21 **Abstract**

22 Secondary organic aerosol (SOA) has been identified as a major contributor to fine
23 particulate matter (PM_{2.5}) in North China Plain (NCP). However, the chemical mechanisms
24 involved are still unclear due to incomplete understanding of its multiple formation processes.
25 Here we report field observations in summer in Handan of NCP, based on high-resolution
26 online measurements. Our results reveal the formation of SOA via photochemistry and two
27 types of aqueous-phase chemistry, the latter of which include nocturnal and daytime processing.
28 The photochemical pathway is the most important under high O_x (=O₃ + NO₂) conditions (65.1
29 ± 20.4 ppb). The efficient SOA formation from photochemistry (O_x-initiated-SOA) dominated
30 the daytime (65% to OA) with an average growth rate of 0.8 μg m⁻³ h⁻¹. During the high relative
31 humidity (RH: 83.7 ± 12.5 %) period, strong nocturnal aqueous-phase SOA formation (aq-SOA)
32 played a significant role in SOA production (45% to OA) with a nighttime growth rate of 0.6
33 μg m⁻³ h⁻¹. Meanwhile, an equally fast growth rate of 0.6 μg m⁻³ h⁻¹ of O_x-initiated-SOA from
34 daytime aqueous-phase photochemistry was also observed, which contributed 39% to OA,
35 showing that photochemistry in the aqueous phase is also a non-negligible pathway in summer.
36 The primary-related-SOA (SOA attributed to primary particulate organics) and aq-SOA are
37 related to residential coal combustion activities, supported by distinct fragments from
38 polycyclic aromatic hydrocarbons (PAHs). Moreover, the conversion and rapid oxidation of
39 primary-related-SOA to aq-SOA could be possible in the aqueous phase under high-RH
40 conditions. This work sheds light on the multiple formation pathways of SOA in ambient air of
41 complex pollution, and improves our understanding of ambient SOA formation and aging in
42 summer with high oxidation capacity.

45 phase chemistry, complex air pollution

46

47 1. Introduction

48 Rapid economic growth and urbanization processes have led to severe particulate air
49 pollution in China, affecting air quality, climates and human health (Huang et al., 2014;
50 Cohen et al., 2017; An et al., 2019). Organic aerosol (OA) is a major component of aerosol
51 particles, consisting of 20-90% of fine particle mass (Jimenez et al., 2009; Zhang et al., 2011).
52 OA is either emitted directly from primary sources (referred to as primary OA, POA) such as
53 traffic, cooking, coal combustion, and biomass burning, or produced through gas-to-particle
54 conversion (referred to as secondary OA, SOA) in the atmosphere. In recent years, with the
55 implementation of control measures, the POA fraction is decreasing and SOA fraction is
56 increasing in North China Plain (NCP), indicating that SOA is becoming more critical for urban
57 air quality (Huang et al., 2019; Xu et al., 2019; Gu et al., 2020). However, our understanding
58 of the formation mechanisms and evolution processes of SOA is still limited.

59 Generally, SOA can be formed through gas-phase photochemical oxidation of volatile
60 organic compounds (VOCs) followed by nucleation or condensation of oxidation products onto
61 the preexisting particles (Donahue et al., 2006). Herndon et al., (2008) showed that oxygenated
62 organic aerosol (OOA), a surrogate of SOA, was well correlated with odd oxygen ($O_x = O_3 +$
63 nitrogen dioxide (NO_2)) during photochemical processing. SOA can also be formed in the
64 aqueous phase on wet aerosols, clouds and fogs through further chemical processes of water-
65 soluble organic compounds or organic products of gas-phase photochemistry (Ervens et al.,
66 2011, 2014). A growing number of laboratory studies and field measurements have indicated
67 that aqueous-phase processes contribute efficiently to the formation of SOA (Gilardoni et al.,
68 2016; Bikkina et al., 2017). However, how photochemistry and aqueous-phase chemistry
69 coordinate to affect the formation of SOA is still unclear, despite numerous measurements to
70 explore this question using aerosol chemical speciation monitor (ACSM) or aerosol mass
71 spectrometer (AMS) (Hu et al., 2016b; Hu et al., 2017; Sun et al., 2016; Li et al., 2017; Sun et
72 al., 2018b; Huang et al., 2019; Gu et al. 2020; Kuang et al., 2020). Field measurements in
73 Beijing suggested that gas-phase photochemical oxidation can play a dominant role in SOA
74 formation (Sun et al., 2016; Hu et al., 2016a). Xu et al., (2017) showed that less oxidized-OOA
75 (LO-OOA) was mainly formed through photochemical oxidation, while the more oxidized-
76 OOA (MO-OOA) formation was dominantly formed by aqueous-phase chemistry in Beijing
77 for different seasons. Kuang et al. (2020) investigated the effects of gas-phase and aqueous-
78 phase photochemical processes on the formation of SOA and found that photochemical
79 aqueous-phase SOA formation dominantly contributed to daytime OOA formation in winter
80 Gucheng, located between Beijing (~100 km) and Baoding (~40 km) on the NCP. We found
81 that photochemical processing attributed mostly to MO-OOA in summertime Beijing (Gu et al.,
82 2020). Although these studies provided important insights into SOA formation processes, our
83 understanding on the photochemical and aqueous-phase formation pathways for SOA and their

84 impacts on oxidation degree are far from complete. This lack of understanding is especially so
85 under the conditions that atmospheric oxidative capacity and pollution characteristics have been
86 largely changing in China due to large reduction in direct emissions of air pollutants.

