

20 **Abstract**

21 Ozone (O_3) is a secondary pollutant in the atmosphere formed by
22 photochemical reactions that endangers human health and ecosystems. O_3 has
23 aggravated in Asia in recent decades and will vary in the future. In this study, to
24 quantify the impacts of future climate change on O_3 pollution, near-surface O_3
25 concentrations over Asia in 2020–2100 are projected using a machine learning
26 (ML) method along with multisource data. The ML model is trained with
27 combined O_3 data from a global atmospheric chemical transport model and real-
28 time observations. The ML model is then used to estimate future O_3 with
29 meteorological fields from multi-model simulations under various climate
30 scenarios. The near-surface O_3 concentrations are projected to increase by 5–
31 20% over South China, Southeast Asia, and South India and less than 10%
32 over North China and Gangetic Plains under the high forcing scenarios in the
33 last decade of 21st century, compared to the first decade of 2020–2100. The O_3
34 increases are primarily owing to the favorable meteorological conditions for O_3
35 photochemical formation in most Asian regions. We also find that the
36 summertime O_3 pollution over eastern China will expand from North China to
37 South China and extend into the cold season in a warmer future. Our results
38 demonstrate the important role of climate change penalty on Asian O_3 in the
39 future, which provides implications for environmental and climate strategies of
40 adaptation and mitigation.

41 **1. Introduction**

42 Tropospheric ozone (O_3) is a primary air pollutant, formed by
43 photochemical oxidation of nonmethane volatile organic compounds (NMVOCs)
44 and carbon monoxide (CO) in the presence of nitrogen oxides ($NO_x = NO +$
45 NO_2) and sunlight. It has adverse effects on human health (Malley et al., 2017;
46 Cakmak et al., 2018), vegetation growth (Yue et al. 2017; Mills et al., 2018) and
47 climate change (Checa-Garcia et al., 2018; Gaudel et al., 2018). A better
48 understanding of the causes of changes in O_3 concentrations is useful for
49 developing effective environment and climate strategies.

50 Since mid-1990s, Asian regions, including South Asia, East Asia and
51 Southeast Asia, have experienced the fastest O_3 increase rate of 2–8
52 ppb/decade at remote surface sites and in the lower free troposphere across
53 the world (IPCC, 2021). A number of air quality monitoring stations administered
54 by China National Environmental Monitoring Center (CNEMC) have been
55 established in China since 2013 to measure real-time near-surface particulate
56 matter, O_3 , and other air pollutants. The measurements showed an increasing
57 trend of urban warm-season daily maximum 8-hour average (MDA8) O_3
58 concentrations of 2.4 ppb (5%) yr^{-1} that is faster than any other regions
59 worldwide during 2013–2019 (Lu et al., 2020). However, many regions in Asia
60 lack O_3 observations with sufficient spatial and temporal coverage. Also, most
61 of the present regional observations are collected only near population clusters,
62 which are not representative of the entire region (Zhou et al., 2022).

63 To supplement the limited near-surface O₃ measurements, many studies
64 utilized global and regional models with comprehensive physical and chemical
65 processes to simulate O₃ concentrations (Zhu et al., 2017; Gao et al., 2020;
66 Yang et al., 2022). Moreover, statistical models have also been used to estimate
67 O₃ concentrations (Chen et al., 2020; Zhang et al., 2020). In recent years,
68 machine learning (ML) approaches, such as random forest (Xue et al., 2020;
69 Wei et al., 2022), neural network (Di et al., 2017), support vector machine (Su
70 et al., 2020), extreme gradient boosting (Li et al., 2020), and ensemble learning
71 (Liu et al., 2022), were widely applied to estimate O₃ levels based on potential
72 influential factors (e.g., precursor emissions, meteorological conditions, land
73 use, surface elevation, gross domestic product, population density, and
74 geographical variables).

75 Meteorological factors and synoptic conditions play important roles in
76 affecting O₃ pollution (Fu and Tai, 2015; Gong and Liao, 2019; Yin et al., 2019;
77 Liu et al., 2020; Dang et al., 2021). Gong et al. (2019) illustrated that hot, dry,
78 and stagnant weather conditions are favorable for the formation and
79 persistence of severe O₃ pollution over northern China. High air temperature
80 along with intense incoming shortwave radiation accelerates both
81 photochemical reaction rates and natural precursor emissions for O₃ production
82 (Jacob and Winner, 2009). Under high relative humidity conditions, O₃
83 concentrations decrease due to many complex physical and chemical
84 mechanisms (Jeong and Park, 2013; Kavassalis and Murphy., 2017; Lu et al.,

85 2019; Li et al., 2021). Cloud and precipitation impact O₃ levels through reducing
86 the downwelling solar radiation and washout of pollutants (Toh et al., 2013).
87 Anomalous sea level pressure patterns can affect the long-range transport of
88 O₃ by influencing atmospheric circulation (Santurtún et al., 2015). By changing
89 the air stagnant condition and transport of pollutants, wind fields can also affect
90 O₃ concentrations in local and downwind areas of emission sources (Doherty
91 et al., 2013).

