the](#) simulated CH₄ concentration.

473

474 To quantify the bias sources and constrain corresponding *a priori* emissions for Hangzhou city, we
475 applied the scaling factor Bayesian inversion approach with three different cases as introduced in
476 [the](#) Method section. Instead of only using daytime CH₄ observations to constrain *a priori*
477 emissions, we choose to use all-day hourly data at Hangzhou site to constrain emissions for
478 Hangzhou city, [for the](#) following three reasons: (1) the enhancements contributed by Hangzhou
479 city at [the](#) Hangzhou site was 69.3%, and much larger than 34.0%, and 16.9% for Linan site and
480 Damingshan site, respectively; (2) the waste treatment dominated anthropogenic CH₄ emissions in
481 Hangzhou city, which is caused by biological process and should be temperature dependent. [Since](#)
482 [the](#) observed temperature [varied diurnally](#) by 20 °C, the use of only daytime observations without
483 considering diurnal CH₄ emissions will bring significant bias when using derived daytime
484 emissions to represent all-day averages. The annual averages of daytime and all-day average
485 concentrations were 2112.4 and 2156.0 ppb at Hangzhou site, respectively, [the reason why higher](#)
486 [emissions in daytime correspond to lower concentration than in all-day and nighttime is that lower](#)
487 [PBLH in nighttime will leads to higher concentration](#), and more comparisons between daytime
488 and all-day average concentrations are displayed in Figure 5 for three sites; (3) previous [studies](#)
489 using daytime observations were mainly conducted [for](#) regions dominated by industry or energy
490 production, which have much smaller diurnal variations than waste treatment as stated above
491 (Mønster et al., 2019; Kumar et al., 2022).

492

493 The derived monthly *posteriori* SFs for each emission source [are](#) displayed in Table 1 for
494 Hangzhou city. [The results show that](#) the *posteriori* SFs for waste treatment [are](#) much smaller in
495 winter and higher in summer, indicating obvious seasonality and the overestimation in winter was
496 mainly contributed by waste treatment. The annual mean *posteriori* SFs for waste treatment [vary](#)
497 between 0.50 and 0.56 in all three cases, illustrating overestimation at annual average for the *a*
498 *priori* waste treatment emissions. Besides, the annual mean *posteriori* SFs [vary](#) between 0.87 and

499 0.94 for the rest of the total anthropogenic categories (excluding agricultural soil), and are 0.97 for
500 PRO (fuel exploitation) and 0.91 for RCO (energy for building), respectively; the annual mean
501 *posteriori* SF is 1.05 for wetland (including agricultural soil and natural wetland). These *posteriori*
502 SFs for the rest anthropogenic categories and wetland indicate much smaller bias than waste
503 treatment. The monthly *posteriori* SFs for PRO and RCO also illustrate obvious seasonal
504 variations, but are still smaller than the *a priori* seasonality in the inventory (Figure S9). Although
505 the evaluations of hourly PBLH simulations have illustrated good performance in both daytime
506 and nighttime (Figure S6), we also conducted inversions by only using daytime observations to
507 constrain CH₄ emissions. Considering results from Case 2 varied between Case 1 and Case 3, here
508 we only display the results from Case 1 and Case 3 (Table S2), it shows similar seasonal variations
509 as using all all-day observations. We notice the values are larger than later, which is reasonable
510 because CH₄ emissions in daytime should be larger than all-day and nighttime emissions. In
511 general, *posteriori* SFs by using all-day concentration observations will be used to represent total
512 CH₄ emissions from monthly to annual scales.

513

514 To evaluate whether the *posteriori* SFs have significantly improved CH₄ emissions, we used these
515 SFs to derive the *posteriori* emissions and re-simulated hourly concentrations in Figure 6 (and
516 daily averages in Figure S9). Results show the hourly overestimation by using *a priori* emissions
517 is largely reduced by using *posteriori* emissions when compared with observations in Figure 6a-b,
518 and the regression slopes between daily averaged observations and simulations decrease from
519 1.51(±0.15) for *a priori* simulations to 0.85(±0.07) for *posteriori* simulations in Figure 6c. The
520 mean bias (MB), root mean squared errors (RMSE), correlation coefficient (R) between daily
521 observations and *a priori* simulations are 64.1 ppb, 129.2 ppb and 0.44, respectively, and these
522 statistics change to -22.2 ppb, 72.3 ppb and 0.58 for *posteriori* simulations. These results indicate
523 the *posteriori* SFs obviously decrease the bias in *a priori* emissions and are closer to observations,
524 when considering there are no system biases in simulated monthly PBLH.