87 In this study, we investigated the photochemical versus aqueous-phase processing for SOA
88 composition and oxidation degree of OA in summertime Handan, which is a typical
89 industrialized city in the NCP region. The city is located at the intersectional area of Hebei,
90 Shanxi, Henan, and Shandong—four heavily urbanized and industrialized provinces (Fig. S1),
91 and it is therefore an ideal site to investigate the SOA formation pathways in the NCP region.
92 The multiple formation pathways, evolution of SOA composition, and oxidation degree under
93 different meteorological conditions were discussed, which sheds light on the aqueous-phase
94 chemistry and photochemical processing in SOA formation in the NCP region of China.

95 **2. Experimental methods**

96 **2.1 Sampling site**

97 Measurements were conducted from 10th August 2019 to 17th September 2019 on the campus
98 of Hebei University of Engineering (36.57 N, 114.50 E), located at the southeast edge of urban
99 Handan (Fig. S1). The site is surrounded by a school and residential areas, ~300 m north to
100 South Ring Road and ~400 m northeast to the Handan Highway (S313). The sampling site is
101 on the rooftop of a four-floor building, approximately 12 m above the ground.

102 **2.2 Instrumentation**

103 Real-time non-refractory PM_{2.5} composition was measured by a soot particle long time-of-
104 flight aerosol mass spectrometer (SP-LToF-AMS, Aerodyne Research Inc.) with a time
105 resolution of 1 min. The detailed instrument description and operation of AMS were reported
106 in Onasch et al., (2012). Compared to the conventional AMS, the LToF mass analyzer can
107 provide much better mass resolution of ~8000. During the campaign, the instrument was
108 operated in the “laser off” mode and only the standard tungsten vaporizer was applied.
109 Therefore, only non-refractory PM_{2.5} components (NR-PM_{2.5}) were measured, including
110 organics (Org), nitrate (NO₃), sulfate (SO₄), ammonium (NH₄), and chloride (Chl). Ambient
111 air was sampled and dried by a Nafion dryer (MD-700-24S, Perma Pure, Inc.) at a flow rate of
112 5 L min⁻¹, and then sub-sampled into the SP-LToF-AMS at a flow rate of ~ 0.1 L min⁻¹. An
113 aerodynamic PM_{2.5} lens was used to focus the particle into a beam, which was then impacted
114 on the heated tungsten surface (~ 600 °C) and flash-vaporized. Electron ionization with 70 eV
115 was used to ionize the vaporized gases. The ionization efficiency (IE) and the relative ionization
116 efficiency (RIE) calibrations (Jimenez et al., 2003) were conducted by using 350 nm
117 ammonium nitrate (NH₄NO₃) and ammonium sulfate ((NH₄)₂SO₄) particles.

118 Gaseous pollutants including SO₂ (9850 SO₂ analyzer, Ecotech), NO₂ (Model 42i NO-NO₂-
119 NO_x analyzer, Thermo Scientific), CO (Model 48i carbon monoxide analyzer, Thermo
120 Scientific), O₃ (Model 49i ozone analyzer, Thermo Scientific), and meteorological parameters
121 including RH and temperature were also measured during the observation period. Furthermore,
122 an aethalometer (Model AE-33, Magee Scientific) was deployed to measure the mass
123 concentration of black carbon (BC) at a time resolution of 1 min.

124 **2.3 Data Analysis**

125 The data analysis software (SQUIRREL, version 1.63I and PIKA, 1.23I) within Igor Pro 6.37
126 (WaveMetrics) was used to analyze the AMS data. The experimental RIE values of 4 (NH₄)
127 and 1.2 (SO₄) and the standard RIE values of 1.4 (Org), 1.1 (NO₃) and 1.3 (Chl) were used.
128 The composition-dependent collection efficiency (CDCE, Middlebrook et al., 2012) was used
129 to compensate for the incomplete detection caused by particle bounce on the vaporizer. An
130 improved Ambient (I-A) method was adopted for the elemental ratio analysis of high-resolution
131 (HR) OA mass spectra, such as oxygen-to-carbon (O:C), and hydrogen-to-carbon (H:C) ratios
132 (Canagaratna et al., 2015), which reflect the relative composition and oxidation degree for
133 different OA source. In our study, PMF was performed on HR mass spectra of OA for ions with
134 m/z values of 12-120, together with the signals from integer m/z values between 121 to 300 (i.e.,
135 unit mass resolution, UMR) using SoFi (version 6.3) in Igor Pro (Paatero, 1999; Canonaco et
136 al., 2013). The data and error matrices were preprocessed according to Elser et al., (2016) and
137 detailed description of PMF analysis was given elsewhere (Canonaco et al. 2013; Elser et al
138 2016). Unconstrained PMF solutions with varied factor numbers were analyzed and six factors
139 were resolved, including two primary and four secondary organic factors (Fig. 3). The six-factor
140 solution was preferred because the five-factor solution was not able to separate high signal of
141 m/z 44 (which represents high oxidation state) from primary organic aerosol (POA) factors,
142 while the seven-factor solution added additional OOA factors with similar profiles and noisy
143 time series for which no physical interpretation could be found. The two POA factors consisted
144 of a traffic-related factor (hydrocarbon-like OA, HOA) and a cooking-related factor (COA),
145 which had been resolved in previous summer studies in NCP (Elser et al., 2016; Hu et al., 2016b;
146 Sun et al., 2016; Huang et al., 2019). AMS source apportionment studies often report one or
147 two oxygenated organic aerosol (OOA) factors that are distinguished by the extent of
148 oxygenation and linked to volatility or oxidation degree. Owing to higher mass resolution of
149 LTOF-AMS and the inclusion of integer-mass signals for m/z from 121 to 300 for high-
150 molecular-weight species such as polycyclic aromatic hydrocarbons (PAHs), we herein
151 resolved four SOA factors. These four SOA factors include aq-SOA attributable to aqueous-
152 phase chemistry, O_x-initiated-SOA attributable to photochemistry, primary-related-SOA
153 attributable to prompt oxidation of POA during emission, and fresh-SOA with a lower f_{44}/f_{43}
154 ratio (fraction of m/z 44 and 43 in OA).