92 Future climate change corresponding to the different climate scenarios can
93 impact O₃ through altering meteorological conditions (Wang et al., 2013, Fu and
94 Tian et al., 2019). Using regional climate fields downscaled from general
95 circulation models to investigate potential O₃ variations in the U.S. due to
96 changing climate, Fann et al. (2015) projected the MDA8 O₃ to increase by 1–
97 5 ppb as daily maximum average temperature increases by 1–4°C in 2030
98 relative to 2000. Colette et al. (2015) estimated that the climate penalty for
99 future summertime surface O₃ reaches 0.99–1.5 ppb by the end of the 21st
100 century (2071–2100) in Europe compared to present-day levels using an
101 ensemble of eight global coupled climate-chemistry models under the RCP
102 (Representative Concentration Pathway) 8.5 scenario. Through fixing sea
103 surface temperature at present-day and future conditions in five atmospheric-
104 only models as part of the AerChemMIP (Aerosol Chemistry Model
105 Intercomparison Project), Zanis et al. (2022) projected the climate change
106 penalties and benefits on global surface O₃ concentrations from 2015 to 2100

107 under the SSP3-7.0 scenario. They found O₃ reductions in most regions of the
108 globe, except a robust O₃ climate penalty of 1–2 ppb °C⁻¹ in South and East
109 Asia under global warming following the SSP3-7.0 pathway. However, SSP3-
110 7.0 is not a good representative scenario for both air quality and climate in Asia.
111 The emissions of greenhouse gases (GHGs) and air pollutants over East Asia
112 in SSP3-7.0 are assumed to significantly increase in the near future and keep
113 at high levels in the middle of the 21st century among all SSPs (Li et al., 2022),
114 while the emissions of air pollutants have been cut by a lot since 2010s in the
115 real world (Wang et al., 2021). The GHGs and pollutant emissions are very likely
116 to continually decline in the future related to the carbon neutrality commitment
117 (Cheng et al., 2021).

118 In this study, we aim to better characterize the impact from future climate
119 change on Asian O₃ pollution using multiple state-of-the-art modeling tools and
120 data. It is important for policy-makers that mitigating global climate change
121 potentially has positive benefits to surface air quality through meteorological
122 factors, not only the reduction in fossil fuel co-emissions. The near-surface O₃
123 concentrations covering 2020–2100 in Asia are projected using a ML method
124 integrated with multisource data, including assimilated O₃ data that combine
125 ground observations and simulations from a global 3-D chemical transport
126 model (GEOS-Chem), meteorological fields under various climate scenarios
127 from the latest Coupled Model Intercomparison Project Phase 6 (CMIP6) multi-
128 model simulations, and other auxiliary data (e.g., emissions, land use,

129 topography, population density, and spatiotemporal information). ML approach
130 gives the capacity to explore many scenarios more rapidly and for longer time
131 periods than the chemical transport model process-based modeling. Details of
132 the data and methodology used in this study are described in section 2. Section
133 3 analyzes the results of climate-driven O₃ variations over different key regions
134 of Asia. Section 4 summarizes the main conclusions and discusses potential
135 uncertainties in this study.

136 **2. Materials and Methods**

137 **2.1 GEOS-Chem model description**

138 To assimilate O₃ data for the ML model training, the near-surface O₃
139 concentrations from 2014 to 2019 are firstly simulated using the nested-grid
140 version of the 3-D GEOS-Chem model (version 12.9.3), driven by the Modern-
141 Era Retrospective analysis for Research and Applications, Version 2 (MERRA-
142 2) reanalysis meteorological data (Gelaro et al., 2017). The nested GEOS-
143 Chem has 47 vertical layers from the surface up to 0.01 hPa, with a horizontal
144 resolution of 0.5° latitude × 0.625° longitude over the Asia domain (11°S–55°N,
145 60–150°E). The lateral boundaries of chemical tracer concentrations are
146 provided by global simulations at 2° latitude × 2.5° longitude horizontal
147 resolution. The model includes fully coupled aerosol-O₃-NO_x-hydrocarbon
148 chemical mechanisms (Park et al., 2004; Pye et al., 2009; Mao et al., 2013),
149 with about 300 species participated in over 400 kinetic and photochemical
150 reactions (Bey et al., 2001). The stratospheric O₃ chemistry is simulated

151 through linearized O₃ parameterization scheme (LINOZ; McInden et al., 2000),
152 and the planetary boundary layer mixing is calculated by a nonlocal scheme
153 (Lin and McElroy, 2010). GEOS-Chem has shown a good performance in
154 reproducing spatiotemporal distributions of O₃ concentrations (e.g., Ni et al.,
155 2018; Li et al., 2019).

156 The historical (2014–2019) anthropogenic emissions of O₃ precursor
157 gases, including NO_x, NMVOCs, and CO, utilized in the nested domain are
158 obtained from the Community Emissions Data System (CEDS; Hoesly et al.,
159 2018) version 2021_04_21, which fully considered the recent emission
160 reductions in China related to clean air measures. The biomass burning
161 emissions are acquired from the Global Fire Emissions Database version 4
162 (GFED4; van der Werf et al., 2017). Biogenic emissions of NMVOCs from the
163 Model of Emissions of Gases and Aerosols from Nature (MEGAN) version 2.1
164 are employed, with updates from Guenther et al. (2012). Soil NO_x sources are
165 calculated with an updated version of the Berkeley-Dalhousie Soil NO_x
166 Parameterization scheme (Hudman et al., 2012). NO_x emissions from lightning
167 are as described by Murray et al. (2012), and the vertical distribution of
168 emissions follows Ott et al. (2010).