525

526 The comparisons of monthly CH₄ emissions between *a priori* and *posteriori* waste treatment and
527 other anthropogenic sources (excluding agricultural soil) in Hangzhou city are displayed in

528 Figures 7a and S7. For the *a priori* inventory, there is not seasonal variations for waste treatment
529 with constant monthly emissions of 8.67×10^3 t, and other anthropogenic sources show
530 seasonality with much higher in winter (i.e. 5.22×10^3 t in January) than in summer (i.e. $3.06 \times$
531 10^3 t in August). The seasonality in *a priori* EDGAR inventory is mainly dominated by RCO
532 (Energy for buildings), with proportions to total anthropogenic emissions changing from the
533 highest 22% in winter to lowest 8% in summer. Such information indicates the *a priori* inventory
534 assigned more leaks from natural gas distribution infrastructure in winter than in summer. As
535 discussed above, constant emissions from waste treatment should be wrong because of its large
536 temperature sensitivity, and the observed monthly temperature difference between summer and
537 winter was larger than 25°C in Hangzhou city in study period. After including the constraints from
538 the observed concentrations, the *posteriori* emissions for waste treatment show obvious
539 seasonality with highest emission in July ($7.66 \pm 0.09 \times 10^3$ t) and lowest emission in February
540 ($2.20 \pm 0.87 \times 10^3$ t). And emissions from other anthropogenic categories show much smaller
541 seasonality (highest emission in January of $4.18 \pm 0.69 \times 10^3$ t and lowest emission in August of
542 $2.88 \pm 0.15 \times 10^3$ t) than *a priori* emissions. In general, the annual emissions from waste treatment
543 were 10.4×10^4 t in the *a priori* EDGAR inventory and decreased to $5.5 (\pm 0.6) \times 10^4$ t for the
544 *posteriori* emissions, a decrease of 47.1%. The *a priori* emissions from other anthropogenic
545 sources were 4.5×10^4 t and only slightly decreases to $4.1 (\pm 0.3) \times 10^4$ t for the *posteriori*
546 emissions, an 8.9% decrease. The proportion of waste treatment to total anthropogenic emissions
547 decreases from *a priori* 69.3% to *posteriori* 57.3%. To summarize, the annual total anthropogenic
548 CH₄ emission (excluding agricultural soil) decreases from 15.0×10^4 t to $9.6 (\pm 0.9) \times 10^4$ t,
549 indicating overestimation of 36.0% in Hangzhou city for the *a priori* emissions.

550

551 However, as concluded above the observations and simulations at Linan site, which represents the
552 much larger region of Zhejiang province or YRD area, data from that site indicated slightly
553 different results that CH₄ simulations were underestimated from spring to autumn and
554 overestimated in winter (Figure 4b and Figure 5e-h). Here we used the multiplicative scaling
555 factor (MSF) method and observations at Linan site to derive SFs at seasonal scale (Sargent et al.,
556 2018; He et al., 2020), where we used 10 ppb as the potential CH₄ background uncertainty in

557 winter, spring and autumn, and 20 ppb in summer, see details in the Supplementary Material
558 (Section S2). The derived *posteriori* SFs were 0.87 (± 0.08), 1.07 (± 0.11), 1.19 (± 0.24), and 1.16
559 (± 0.11) for winter, spring, summer, and autumn, respectively. The results for the Linan site
560 showed similar seasonal variations as found for Hangzhou city and was 1.07 (± 0.14) of *a priori*
561 anthropogenic emissions for the annual average. Our observations at Hangzhou site and Linan site
562 together indicate the *a priori* emissions were largely biased on both seasonal and annual scales,
563 and the annual anthropogenic CH₄ emission was largely overestimated by 36.0% in Hangzhou city,
564 but was underestimated by 7.0% in the larger region of Zhejiang province or YRD area.