155 2.4 Aerosol liquid water content

156 The aerosol liquid water content (ALWC) was simulated by ISORROPIA-II model (Fountoukis
157 and Nenes, 2007; Hennigan et al., 2015) using the measurements of ambient inorganic species
158 (NO₃, SO₄, NH₄, and Chl) and meteorological parameters (temperature and RH). The
159 simulation was run in “metastable” mode where all components are assumed to be deliquescent
160 and contain no solid matter. The concentrations and speciation (if dissociated) of those
161 inorganic species in thermodynamic equilibrium was then simulated by the model and then the
162 ALWC was calculated. The inorganic cations such as Na⁺, K⁺, Ca²⁺, Mg²⁺ were not measured
163 and included in the simulation on account of that these crustal ions constituted relatively small
164 fractions of aerosol, and had relatively weak effects on ALWC accumulation (Fountoukis and
165 Nenes, 2007; Su et al., 2022). The ISORROPIA-II model does not consider the contribution
166 to ALWC from organics, since inorganic aerosols dominate the water uptake by ambient
167 particles with a contribution of approximate >80% of the total ALWC (Huang et al., 2020).

168 3. Results and discussion

169 3.1 SOA sources

170 In our study, SOA accounted for 69% (13.5 $\mu\text{g m}^{-3}$) of the total OA (19.6 $\mu\text{g m}^{-3}$),
171 representing the dominant fraction in OA in summer Handan. Among the four PMF-resolved
172 SOA sources (Fig. 1), O_x-initiated-SOA dominated (31% to total OA), followed by fresh-SOA
173 (18%), aq-SOA (15%), and primary-related-SOA (5%). Since we focus on SOA formation in
174 this study, detailed descriptions of the HOA (12%) and COA (19%) is provided in section 1.1
175 in the SI. The mass spectral profiles of the six OA source factors are shown in Fig. 1, while the
176 time series of the SOA factors are shown in Fig. 2. In particular, a remarkable continuous
177 growth of aq-SOA concentration (from $\sim 0.3 \mu\text{g m}^{-3}$ to $25.2 \mu\text{g m}^{-3}$) and ALWC (from $3.1 \mu\text{g m}^{-3}$
178 3 to $486.1 \mu\text{g m}^{-3}$) occurred on 24th-28th August (Fig. 2d). Meanwhile, the O:C ratio indicative
179 of OA oxidation state displayed a continuous increase from 0.52 to a maximum of 0.93 during
180 this time (Fig. 2e), consistent with the continuous increase in RH (reaching over 95%). This
181 observation hints that during this period aqueous-phase processing might have played an
182 important role in aq-SOA formation. This role of aqueous-phase processing in SOA formation
183 is not just specific to this particular event, but also important in the whole campaign, which is
184 discussed in detail in section 3.3 later.

185 SOA factors were resolved depending on the oxidation state, which correspond to aged SOA
186 and fresh SOA respectively (Jimenez et al., 2009). One factor is attributed to aqueous-phase
187 chemistry (aq-SOA) and the other to photochemistry (O_x-initiated-SOA), while fresher factor
188 is produced by fresh-source (fresh-SOA) with a lower f_{44}/f_{43} ratio, and the other considered as

189 oxidized primary sources denoted as primary-related-SOA. Although all of the SOA factors
190 were characterized by higher m/z 44 (CO_2^+) and m/z 28 (CO^+) signal compared with POA
191 factors, their mass spectrum and temporal trends were noticeably distinguishable,
192 corresponding to different formation mechanism, which will be discussed in the following
193 section.

194 As shown in Fig. S3, the aq-SOA was identified as it increased with ALWC but decreased
195 with O_x , which might be produced/influenced by aqueous-phase chemistry and is defined as aq-
196 SOA. This indicates that aq-SOA was either formed via aqueous phase reactions or
197 absorbed/dissolved into aerosol liquid water. It exhibits the highest O:C ratios of all factors (0.7)
198 and a higher $f_{\text{CO}_2^+}$ to the total signal of 21.7%, but a low H:C ratio of 1.24 (Fig. 1). The O_x -
199 initiated-SOA in our study is photochemical production SOA whose formation initiated with
200 the presence of O_x . As O_x has been shown to be a conserved tracer to during photochemical
201 processing (Xu et al., 2017), the relationship between O_x and O_x -initiated-SOA can represent a
202 metric to characterize SOA formation mechanisms associated with ozone production chemistry
203 SOA (Herndon et al., 2008). O_x -initiated-SOA presented an opposite trend with significant
204 increase as function of O_x but decreased as a function of ALWC (Fig. S3), suggesting the
205 dominant role of photochemical processing in the formation of O_x -initiated-SOA.