169 **2.2 Ground O₃ observations**

170 To improve the performance of the ML model in predicting O₃
171 concentrations, the nationwide hourly near-surface O₃ concentrations in China
172 during 2014–2019 are obtained from the CNEMC and used for O₃ data

173 assimilation. The observational network had about 500 monitoring sites in 2013,
174 and expanded to more than 1500 sites after 2019, covering 360 cities in
175 mainland China. The O₃ observations are averaged within each 0.5° latitude ×
176 0.625° longitude grid of the GEOS-Chem model.

177 **2.3 Data assimilation**

178 The assimilation system, which is used to combine the O₃ observations
179 with results from GEOS-Chem simulations, is based on a three-dimensional
180 variational (3DVar) data assimilation. The goal of the 3DVar is to find the
181 maximum likelihood estimation of a state vector \mathbf{x} , which is the O₃
182 concentrations here in this study, given the available observations \mathbf{y} through
183 minimizing the cost function:

$$184 \quad J(\mathbf{x}) = \frac{1}{2}(\mathbf{x} - \mathbf{x}^b)^T \mathbf{B}^{-1} (\mathbf{x} - \mathbf{x}^b) + \frac{1}{2}(\mathbf{y} - \mathbf{H}(\mathbf{x}))^T \mathbf{O}^{-1} (\mathbf{y} - \mathbf{H}(\mathbf{x}))$$

185 Here \mathbf{x}^b represents the priori simulation, \mathbf{B} is the empirical background
186 covariance matrix representing the uncertainty. \mathbf{H} denotes the operator that
187 converts the simulation results into the observation space, and \mathbf{O} is a diagonal
188 covariance matrix storing the uncertainty of the measurements used.

189 Comparisons between observed and assimilated O₃ concentrations over
190 2014–2019 are shown in Figure 1. The overall correlation coefficient (R) is 0.94,
191 and the normalized mean bias (NMB) is −0.1%, suggesting that the assimilated
192 data have an excellent representation of O₃ observations and minimize the
193 uncertainties of GEOS-Chem simulations.

194 **2.4 Predicting O₃ using a machine learning method**

195 In this study, a random forest (RF) model is used to predict O₃
196 concentrations, similar to our previous studies (Li et al., 2021, 2022), with input
197 data of assimilated O₃ concentrations that combine observations and results
198 from GEOS-Chem model simulations, MERRA-2 meteorological variables, O₃
199 precursor emissions, land cover (LC), normalized difference vegetation index
200 (NDVI), topography (TOPO), population density (POP), and the month of the
201 year (MOY) and geographic location of each model grid as spatiotemporal
202 information. Details of the datasets are summarized in Table 1.

203 For predicting future climate-driven near-surface O₃ concentrations, the ML
204 model is trained with samples over 2014–2018 and the remaining 2019 data
205 are used for model validation. To obtain an optimal ML model, hyperparameters
206 are firstly tuned using the 10-fold cross-validation (Rodroquez et al., 2010).
207 Several statistical metrics, including coefficient of determination (R²), mean
208 absolute error (MAE), root mean square error (RMSE) and mean relative error
209 (MRE) are used to evaluate the performance of ML model. Then the climate-
210 driven near-surface O₃ concentrations during 2020–2100 under four SSPs
211 (SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5) in Asia can be estimated using
212 the trained ML model with varying meteorological factors under the climate
213 change scenarios. Both anthropogenic and natural emissions of O₃ precursors
214 are fixed at the present-day levels for the prediction.

215 **2.5 Meteorological fields from CMIP6 multi-model simulations**

216 Monthly meteorological parameters under four different future climate

217 scenarios, including SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5, are fed to
218 a ML model to predict ground-level O₃ concentrations. The Scenario Model
219 Intercomparison Project (ScenarioMIP) as part of CMIP6 provides multi-model
220 projections of climate variables driven by future emission and land use changes
221 under different SSPs (O'Neill et al., 2016). In our study, meteorological fields,
222 such as air temperature (at 2m, 850 hPa, and 500 hPa), wind fields (at 850 and
223 500 hPa), surface relative humidity, incoming shortwave radiation at the surface,
224 total cloud cover, precipitation rate, and sea level pressure, are chosen as the
225 key meteorological predictors for ground-level O₃ concentrations, which are
226 obtained from 18 global climate models, i.e., ACCESS-CM2, ACCESS-ESM1-
227 5, CanESM5, CESM2-WACCM, CMCC-CM2-SR5, EC-Earth3-Veg, EC-Earth3,
228 FGOALS-f3-L, FGOALS-g3, GFDL-ESM4, INM-CM5-0, IPSL-CM6A-LR,
229 MIROC6, MPI-ESM1-2-HR, MPI-ESM1-2-LR, MRI-ESM2-0, NorESM2-LM,
230 and NorESM2-MM. Before being applied to the ML model, future meteorological
231 fields from ScenarioMIP are adjusted to minimize the inconsistencies in the
232 initial conditions in models and reanalysis data following Li et al. (2022).