565

566 **3.5 Temperature sensitivity of waste treatment CH₄ EFs and projected changes**

567 Although the derived *posteriori* monthly SFs on waste treatment reflected changes on emissions,
568 considering the monthly activity data does not have obvious monthly changes, these SFs can
569 mainly reflect relative variations of monthly EFs and contain meteorological dominated changes
570 especially for temperature. To evaluate the temperature sensitivity of its EFs, we first calculated
571 the normalized monthly SFs by dividing monthly SFs by annual averages (Tables 1 and S3), and
572 quantified the relationship between observed T_{2m} and normalized SFs. Note decomposition of
573 organic waste by methanogens mostly takes at depth within the landfills and temperature can be
574 higher than at the surface, hence the temperature within landfills should be much more related to
575 methanogens activities and CH₄ emissions than T_{2m}. However, considering (1) we do not have
576 direct temperature observations under landfills, (2) T_{2m} can be used as indicator of methanogens
577 activities, and (3) T_{2m} is commonly used meteorological data that can be provided for future RCP
578 scenarios, hence the relationship between waste CH₄ emissions and T_{2m} is constructed and used to
579 predict how will CH₄ EFs change in different climate scenarios. The normalized SFs illustrate
580 significant linear relationship with monthly T_{2m} (Figure 7b), where the slopes imply that
581 normalized SFs (and EFs) will increase by 38%~50% with temperature increase by 10°C at city
582 scale. We also analyzed the temperature sensitivity by only using daytime CH₄ observations and
583 simulations in Figure S10, it still shows strong linear relationship between normalized SFs and
584 T_{2m}, with the slopes of 0.046 and 0.060. These results are in high consistency with using all-day
585 observations of 0.038 and 0.050, indicating similar results of using 24 hours observations and only

586 using daytime observations, and less influence of simulated nighttime PBLH bias on
587 corresponding temperature sensitivity.

588

589 We should note the precipitation, soil water content and atmospheric pressure can also have
590 obvious influence on CH₄ emissions, and considering the fact that we have not conducted field
591 measurement in landfills and landfills are usually covered by metal or plastic in China to avoid the
592 spread of odors, hence reanalysis data cannot represent real soil water contents in these site scale
593 landfills. Precipitation and atmospheric pressure show obvious linear relationship with
594 temperature as displayed in Figure S11. They display positive linear relationship between
595 precipitation (affect water content) and T_{2m}, and negative linear relationship between monthly
596 averaged atmospheric pressure and T_{2m}. We also found negative relationship between atmospheric
597 pressure and normalized SFs, and positive relationship between T_{2m} and normalized SFs (Figures
598 7b and S11). Considering air temperature always displays negative relationship with atmospheric
599 pressure as warmer air temperature coincides with lighter air mass and lower atmospheric pressure
600 in summer as displayed in Figure 11b, and colder air temperature coincides with heavier air mass
601 and higher atmospheric pressure in winter. Hence, the temperature can be used to represent
602 co-influence of both temperature and atmospheric pressure, and we only focus on the influence of
603 temperature on CH₄ emissions and will add more supporting data in following studies.

604

605 Our findings for the high sensitivity of waste treatment CH₄ emissions to temperature also suggest
606 a dramatic increase with the projection of future global warming trends. We further derived the
607 T_{2m} trends for four different RCP scenarios as RCP8.0, RCP6.0, RCP4.5 and RCP2.6 (Figure 8a).
608 The results show T_{2m} will increase by 0.50°C, 0.28°C, 0.16°C, 0.10°C per decade for Hangzhou
609 city, respectively. These different warming trends also indicate distinct temperature-dominated
610 influence on future CH₄ EFs and emissions from waste treatment. We then used the slopes from
611 Figure 7b and annual temperature from 2021 to 2100 to derive relative changes of EFs in future 80
612 years, where observations for year 2021 were treated as the baseline year. As displayed in Figure
613 8b, the EFs in RCP8.5, RCP6.0, RCP4.5 and RCP2.6 scenarios will increase with the rates of
614 2.2%, 1.2%, 0.7% and 0.5% per decade, respectively. And CH₄ EFs for waste treatment will be

615 higher by 17.6%, 9.6%, 5.6%, and 4.0% at the end of this century.