206 The fresh-SOA showed an increase substantially as ALWC increasing, similar to aq-SOA.
207 Whereas it also showed a slight increase trend following O_x when $\text{O}_x < 100$ ppb (Fig. S3).
208 Therefore, both aqueous-phase chemistry and photochemical processing were thought to have
209 positive impacts synchronously on the formation of fresh-SOA. In this study, the fresh-SOA
210 had the lowest atomic O:C ratio of 0.41 and the highest atomic H:C ratio of 1.41 among the
211 four SOA factors, corresponding with the $f_{\text{CO}_2^+}$ of 8.3%, these characteristics are consistent with
212 the global average O:C ratio of LO-OOA of 0.35 ± 0.14 , (Ng et al., 2010), demonstrating it
213 is more fresh SOA. Although the primary-related-SOA constituted a small fraction and showed
214 little variation during P1~P3 (3%~5%), this SOA source is also of particular interest because
215 of its distinctive fragments with high m/z values in the mass spectrum (Fig. 1d). At $m/z < 120$,
216 the primary-related-SOA had higher intensities for m/z 43 (mainly $\text{C}_2\text{H}_3\text{O}^+$) and m/z 44 (mainly
217 CO_2^+) than those in POA, indicating a typical nature of less-oxidized SOA. At $m/z > 120$, PAH-
218 derived fragments are clearly evident in the mass spectrum of the primary-related-SOA, as
219 indicated by PAH-like ions (described in SI 1.2) (Dzepina et al., 2007). Previous AMS studies
220 have observed pronounced peaks of PAH ions in POA mass spectra, such as those in coal
221 combustion organic aerosol (CCOA) and biomass burning organic aerosol (BBOA) (Hu et al.,
222 2016b; Zhao et al., 2019), but rarely in SOA. This observation implies that the factor may be
223 related to the POA originated from domestic coal combustion and here it is termed as primary-
224 related-SOA (Xu et al., 2006). Moreover, this SOA factor exhibited relatively better
225 correlations with some gaseous pollutants (Fig. S4), such as CO ($R = 0.6$) and NO_2 ($R = 0.5$),

226 and also tracked with HOA ($R = 0.4$). These observations suggest that the primary-related-SOA
227 might be transformed from locally emitted POA as a non-negligible source to SOA.

228 To further investigate the SOA formation mechanism, the dataset was segregated into three
229 periods according to different features depends on meteorological parameters (Fig. 2), i.e., the
230 reference period (P1), high- O_x period (P2) and high-RH period (P3). Briefly, the reference
231 period, P1, was characterized by a low average OA concentration ($15.4 \pm 3.2 \mu\text{g m}^{-3}$) and was
232 mainly affected by clean air from southwest of the sampling site and precipitation activities
233 (Table S1). The high- O_x period (P2) was featured by a high O_x concentration (65.1 ± 20.4 ppb),
234 warmer temperatures (26.4 ± 4.0 °C) but lower RH (57.7 ± 17.5 %). The mass loadings of OA
235 ($19.8 \pm 4.7 \mu\text{g m}^{-3}$) and other pollutants in P2 were higher than those in P1 (Table S1). P3 was
236 assigned as a high-RH period because of the noticeably high RH (83.7 ± 12.5 %) and high
237 ALWC ($95.4 \pm 114.2 \mu\text{g m}^{-3}$). Winds were weak ($<1.0 \text{ m s}^{-1}$) throughout this period, indicative
238 of stagnant conditions, which facilitated pollutant accumulation and resulted in the highest
239 average OA concentrations ($25.0 \pm 6.2 \mu\text{g m}^{-3}$).

240 During the reference period (P1), SOA had the lowest contribution to OA (57%), and the O_x -
241 initiated-SOA and aq-SOA constituted 22% and 21% to total OA, respectively. For the high-
242 O_x period (P2), enhanced SOA formation was found, with the SOA fraction increased to 71%
243 of the total OA. The O_x -initiated-SOA showed the highest mass loading of $7.3 \mu\text{g m}^{-3}$ and
244 highest contribution of 37% to total OA. These increases suggest that high- O_x condition
245 facilitates the production of SOA by photochemistry, making the O_x -initiated-SOA the major
246 source of SOA during P2. During the high-RH period (P3), SOA fraction continually increased,
247 approaching 79% in total OA, and the SOA was mainly contributed by aq-SOA and fresh-SOA.
248 The mass contribution of aq-SOA increased dramatically from 9% to total OA during P2 to 33%
249 during P3 (Fig. S2), and average mass concentrations from $1.8 \mu\text{g m}^{-3}$ to $8.3 \mu\text{g m}^{-3}$, which
250 suggests rapid SOA production through the aqueous-phase chemistry. Comparatively, the
251 contribution of fresh-SOA was about ~20% in both P2 and P3, but lower in P1 (9%), suggesting
252 that the formation fresh-SOA was affected by both high O_x and high RH. It should also be noted
253 that O:C ratio increased in the succession from P1 (0.73) to P2 (0.74) and further to P3 (0.77),
254 accompanied by continually decrease of H:C ratio from 1.64 to 1.56, and to 1.53 (Fig. 3),
255 suggesting the increase of OA oxidation degree. As a result, the high O_x in P2 and high RH in
256 P3 (as compared to P1) promoted the formation of SOA, specifically O_x -initiated-SOA (in P2)
257 and aq-SOA (in P3), leading to the increase in the degree of oxygenation in total OA.