233 **3. Results**

234 **3.1 Predictive capability of the machine learning model**

235 The ML predicted monthly O₃ concentrations over Asia in 2019 by the ML
236 model are in good agreement with the assimilated O₃ data constructed with
237 observations and GEOS-Chem model results (Fig. 2). The overall R² between
238 the predicted and assimilated O₃ concentrations is as high as 0.92 and the ML

239 model has a low MRE of 9% in predicting O₃ concentrations over the Asia
240 domain. Overall, these statistical indices indicate that the RF model is promising
241 for predicting the spatial distributions and temporal variations of near-surface
242 O₃ concentrations over Asia, which can provide a practical means for studying
243 long-term variations in O₃ under the future climate change.

244 Meanwhile, the ML model predictive capability for each grid cell over the
245 entire domain during 2014–2019 is further evaluated and demonstrated in
246 Figure 3. Regarding the spatial performance, the estimated O₃ concentrations
247 are highly correlated to the assimilated data in most regions of Asia with small
248 biases, indicating a strong spatial predictive ability of the RF model. More than
249 80% of land areas have a R² greater than 0.9. In terms of model uncertainties,
250 about 95% of land areas have a RMSE (MAE) less than 3 (2) parts per billion
251 (ppb). Furthermore, approximately 86% of land areas show small modeling bias
252 with MRE below 5%. Note that several grid cells show MRE over 5% but still
253 below 15%, which is related to the data assimilation using monitored and
254 simulated O₃ concentrations in China and the coarse resolution for coastal
255 areas and islands over Southeast Asia.

256 Figure 4 shows the importance score of independent variables that
257 contribute to the prediction of trained ML model. The results suggest that among
258 all the input predictors, relative humidity, incoming solar radiation at the surface,
259 and topography are the top-three most influential variables for the model
260 construction of near-surface O₃ in Asia, with importance scores of 15%, 12%

261 and 10%, respectively. The primary importance of relative humidity has also
262 been reported in previous studies (e.g., Han et al., 2020; Qian et al., 2022).
263 Other meteorological parameters, such as cloud cover, sea level pressure, air
264 temperature, precipitation, also have a substantial impact on the O₃ estimates,
265 with importance scores ranging from 4% to 8%. In the ML model, the emissions
266 of three primary O₃ precursors, including NMVOCs, NO_x, and CO, have a
267 relatively low importance score of 4–5% individually due to the spatiotemporal
268 diversity of O₃ production regimes.

269 **3.2 Predicted future climate-driven O₃ variations**

270 Figure 5 shows the predicted absolute and percentage changes in annual
271 mean surface O₃ concentrations in response to climate change between the
272 first and last decades of 2020–2100 based on the future meteorological fields
273 from the 18 CMIP6 models. Fig. 6 shows the time series of the regional
274 averaged values over six sub-regions of Asia during 2020–2100. Under the
275 global warming trends of all future scenarios, the climate-driven near-surface
276 O₃ concentrations increase constantly from 2020 to 2100 over many key
277 regions in Asia, such as North China (NC), South China (SC), Southeast Asia
278 (SEA), South India (SI) and Gangetic Plains (GP), except the Tibetan Plateau
279 (TP). The O₃ concentrations over SC, SEA, and SI are projected to increase
280 considerably with the maximum increase up to 5 ppb (20%) in 2095 (2091–
281 2100 mean) compared to 2025 (2020–2029 mean) under the SSP5-8.5
282 scenario, revealing a strong O₃-climate penalty in most Asian regions. The

283 climate-driven changes in O₃ concentrations are smaller under the less warming
284 scenarios, especially in SSP1-2.6 that has O₃ changes less than 5% across
285 Asia. These suggest that future climate following low emissions and sustainable
286 pathways is more favorable for the mitigation of O₃ pollution in Asia than high
287 forcing scenarios.

288 The strong O₃-climate penalty over eastern China can be attributed to the
289 particularly high O₃ precursor emissions (Fig. S1), relative to western China,
290 which lead to a positive local net O₃ production close to sources in a warming
291 climate (Fig. S2) (Zanis et al., 2022). The absolute and percentage changes in
292 regional averaged surface O₃ concentrations between 2025 and 2095 under the
293 four scenarios are shown in Figure 7. The climate-driven changes in O₃
294 concentrations are gradually stronger from north (2–3%) to south (3–8%) of
295 China, which demonstrates that the changes in meteorology exert a greater
296 impact on ground-level O₃ concentrations over SC than NC under future climate
297 change. By the end of the 21st century, the relative humidity will decrease (Fig.
298 S3) and downward solar radiation will increase (Fig. S4) over SC compared to
299 those in 2025, which are conducive to the O₃ productions, while NC has the
300 opposite changes. Moreover, cloud cover will decrease more over SC than NC
301 (Fig. S5), contributing to the larger increase in O₃ productions and
302 concentrations over SC than NC in a warming climate.

303 In South Asia, climate change also enhances O₃ concentrations by <5%
304 over GP and SI (Fig. 7), due to the massive precursor emissions (Fig. S1) and

305 O₃ productions. Over SI, the decreases in relative humidity (Fig. S3) and cloud
306 amount (Fig. S5), and increases in downward solar radiation at the surface (Fig.
307 S4) favor photochemical production of O₃ and induce the large increases in O₃
308 concentrations in this region. Averaged over SEA, O₃ concentrations driven by
309 higher temperature (Fig. S2), more downward solar radiation (Fig. S4) and
310 lower relative humidity (Fig. S3) and cloud cover (Fig. S5) in 2095 are projected
311 to increase O₃ concentrations by 5–7% in SSP3-7.0 and SSP5-8.5 and 0–3%
312 in SSP1-2.6 and SSP2-4.5 scenarios, relative to 2025 (Fig. 7).