616

617 The spatial distribution of T_{2m} trends for all of China is also displayed in Figure S12, which shows
618 heterogeneous distribution across China for four global warming scenarios. Because East China
619 has high population density, with the majority of the national population (Figure S1), and is
620 responsible for the largest domestic garbage induced CH_4 emissions (Figure S2), these combined
621 factors indicate considerable CH_4 emissions changes from waste treatment in such a
622 temperature-sensitivity area. Considering that the temperature sensitivity of waste treatment CH_4
623 EFs is caused by microbial process at regional scales, the sensitivity can represent general
624 conditions of different cities or landfills. And if we assume the derived temperature sensitivity
625 (increase by 44% with temperature increases of $10^\circ C$ on average) is applicable for China as a
626 whole, especially for East China, the relative changes of waste treatment CH_4 EFs can be
627 calculated by multiplying this value by air temperature trends. The spatial distribution of global
628 warming induced EF changes at the end of this century is displayed Figure 9. For RCP2.6 scenario,
629 EFs for waste treatment will slightly increase by 4.0-6.5% in the north eastern China and increase
630 by 3.0-4.0% in south eastern China. The RCP6.0 also displayed heterogeneous changes in East
631 China, with EFs in the north eastern China increasing by 10.5-13.0% and in south eastern China
632 increasing by 9.0-10.5%. Relative changes in RCP4.5 and RCP8.5 are more homogeneous for East
633 China, which indicates EFs will significantly increase by 5.0-7.5% and 17.5-19.5%, respectively.
634 The largest changes will occur in West China for RCP8.5, with EFs increasing by $>20.0\%$, but this
635 area has low population density and CH_4 emissions, and therefore these effects of global warming
636 can be ignored (Figure S12). Finally, we should note these derived relative changes are only
637 caused by global warming, and the influence of activity data, management technology and other
638 factors is not considered and out of the scope of this study.

639

640 **4 Discussions and implications**

641 Many previous studies have compared total CH_4 emissions and its components for different
642 inventories and bottom-up methods, which illustrated large uncertainty and bias at city scale and
643 these biases were much larger for waste treatment (Peng et al., 2016; Sauniois et al., 2020; Lin et

644 al., 2021; Bian et al., 2022). A recent bottom-up research compared wastewater CH₄ EFs in China,
645 which largely varied by four-fold in different provinces and the uncertainty in the same province
646 were even two-fold larger than its average, implying considerable [uncertainty](#) in recent
647 understanding of waste treatment EFs at regional scale (Hua et al., 2022). And for the national
648 total emissions, [waste treatment CH₄ emissions](#) varied between 5 and 15 Tg a⁻¹ (Peng et al., 2016;
649 EDGAR v6). There are also other atmospheric inversion studies in estimating China's CH₄
650 emissions (Hopkins et al., 2016; Hu et al., 2019; Huang et al., 2021; Miller et al., 2019; Lu et al.,
651 2021; Chen et al., 2022). These studies found large [variations](#) of national emissions for almost all
652 inventories, which were mainly caused by fossil fuel exploitation, agricultural sector (livestock
653 and rice paddies) and waste treatment. For the comparisons of waste treatment emissions, these
654 satellite-based inversions also largely varied between 6 and 9 Tg a⁻¹ by 1.5-fold (Miller et al.,
655 2019; Lu et al., 2021; Chen et al., 2022; Zhang et al., 2022).

656

657 The [reported](#) discrepancies between “bottom-up” and “top-down” approaches indicate large
658 uncertainty in understanding China's national CH₄ emissions from waste treatment. And it is well
659 known the uncertainties [will](#) increase from national scale to regional and [city scales](#), also implying
660 considerable [uncertainties](#) in city-scale emissions for inventories. But the atmospheric inversion
661 approach for city scale waste treatment, which can act as [an](#) independent evaluation, is still rare
662 not only for China but also globally. To our best knowledge, there is only one recent atmospheric
663 [inversion](#) research focused on CH₄ emissions from city-scale waste treatment, which used
664 satellite-based observation to constrain emissions from four cities in India and Pakistan, that
665 concluded underestimation of landfills CH₄ emissions by 1.4 to 2.6 times for EDGAR inventory
666 (Maasackers et al., 2022). In our study, we found annual waste CH₄ emissions were overestimated
667 by 47.1% for Hangzhou city, our findings are different [from](#) results in India and Pakistan. These
668 differences indicate bias of waste treatment CH₄ emissions considerably varied in different
669 countries and climate divisions. Our results highlight there is [a](#) large knowledge gap in
670 understanding [waste treatment emissions mechanisms](#) and estimating urban waste treatment CH₄
671 emissions especially in China.