258 Overall, our results suggest that SOA could be formed through different pathways, in
259 particular photochemistry, aqueous-phase chemistry, and conversion of POA to SOA
260 contributed to SOA formation.

261 3.2 Photochemistry

262 As expected for summertime, photochemistry associated with O_x has significant impacts on
263 the formation and evolution of SOA. Herein, the relationships between OA factors and O_x were
264 investigated to offer insights into the formation mechanisms of SOA associated with the ozone
265 production chemistry (Herndon et al., 2008). During P2, as O_x increased, the mass loadings of
266 O_x -initiated-SOA showed a substantially increasing trend when O_x was > 30 ppb and eventually
267 saturated when O_x was >100 ppb, raising the contribution of O_x -initiated-SOA from 20% to 61%
268 of total OA (Fig. 4). This observation indicates the importance of photochemistry in the
269 formation of O_x -initiated-SOA in summer, in which high O_x concentration as well as
270 temperature corresponding to strong atmospheric oxidative capacity, can accelerate the
271 photochemical formation (Duan et al., 2021). As a comparison, the mass concentrations of other
272 OA factors except O_x -initiated-SOA showed decreasing trends as O_x increased (Fig. 4c). Such
273 differences between SOA factors are likely due to the enhanced secondary
274 production/transformation from POA and fresher SOA factors to the more aged O_x -initiated-
275 SOA. Note that the O:C ratio presented a faster increasing rate as a function of O_x (from 0.6 to
276 1.0, Fig. 4d) than those in P1 and P3, suggesting that photochemistry might result in higher OA
277 oxidation state during P2.

278 The typical episode with high- O_x period (P2) was dominated by a series of daytime
279 photochemical evolutions. To evaluate the relative contributions of photochemical and
280 aqueous-phase processing production and the transformation of these SOA factors in different
281 meteorological stages, the average diurnal variations of OA factors, O:C ratios, O_x , temperature,
282 AWLC and primary gas pollutants during different periods are shown for comparison. Fig. 6
283 shows that O_x increased rapidly from 6:00 to 14:00 in all periods, but was highest in
284 P2. Correspondingly, a lower mean value of ALWC ($8.4 \mu\text{g m}^{-3}$) was also observed in P2 than
285 in P1 and P3. During P2, O_x -initiated-SOA was produced quickly and played the dominant role
286 during daytime, while its concentration typically decreased during nighttime. The average
287 concentration of O_x -initiated-SOA increased continually from $4.2 \mu\text{g m}^{-3}$ at 7:00 local time (LT)
288 to $10.4 \mu\text{g m}^{-3}$ at 15:00 LT in 8 h, with the maximum O_x -initiated-SOA mass fraction in OA
289 reaching 65% at 15:00 LT (Fig. S6c). This high average growth rate of $0.8 \mu\text{g m}^{-3} \text{ h}^{-1}$ in O_x -
290 initiated-SOA corresponded to the high O_x concentration, high temperature and strong solar
291 radiation in daytime, suggesting enhanced photochemistry reaction. In contrast, the
292 concentrations and the contributions of other SOA factors decreased continuously at the same
293 time (Fig. 6). The opposite trends between O_x -initiated-SOA and other OA factors from 7:00
294 to 15:00 LT suggest that some part of POA and fresh-SOA may convert to O_x -initiated-SOA
295 by photochemical oxidation. This conclusion is consistent with findings reported by Li et al.,
296 (2020) in urban Beijing, where less-oxidized SOA may transform to more-oxidized SOA
297 through photochemical processing as well. The O:C ratio of OA presented a significant
298 increasingly diurnal variation with a noon peak around 14:00 ~ 16:00 LT in P2, which had the

299 highest value of 0.74 compared with P1 and P3, suggesting the potential transformation from
300 POA factors and fresh SOA factors to O_x -initiated-SOA could also noticeably affect OA
301 characteristics such as oxidation state in summer daytime. It is further indicated by a small
302 afternoon peak of the more oxidized tracer CO_2^+ (m/z 44) and the decrease in a less oxidized
303 tracer $C_2H_3O^+$ (m/z 43) (Fig. 7b). As a result, the mass spectra, which were initially fresh SOA
304 products evolved to become aged SOA products as the photochemical age increased. Overall,
305 with little water in the particles, the high solar radiation and high O_x concentration during
306 daytime associated with a relatively high degree of oxygenation of OA suggest that gas-phase
307 oxidation and partitioning processes are probably the dominating process in SOA formation
308 during P2.

309 In addition, these results further support the idea that during the high- O_x period of summer,
310 photochemistry has significant impacts on SOA formation, especially on O_x -initiated-SOA.
311 Note that the role of photochemistry in the formation of O_x -initiated-SOA is not only limited to
312 the gas-phase photochemistry, but also can also occur in the aqueous phase (Kuang et al., 2020).
313 This is the case for P3 in our study, which is discussed further in section 3.3 below.