313 The Tibetan Plateau (TP), known as the highest topography in China with
314 more solar radiation at the surface, has strong stratosphere-troposphere
315 exchanges of O₃ compared with other regions leading to high O₃ concentrations
316 over this region (Fig. S6). Climate-driven O₃ concentrations are projected to
317 decline by less than 2% over TP from 2025 to 2095 (Fig. 7). It is likely because
318 less solar radiation (Fig. S4) and more frequent occurrence of rainy weather
319 (Fig. S7) in the future would reduce the local chemical production of O₃.

320 **3.3 The seasonality of future climate-driven O₃ variations**

321 Climate over Asia has obvious seasonal variation related to the Asian
322 monsoon system. Figure 8 shows the spatial distributions of percentage
323 changes in projected climate-driven O₃ concentrations in spring (March–April–
324 May, MAM), summer (June–July–August, JJA), autumn (September–October–
325 November, SON), and winter (December–January–February, DJF) between
326 2025 and 2095 under the four scenarios. In general, air quality in many regions

327 of Asia will deteriorate in all seasons associated with intensified O₃ pollution
328 under climate change.

329 In eastern China, O₃ pollution occurs most frequently in summer and is
330 more severe in NC than SC currently (Li et al., 2019). Under future climate
331 warming, JJA O₃ concentrations will increase by 5–20% in SC under the high
332 forcing scenarios, while the changes in NC are less than 5%. It suggests that
333 future climate change will expand the summertime O₃ pollution from NC to SC
334 over eastern China. Another feature is the strong increases in O₃
335 concentrations by 10–20% throughout eastern China and exceeding 20% over
336 Sichuan Basin in SON, which relate to the significant increases in temperature
337 (Fig. S8) and solar radiation (Fig. S9) in this season over central-eastern China
338 under the high forcing scenarios. It further indicates that future climate change
339 will extend the O₃ pollution from summer into autumn.

340 In South Asia, the climate-driven increases in O₃ concentrations vary from
341 JJA over SI to DJF over GP. Relative to 2025, in summer of 2095, anomalous
342 high pressure (Fig. S10) along with anticyclone (Figs. S11 and S12) dominates
343 South Asia, which is not conducive to O₃ diffusion, leading to increases in JJA
344 O₃ concentrations over SI. The intensified O₃ pollution across GP in DJF under
345 climate change is related to the strong surface warming (Fig. S8), decreases in
346 relative humidity (Fig. S13), cloud cover (Fig. S14) and rainfall (Fig. S15), as
347 well as increases in solar radiation at the surface (Fig. S9), favoring the
348 photochemical production of O₃. In north part of Southeast Asia, JJA has the

349 largest O₃ rise via the same mechanism as for SI, while O₃ increases by the
350 same magnitude in all seasons in south part of Southeast Asia driven by future
351 climate change.

352 **4. Conclusions and discussion**

353 Ground-level O₃ pollution has been increasing over Asia in recent decades,
354 which harms human health and vegetations. In the future warmer climate, O₃
355 pollution over Asia can be modulated by changes in meteorological fields. In
356 this study, to examine the variations in O₃ concentrations over Asia due to the
357 future climate change, monthly surface O₃ concentrations from 2020 to 2100
358 under four climate scenarios (SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5)
359 are predicted using a ML model with input data from assimilated O₃ combining
360 GEOS-Chem simulations and real-time observations, future meteorological
361 parameters from CMIP6 multi-model simulations, emissions of O₃ precursors,
362 land use, topography, population density and spatiotemporal information. Our
363 results suggest that the future O₃ pollution over Asia will be significantly
364 exacerbated in a warming climate, especially under high forcing scenarios.

365 Trained by the assimilated O₃ concentrations and reanalysis data, the ML
366 model can well predict O₃ over Asia with the coefficient determination of 0.92
367 between assimilated and predicted O₃ concentrations and relative error of 9%.
368 Then the future Asian O₃ concentrations from 2020 to 2100 driven by climate
369 change are projected in the ML model with varying meteorological fields from
370 18 CMIP6 models under four future climate scenarios.

371 The climate penalty on O₃ is robust over most regions of Asia. The annual
372 mean O₃ levels in 2095 are projected to increase by 5–20% relative to 2025
373 under the high forcing scenarios over South China, Southeast Asia, and South
374 India and less than 10% over North China and Gangetic Plains, due to more
375 favorable meteorological conditions for O₃ photochemical production, while
376 there is a decrease of <5% over the Tibetan Plateau. The climate-driven
377 changes in O₃ concentrations are smaller under the less warming scenarios,
378 suggesting that future climate following low emissions and sustainable
379 pathways would be more effective in the mitigation of O₃ pollution in Asia than
380 the high forcing scenarios. Seasonal variation analysis reveals that the
381 summertime O₃ pollution over eastern China will expand from North China to
382 South China and extend into the cold season under the future climate change.
383 In addition, South Asian O₃ pollution will increase over South India in summer
384 and over Gangetic Plains in winter.