672

673 Different from fossil-type sources that have much smaller monthly variations, CH₄ emission from
674 waste treatment is biological processes-based source and its EFs are highly sensitive to
675 meteorological conditions especially for temperature. These factors lead to obvious bias in waste
676 treatment CH₄ emissions not only for annual average but also for its seasonality. Besides, although
677 there were a few studies that aimed to predict future CH₄ emissions from waste treatment, these
678 studies were mainly based on activity data changes without considering the EFs variations caused
679 by future global warming trends or only based on site-specific observations (USEPA 2013; Cai et
680 al., 2018; Spokas et al., 2021). Of these three cited studies, USEPA (2013) and Cai et al. (2018)
681 only predicted emissions changes due to changes in activity data and management technology.
682 And the CH₄ emissions for year 2030 by Cai et al. (2018) was 23.5% lower than the USEPA
683 (2013) estimation, which was caused by the consideration of new policies and low-carbon policy
684 scenarios. Spokas et al. (2021) modeled the CH₄ emission changes with increasing air
685 temperature, where CH₄ emissions did not show obvious changes even with temperature
686 increasing by ~5°C by the end of year 2100. To our best knowledge, there are no inventories that
687 considered the temperature-induced changes on both seasonal variations and annual trends of CH₄
688 emissions. Hence, it is still unclear in all inventories how EFs will change with different global
689 warming scenarios at city scale.

690

691 A few observation-based measurements were conducted for waste treatment but only at some
692 specific sites with large discrepancies of EFs (Du et al., 2017; 2018; Cai et al., 2018; Zhao et al.,
693 2019; NBSC, 2015; Wang et al., 2015; Florentino et al., 2010; Tolaymat et al., 2010; Cai et al.,
694 2014; 2018). And only one of our previous studies used year-round atmospheric CH₄ observations
695 to constrain regional scale CH₄ emissions at Nanjing city in YRD area (Huang et al., 2021), where
696 it found much higher emissions of the landfilling waste in summer than in winter: CH₄ emissions
697 in July were around four times those in February. But there is no study that has quantified the
698 temperature sensitivity of waste CH₄ emissions at city scale or much larger regional scales. These
699 two studies in different cities confirmed temperature as the dominant factor that drives seasonal
700 variations of waste treatment CH₄ emissions. Hence our study appears as the first one that
701 estimated city scale waste treatment CH₄ emissions, its temperature sensitivity and projected

702 changes in different global warming scenarios. Our findings for the large sensitivity to
703 temperature indicate the monthly scaling factors should be considered to better represent CH₄
704 emissions and simulate atmospheric CH₄ concentrations.

705

706 We also note that the predictions of future climate changes are mainly based on different emitting
707 intensity of greenhouse gas, and CH₄ contributed around 20% of direct anthropogenic radiative
708 forcing (Seto et al., 2014). The CH₄ emissions in different global warming scenarios were mainly
709 calculated by predicting energy use data without considering the changes of EFs. In this study, we
710 found there should be large positive feedback between global warming and CH₄ emissions,
711 especially in the RCP 8.0 scenario where global warming induced CH₄ emissions from waste
712 treatment will increase by 17.6%. Hence the projected emissions from waste treatments and other
713 biological process based sources, together with positive feedback between temperature and their
714 emissions are strongly suggested in future climate change models. Besides, it is well known that
715 CH₄ concentration simulations are essential for modeling air pollutions (e.g. O₃, NO_x, and CO)
716 especially in the stratosphere (Isaksen et al., 2011; Kaiho et al., 2013). Considering that waste
717 treatment CH₄ emissions accounted for ~25% of total anthropogenic emissions (EDGAR v6.0) in
718 East China where severe air pollution frequently occurred, we also believe the coupling of
719 temperature-dependent CH₄ emissions and the monthly scaling factors on CH₄ emissions can
720 improve air pollution modeling in East China.