314 **3.3 Aqueous-phase chemistry**

315 The aqueous-phase chemistry has imposed significant impacts on SOA formation during this
316 field campaign. To further explore the formation mechanism of SOA associated with aqueous-
317 phase chemistry, the relationships between different OA factors and ALWC were investigated.
318 During P3, the mass concentration of aq-SOA increased from $5 \mu g m^{-3}$ to $17 \mu g m^{-3}$, yet its
319 fraction showed a particularly pronounced rise from 22.5% to 52% of total OA when ALWC
320 increased from 0.3 to $200 \mu g m^{-3}$ (Fig. 5e and f). Note that there are still consistent mass
321 concentrations of aq-SOA even when ALWC is very low (data interval ranging from 0~40 μg
322 m^{-3}), which is due to that over 80% of ALWC mass concentration were loaded in the first
323 interval, leading to a higher mean value of aq-SOA mass concentration. Actually ALWC
324 showed quite low mass loading in most period time but increased dramatically during P3, yet
325 the time series of aq-SOA and ALWC were remarkably well correlated throughout the entire
326 campaign ($R=0.7$, Fig. S4) rather than a strong correlation observed only in P3. This general
327 correlation further confirms the important role of aqueous-phase chemistry in the formation of
328 aq-SOA and characterized the aqueous-phase formation of aq-SOA throughout the campaign
329 rather than only in the high-RH event as shown in section 3.1 earlier. We also found that the
330 concentration and fraction of aq-SOA became stable when ALWC was $> 200 \mu g m^{-3}$, which is
331 probably attributable to that the aq-SOA formation within droplets was soon outweighed by the
332 scavenging processes when RH was high enough ($> 95\%$). The O:C ratio shows an obvious
333 increase from 0.7 to around 0.85 when ALWC increases to $200 \mu g m^{-3}$, after which it remains

334 relatively stable (0.85) as the ALWC increases further (Fig. 5). These results suggest that
335 aqueous-phase chemistry can affect the oxidation degree of OA by changing SOA composition,
336 especially the enhanced contribution of aq-SOA. However, the growth rate of O:C ratios as
337 ALWC increases in P3 was lower than that in P2 (up to 1 as O_x increases). Also, the correlation
338 between O:C vs. O_x in P2 ($R=0.6$) was stronger than O:C vs. ALWC ($R=0.3$) (Fig. S8).

339 Fig. 6 illustrate the different types of aqueous-phase chemistry in daytime and nighttime.
340 During the nighttime in P3, aqueous-phase oxidation was also enhanced during nighttime
341 (19:00–07:00 LT). As shown in Fig. 6, O:C ratio (0.76) at nighttime in P3 was higher than those
342 in P2, while exhibiting a much smaller peak during daytime. Compared with the low ALWC in
343 P2, the much higher ALWC concentration (peak value of $235.9 \mu\text{g m}^{-3}$ at 2:00 LT) and higher
344 RH (peak value of 93.7% at 6:00 LT) during nighttime in P3 suggested a dominant contribution
345 by aqueous-phase processing. The aq-SOA shows a quite clear and unique diurnal pattern in
346 P3, with much higher mass concentration during the whole day (especially at nighttime) than
347 those in P1 and P2. After 17:00 LT, aq-SOA started to increase from $4.7 \mu\text{g m}^{-3}$ to $12.7 \mu\text{g m}^{-3}$
348 at 7:00 LT, which showed a rapid nighttime growth rate of $0.6 \mu\text{g m}^{-3} \text{h}^{-1}$, indicating enhanced
349 SOA formation through aqueous-phase chemistry at night. Whereas O_x -initiated-SOA
350 decreased rapidly from $8.2 \mu\text{g m}^{-3}$ at 17:00 LT until reaching its lowest concentration of 2.6
351 $\mu\text{g m}^{-3}$ until the morning, suggesting the gas-to-particle partitioning at night under high ALWC
352 conditions. Furthermore, this transformation could be supported by the increase in CO_2^+ (m/z
353 44) and the decrease in a less oxidized tracer $\text{C}_2\text{H}_3\text{O}^+$ (m/z 43) at night (Fig. 7c). Since when
354 the ALWC is sufficiently high, it was likely to accommodate much of the precursor organics
355 and oxidants to low-volatility products through aqueous-phase oxidation. In addition, the dark
356 aqueous-phase SOA formation was likely strong enough to counteract the nighttime scavenging
357 processes under high-RH conditions. Therefore, the dark aqueous-phase chemistry forming aq-
358 SOA shows a dominant role (over 40% to OA) during nighttime in P3.