385 Zanis et al. (2022) analyzed the global climate change benefit and penalty
386 on O₃ based on sensitivity simulations from five CMIP6 models under the SSP3-
387 7.0 scenario. They showed positive changes in JJA O₃ concentrations by less
388 than 1 ppb from 2010 to 2095 over East Asia and South Asia driven by climate
389 change, but with large uncertainties due to the model diversity. The ML method
390 in this study gives similar positive changes in O₃ as Zanis et al. (2022). Pommier
391 et al. (2018) applied the EMEP chemical transport model driven by the
392 downscaled meteorological data from the NorESM1-M to investigate the

393 impacts of regional climate change on surface O₃ over India. They showed that
394 near-surface O₃ would increase by up to 4% over Northern India and decrease
395 by 3% over Southern India from 2050 to 2100 under the RCP8.5 scenario. We
396 show that the climate-driven O₃ in this study would increase over both Gangetic
397 Plains (0.2%) and South India (3%) under the SSP5-8.5 scenario in 2050
398 relative to 2016 (2014–2019 mean). The discrepancies may rise from that the
399 results of Pommier et al. (2018) were based on NorESM1-M simulated climate
400 alone, while the climate change predicted by 18 CMIP6 models were applied in
401 this study and the ensemble mean O₃ concentrations were shown here.

402 There are a few uncertainties and limitations in the projected near-surface
403 O₃ concentrations over Asia in terms of input data for the ML model, GEOS-
404 Chem simulations, and CMIP6 multi-model simulations. First, only
405 observational data over 2014–2019 across China were used for the O₃
406 assimilation. Longer-term measurements with broader spatial coverage are
407 more desirable to improve the model performance. Land use data and
408 population density are fixed at present-day conditions when predicting the
409 future O₃ since we focus on the variations in meteorological parameters under
410 climate change, which will vary in the future. In addition, natural O₃ precursor
411 emissions such as biogenic emissions of NMVOCs, and NO_x from soil and
412 lightning sources are fixed at year-2016 levels in the future estimates, which
413 can induce biases in the O₃ projections since climate change can strongly
414 influence natural emissions of O₃ precursors (Liu et al., 2019). Although the

415 climate influence of methane is considered in the future predictions, its role in
416 the O₃ production is not included in the ML model. The GEOS-Chem model has
417 been demonstrated to well capture the magnitude of and spatiotemporal
418 variations in O₃, with an average bias of about 10% over China (Lou et al., 2014)
419 and Southeast Asia (Marvin et al., 2021), and less than 20% over India (David
420 et al., 2019). The future decrease in relative humidity will cause stomatal
421 closure and also increase surface O₃. The O₃-vegetation interactions are not
422 represented in the default GEOS-Chem model. A newly coupled global
423 atmospheric chemistry-vegetation model (Lei et al., 2020) could be applied in the
424 future study. Additionally, the meteorological parameters characterizing future
425 climate change from the CMIP6 multi-model simulations can also give rise to
426 uncertainties in this study (Xu et al., 2021). Also, the good ability of the ML
427 model for the present-day condition may not imply a satisfactorily extrapolation
428 under the future warming condition, which can bias our results and deserves
429 further investigation in future studies.

430 Overall, our study provides a framework of combining real-time
431 observations, chemical transport model simulations and multi-climate model
432 predictions with data assimilation and machine learning methods to estimate
433 future climate driven near-surface O₃ concentrations. The emphasis of this work
434 is to quantify the impacts of future climate change on O₃ pollution in Asia, which
435 is of great significance for the future O₃ pollution mitigation strategies.

436 **Author contributions**

437 YY designed the research. HL performed the model simulations, analyzed data
438 and wrote the initial draft. JJ designed the data assimilation. YY, JJ, HW, and
439 KL helped edit and review the manuscript. All the authors discussed the results
440 and contributed to the final manuscript.

441 **Code and data availability**

442 The GEOS-Chem model is available at
443 <https://zenodo.org/record/3974569#.YTD81NMzagR> (last access: 1 August
444 2022). MERRA-2 reanalysis data can be downloaded at
445 <https://gmao.gsfc.nasa.gov/reanalysis/MERRA-2/> (last access: 1 August 2022).
446 Multi-model projections of climate variables are from Scenario Model
447 Intercomparison Project in Phase 6 of the Coupled Model Intercomparison
448 Project <https://esgf-node.llnl.gov/search/cmip6/> (last access: 1 August 2022).
449 Land cover is derived from <http://maps.elie.ucl.ac.be/CCI/viewer/download.php>
450 (last access: 1 August 2022). Hourly O₃ concentrations are obtained from the
451 public website of the China National Environmental Monitoring Centre
452 <http://www.cnemc.cn/en/> (last access: 1 August 2022). Normalized difference
453 vegetation index is obtained from [https://www.ncei.noaa.gov/data/avhrr-land-
454 normalized-difference-vegetation-index/access/](https://www.ncei.noaa.gov/data/avhrr-land-normalized-difference-vegetation-index/access/) (last access: 1 August 2022).
455 Topography is collected from [https://cgiarcsi.community/data/srtm-90m-digital-
456 elevation-database-v4-1/](https://cgiarcsi.community/data/srtm-90m-digital-elevation-database-v4-1/) (last access: 1 August 2022). Population density is

457 acquired from <https://landscan.ornl.gov/landscan-datasets> (last access: 1
458 August 2022).