721

722 We should note that new technology and other meteorological variables can also influence waste
723 treatment CH₄ emissions. The main reason to only use temperature in this study is that we only
724 constrained the emissions at monthly scale in one year, and derived twelve datasets of *posteriori*
725 CH₄ emissions. Besides, temperature is considered to be the main factor in controlling monthly
726 and annual variations of waste treatment CH₄ emissions, and can be used to represent the
727 co-influence of other meteorological parameters such as atmospheric pressure. We will use
728 multiple years' CH₄ concentration to quantify the influence of new technology and other
729 meteorological variables on waste treatment CH₄ emissions in our following study, and we suggest
730 that other tracers (e.g. ethane, ¹⁴CH₄) are also important to separate CH₄ emissions from biological

731 and fossil CH₄ emissions.

732

733 **5 Summary and Conclusions**

734 To better evaluate bias for city scale anthropogenic CH₄ emissions and understand the sensitivity
735 of temperature on waste treatment CH₄ emissions, we used a three tower-based atmospheric CH₄
736 observation network in Hangzhou city, which is located in the developed YRD region and one of
737 the top 10 megacities in China. One-year hourly atmospheric CH₄ observations were presented
738 from December 2020 to November 2021. We then applied a scaling factor Bayesian inversion
739 method to constrain monthly anthropogenic CH₄ emissions and its components (especially for
740 waste treatments) in Hangzhou city, and also used multiplicative scaling factor method for broader
741 Zhejiang province and YRD area at seasonal scale.

742

743 To the best of our knowledge, our study is the first tower-based CH₄ observation network in China.
744 We found obvious seasonal bias of simulated CH₄ concentrations at the core urban area of
745 Hangzhou city, which was mainly caused by bias of waste treatment at both annual and monthly
746 scales. The derived *posteriori* CH₄ emissions display obvious seasonal variations with peak in
747 summer and trough in winter, which was mainly contributed by waste treatment; the *a priori*
748 annual waste treatment CH₄ emission in Hangzhou city was 10.4×10^4 t and decreased to 5.5
749 $(\pm 0.6) \times 10^4$ t for the *posteriori* emissions, a decrease of 47.1%. Besides, the total anthropogenic
750 CH₄ emissions (excluding agricultural soil) decreased from 15.0×10^4 t to $9.6(\pm 0.9) \times 10^4$ t,
751 indicating overestimation of 36.0% for the whole year of 2021. Observations at Linan site imply
752 that the annual CH₄ emissions was slightly underestimated by 7.0% for the larger region of
753 Zhejiang province or YRD area, which was different from the case of Hangzhou city. Additionally,
754 the *posteriori* monthly CH₄ emissions from waste treatment illustrate significant linear
755 relationship with air temperature, with regression slopes indicating an increase of 38%~50% when
756 temperature increases by 10°C. Finally, we found the waste treatment CH₄ EFs for Hangzhou city
757 will increase by 17.6%, 9.6%, 5.6%, and 4.0% by the end of this century for RCP8.0, RCP6.0,
758 RCP4.5 and RCP2.6 scenarios, respectively. The derived relative changes for whole China also
759 showed high heterogeneity and indicate large uncertainty in projecting future national total CH₄

760 emissions. This study is also the first one that mainly focuses on city scale temperature sensitivity
761 of waste treatment CH₄ emissions from the perspective of atmospheric inversion approach. And
762 based on above results, we strongly suggest the temperature-dependent EFs should be coupled in
763 both recent CH₄ inventories and future CH₄ emission projections.

764

765 **Data availability:** The atmospheric CH₄ observations data can be requested from Cheng Hu and
766 Bing Qi. STILT model is downloaded from <http://www.stilt-model.org/>, the EDGAR inventory is
767 from <https://edgar.jrc.ec.europa.eu/>, and the projected climate data were downloaded from World
768 Data Center for Climate (WDCC, <https://www.wdc-climate.de/ui/>).