359 However, during the daytime, the mass concentration of aq-SOA decreased from 7:00 to
360 17:00 LT in P3, coinciding an obvious increase trend of O_x -initiated-SOA at the same time with
361 an average growth rate of $0.6 \mu\text{g m}^{-3} \text{h}^{-1}$ (Fig. 6). This phenomenon suggests photochemical
362 processing can also occur in the aqueous phase when RH and ALWC were still high.
363 Photochemical reactions through both aqueous-phase and gas-phase can contribute
364 substantially to the SOA formation in polluted areas of NCP, and during haze days with high
365 RH and ALWC the aqueous-phase photochemical processes played a dominant role in daytime
366 SOA formation (Kuang et al., 2020). The rapid daytime O_x -initiated-SOA formation in our
367 study possibly occurred on the particle surface and in the aerosol liquid water (Ervens et al.,
368 2011) under humid conditions with high ALWC but driven by gas-phase direct photolysis and
369 oxidation by photooxidants under high O_x conditions. Under such high-RH level ($\text{RH} > 80\%$),

370 the water-soluble species produced from photochemistry in the gas phase can also partition into
371 the aqueous phase and be further oxidized to form low-volatility products (Carlton et al., 2007;
372 Sullivan et al., 2016). Previous studies have demonstrated that gas-phase oxidants such as OH
373 radicals and H₂O₂ can also partition to the aqueous phase to further oxidize dissolved the
374 oxidized VOCs (OVOCs) into aq-SOA (Ye et al., 2018). Other studies also revealed that
375 photochemical reactions in the aqueous droplets can occur through direct photolysis or through
376 oxidation by oxidants (Ervens et al., 2011; 2014; Ye et al., 2018). Therefore, in our campaign,
377 dark aqueous-phase chemistry is responsible for rapid aq-SOA formation during nighttime,
378 while the aqueous-phase photochemistry during daytime is likely prevail by rapid daytime O_x-
379 initiated-SOA formation during P3. This comparison demonstrates that the nocturnal aqueous-
380 phase chemistry and daytime aqueous-phase photochemistry are both important pathways in
381 the total SOA growth. The aqueous-phase chemistry related to fresh-SOA is more complicated,
382 requiring both daytime radiative conditions and certain amounts of ALWC in nighttime. For
383 example, Fig. 5e shows that the fresh-SOA has a similar increasing trend with aq-SOA as
384 ALWC increased, however, it also increased slightly as O_x increased (Fig. 4e), hinting that both
385 ALWC and the oxidants are critical for fresh-SOA formation and both the aqueous-phase
386 chemistry and the photochemistry (including that in the aqueous phase) participated to produce
387 fresh-SOA simultaneously. It is worth noting that three peaks were found in the diurnal
388 variation of fresh-SOA in P3. The peaks at around 6:00 and 19:00 LT at night were similar to
389 those of aq-SOA and lower than it, while the peak at around 13:00 LT is consistent with the
390 peak in the diurnal cycle of O_x (Fig. 6). Although there is also a smaller peak around 13:00 LT
391 in P3, the whole pattern of aq-SOA is characterized by decreasing trend at daytime. These
392 results suggest that fresh-SOA could be formed through dark nighttime aqueous-phase reactions,
393 which are partially reversible upon the evaporation of aerosol liquid water, and also formed
394 through photochemical aqueous-phase reactions during daytime. Different from aq-SOA,
395 which is highly correlated and limited with ALWC, two types of aqueous-phase chemistry in
396 daytime and nighttime are dominant pathways to the fresh-SOA growth. Our analysis on
397 formation pathways of these SOA factors suggested the potential interactive roles of gas-phase
398 oxidation, gas-particle partitioning, and aqueous-phase oxidation in the formation of SOA.

399 **3.4 SOA from POA transformation**

400 The photochemistry and aqueous-phase chemistry show distinct effects on POA evolution
401 and SOA formation. The relationships between O_x-initiated-SOA /aq-SOA and other POA-
402 related components (HOA + COA + primary-related-SOA) were plotted in Fig. S9. A strong
403 negative correlation ($R=-0.8$) between POA-related components and O_x-initiated-SOA was
404 observed (Fig. S9c), consistent with the decrease in mass concentration of POA-related
405 components during P2. This observation suggests that the production of O_x-initiated-SOA was

406 at least partly facilitated by photochemical transformation of other OA components. However,
407 the better diffusion conditions in P2 might also attribute a great extent to the negative
408 correlation, as the formation period of O_x -initiated-SOA usually occurred during the noontime
409 when the boundary layer was much developed, while the POA usually decreased via horizontal
410 and vertical diffusion. In comparison, POA-related components and aq-SOA correlate weakly.
411 When ALWC ($<20 \mu\text{g m}^{-3}$) and nitrate concentrations were lower ($< 3 \mu\text{g m}^{-3}$), mostly during
412 P1 and P2, POA-related components and aq-SOA showed almost no correlation ($R=0.1$ and $R=-$
413 0.1). However, when ALWC concentration and nitrate concentration were higher than those
414 thresholds above (data points with yellow/red colors mostly during P3), they had a relatively
415 good negative correlation ($R=-0.5$) (Fig. S9f), indicating the importance of ALWC and nitrate
416 in aqueous-phase chemistry. This is consistent with results in winter Beijing (Wang et al., 2021),
417 where POA factor had strong negative correlations with aq-SOA, suggesting that these POA
418 factors might produce aq-SOA by aqueous-phase oxidation. In addition, under high-ALWC
419 conditions, nitrate had similar formation mechanisms with aq-SOA or high nitrate supports the
420 potential formation/transformation from POA-related components to aq-SOA, which is
421 consistent with the results in section 3.3. The phenomenon of negative correlation between
422 POA-related components and SOA at high O_x /ALWC further emphasizes the importance of
423 conversion from POA to SOA.