854 **Table 1.** Summary of detailed datasets used in this study.

Dataset type	Variable	Description	Spatial resolution	Temporal resolution	Time period	Data source	
	O ₃	Near-surface ozone concentrations	0.5°×0.625°	Monthly (historical)	2014–2019 (historical)	Assimilated GEOS-Chem simulations and Observations	
Meteorology	T_2m	Air temperature at 2 meters					
	T_850	Air temperature at 850 hPa					
	T_500	Air temperature at 500 hPa					
	U_850	Zonal wind at 850 hPa					
	U_500	Zonal wind at 500 hPa				MERRA-2 (historical)	
	V_850	Meridional wind at 850 hPa			Monthly (historical)	2014–2019 (historical)	
	V_500	Meridional wind at 500 hPa	0.5°×0.625°	Monthly (future)	2020–2100 (future)	Adjusted CMIP6 (future)	
	RH	Relative humidity					
	PRECP	Precipitation rate					
	CLT	Total cloud cover					
	RSDS	Incoming shortwave radiation at the surface					
	SLP	Sea level pressure					
Emission		Nitric oxide from anthropogenic sources			2014–2019 (historical)		
		NO _x	Nitric oxide from biomass burning		2019 (future)		
			Nitric oxide from soil sources		2016		
			Nitric oxide from lightning sources		2016		
		CO	Carbon monoxide from anthropogenic sources		Monthly (historical)		CEDS (Anthropogenic)
			Carbon monoxide from biomass burning	0.5°×0.625°	Monthly (future)	2014–2019 (historical)	GFED4 (Biomass burning)
			Non-methane volatile organic compounds from anthropogenic sources			2019 (future)	MEGAN V-2.1 (Biogenic)
	NMVOC	Non-methane volatile organic compounds from biomass burning					
		Non-methane volatile organic compounds from biogenic sources			2016		
Land use	LC	Land cover	300 m×300 m		2014–2019 (historical)	ESA CCI	
	NDVI	Normalized Difference Vegetation Index	0.05°×0.05°	Monthly	2019 (future)	AVHRR	
Topography	TOPO	Digital elevation model	90 m×90 m	-	2010	SRTM	
Population	POP	Population density	1 km×1 km	-	2010	Land Scan	

855

856

857 **Figure 1.** Spatial distributions of observed (a) and assimilated (b) O₃
858 concentrations in 2014–2019 over Asia. Correlation coefficient (R) between
859 observed and assimilated O₃ and the normalized mean bias (NMB = \sum
860 (Observed – Assimilated) / \sum Assimilated × 100%) are given at the bottom left of
861 panel (a).

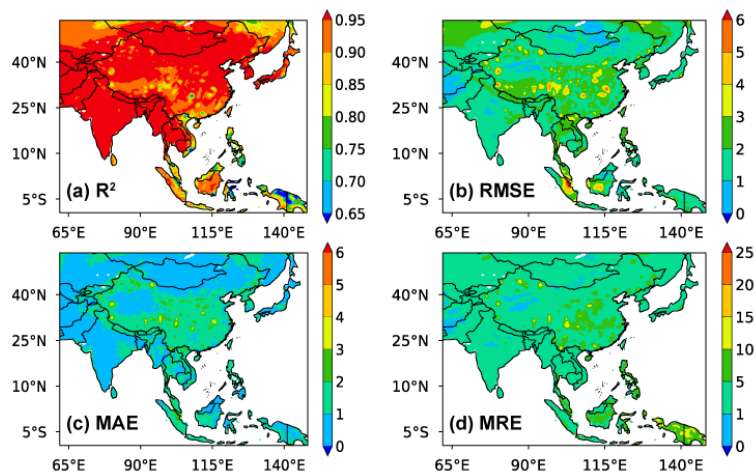

862

863

864 **Figure 2.** Density scatterplots of 10-fold cross-validation results for monthly O₃
865 concentrations (ppb) in 2019 over Asia. The gray and red lines are the 1:1 line
866 and linear regression line, respectively. Statistical metrics including the number
867 of samples (N), correlation of determination (R², unitless), root mean square
868 error (RMSE, ppb), mean absolute error (MAE, ppb), and mean relative error
869 (MRE, %) are shown at the top left.

870

871

872

873

874 **Figure 3.** Spatial distributions of the performance statistics of the random
875 forest (RF) model with regard to (a) R^2 (unitless), (b) RMSE (ppb), (c) MAE
876 (ppb), and (d) MRE (%) during 2014–2019 over Asia.

876

877

879

880 **Figure 4.** Importance scores of independent variables (meteorological
881 parameters, emissions, land use, topography, and population density) used in
882 the ML model for predicting future near-surface O₃ concentrations over Asia.

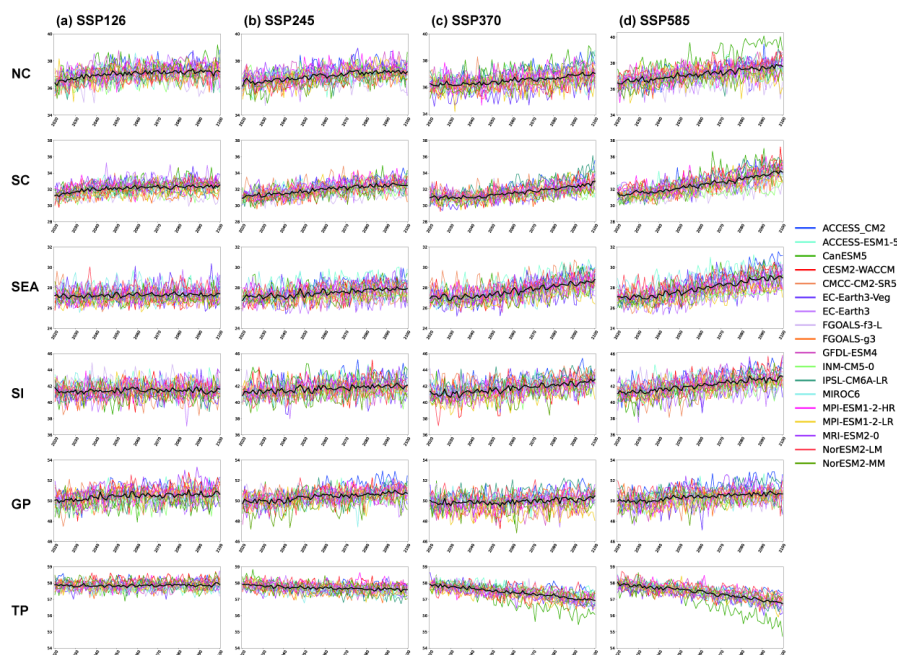

883

884

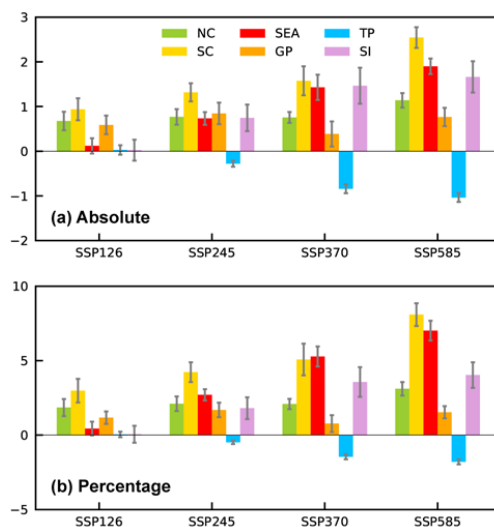

885

886 **Figure 5.** The spatial distributions of absolute (ppb) and percentage difference
887 (%) of surface O_3 level between 2025 (2020–2029 mean) and 2095 (2091–2100
888 mean) driven by climate change under four scenarios (a, e) SSP1-2.6, (b, f)
889 SSP2-4.5, (c, g) SSP3-7.0 and (d, h) SSP5-8.5. The box-outlined areas in (d)
890 are North China (NC, 35°–41°N, 105°–120°E), South China (SC, 22°–33.5°N,
891 105°–120°E), Southeast Asia (SEA, -9.5°S–19°N, 93.75°–140°E), South India
892 (SI, 8°–18°N, 73.125°–80.625°E), Gangetic Plains (GP, 21.5°–23.5°N,
893 85.625°–92.5°E, 23.5°–27°N, 76.25°–92.5°E, and 27°–30°N, 76.25°–81.25°E),
894 and Tibetan Plateau (TP, 28°–31°N, 81.875°–102.5°E and 31°–38°N, 73.125°–
895 102.5°E). No overlaying hatch pattern indicates statistical significance with 95%
896 confidence from a two-tailed t test.

Figure 6. Time series (2020–2100) of annual mean near-surface O₃ concentrations (ppb) driven by climate change under the four scenarios (SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5) over North China (NC, 35°–41°N, 105°–120°E), South China (SC, 22°–33.5°N, 105°–120°E), Southeast Asia (SEA, -9.5°S–19°N, 93.75°–140°E), South India (SI, 8°–18°N, 73.125°–80.625°E), Gangetic Plains (GP, 21.5°–23.5°N, 85.625°–92.5°E, 23.5°–27°N, 76.25°–92.5°E, and 27°–30°N, 76.25°–81.25°E), and Tibetan Plateau (TP, 28°–31°N, 81.875°–102.5°E and 31°–38°N, 73.125°–102.5°E). The black lines are the averages of the predicted O₃ based on meteorological fields from 18 CMIP6 models.

910
911

912 **Figure 7.** Absolute (a, ppb) and percentage (b, %) changes in projected near-
913 surface climate-driven O₃ concentrations in 2095 (2091–2100 mean) relative to
914 2025 (2020–2029 mean) over the six selected key regions of Asia, including
915 NC, SC, SEA, SI, GP, and TP under four future climate scenarios. The error
916 bars indicate one standard deviation.

917

918

919 **Figure 8** The spatial distributions of percentage differences (%) in near-surface
920 O₃ concentrations between 2025 (2020–2029 mean) and 2095 (2091–2100
921 mean) driven by climate change under four scenarios (SSP1-2.6, SSP2-4.5,
922 SSP3-7.0 and SSP5-8.5, from left to right) averaged in MAM (March–April–
923 May), JJA (June–July–August), SON (September–October–November), and
924 DJF (December–January–February) (from top to bottom). No overlaying hatch
925 pattern indicates statistical significance with 95% confidence from a two-tailed
926 t test.