424 As shown in the Van Krevelen (VK) plot (Fig. 8a), O:C and H:C both increase in the
425 succession from primary-related-SOA to O_x -initiated-SOA and eventually to aq-SOA,
426 supporting a successive oxidation sequence from primary-related-SOA to aq-SOA. Generally,
427 H:C shows a decreasing trend as O:C increases for organic compounds during oxidation in
428 other studies (Ng et al., 2011; Gilardoni et al., 2016; Lee et al., 2017; Zhao et al., 2019; Chen
429 et al., 2021), suggesting a general negative correlation between H:C and O:C. This positive
430 relationship of O:C and H:C evolution during oxidative aging in this study is interesting. It
431 might be caused by ring-breaking reactions which could further promote the transformation of
432 aromatic POA to aq-SOA. Previous studies in both laboratory (Huang et al., 2018; Wang et al.,
433 2020) and field (Hu et al., 2016a) demonstrated that the OH-initiated ring-breaking reactions
434 of aromatic species can occur in the aqueous phase and form highly oxidized oxygenated
435 compounds. For example, Hems and Abbatt (2018) suggested that nitrophenol molecules could
436 react rapidly with OH radicals in aqueous solutions with the addition of OH functional groups
437 to the aromatic ring at the initial stage, followed by fragmentation to multifunctional organic
438 species with high H:C and O:C ratios. Wang et al. (2021) found that the ring-breaking oxidation
439 of aromatic FF-POA was the mechanism for aq-SOA formation. Similar to those in primary-
440 related-SOA, PAH-like ions was also found in the mass spectrum of aq-SOA at $m/z > 150$,
441 albeit less pronounced, consistent with a previous study in Beijing (Wang et al., 2021). This is
442 likely due to the oxidation of PAHs in the conversion of primary-related-SOA and aq-SOA,

443 which is caused by enhanced hydroxylation of the aromatic ring and increased yields of
444 carboxylic acids in OH-initiated reactions (Sun et al., 2010). This kind of ring-breaking
445 oxidation of aromatic POA could thus lead to aq-SOA formation (Huang et al., 2018; Wang et
446 al., 2021). In addition, the locations of aq-SOA and the slope of overall OA are near the line
447 with the slope of -1 in the VK plot, indicating more carboxylic acid formation while the
448 replacement of a hydrogen atom with a carboxylic acid group ($-\text{COOH}$) (Heald et al., 2010;
449 Ng et al., 2011). This observation supports that oxidation of PAHs was probably involved in
450 the conversion of primary-related-SOA to aq-SOA through aqueous-phase chemistry, leading
451 to functionalization as carbonyls and carboxylic acids.

452 Specifically, the organic fragments and mass spectrum evolution of OA were analyzed to
453 illuminate the transformation in photochemical processing and aqueous-phase chemistry. Fig.
454 8b shows the mass fractions of CH_2O_2^+ , CH_3SO^+ , HCO_2^+ , and $\text{C}_2\text{H}_2\text{O}_2^+$ ion fragments in OA as
455 a function of ALWC. The aq-SOA was tightly correlated with CH_2O_2^+ ($R^2 = 0.81$) at m/z 46
456 and CH_3SO ($R^2 = 0.78$) at m/z 63 (Fig. S10). Consistently, both of them showed increase trends
457 as ALWC increasing, similar as aq-SOA, which indicating typical fragment characteristics of
458 ions of aqueous-phase processing products (Tan et al., 2009; Sun et al., 2016; Duan et al., 2021).
459 The intensities of HCO_2^+ (m/z 45), a common fragment ion of carboxylic acids, is associated
460 with aqueous oxidation of aromatic compounds. $\text{C}_2\text{H}_2\text{O}_2^+$ (m/z 58) is a tracer ion for glyoxal,
461 which could be a ring-breaking product from the aqueous-phase oxidation of PAHs. The
462 increasing trends of these ions with ALWC suggest that water-soluble organic species such as
463 carboxylic acids and glyoxal are produced as components of aq-SOA following aromatic
464 oxidation and ring breaking. Moreover, the concentration of PAHs increased with the increase
465 of ALWC (Fig. S11), consistent with the oxidation of PAHs from ring-breaking reactions that
466 can take place in the aqueous phase and being involved in the conversion to aq-SOA.

467 **4. Conclusion**

468 The sources and formation mechanisms of SOA were investigated by online aerosol mass
469 spectrometry and statistical (PMF) analysis from August to September of 2019 in Handan, a
470 mid-sized industrialized city in NCP of China. Four specific SOA factors were resolved,
471 including aq-SOA (15% to total OA), O_x -initiated-SOA (31%), fresh-SOA (18%) and primary-
472 related-SOA (5%). By studying the formation of these SOA factors in different selected periods
473 (P1-P3) against O_x and ALWC, we found multiple pathways leading to their formation,
474 sometimes with mixed pathways for one type of SOA.

475 Both photochemistry and aqueous-phase chemistry resulted in enhanced OA oxidation state.
476 During high- O_x period, photochemistry had imposed significant impacts on the formation and
477 evolution of SOA in summertime. The O_x -initiated-SOA contributed up to 65% to total OA in

478 the daytime, with a high average growth rate of $0.8 \mu\text{g m}^{-3} \text{h}^{-1}$, suggesting the efficient daytime
479 formation of SOA from photochemistry. Rapid increases of the concentration and contribution
480 (up to 61%) of O_x -initiated-SOA were found as O_x increased, while all the other OA factors
481 showed decreasing trends with O_x concentration increasing. The difference suggests enhanced
482 secondary transformation from POA/fresh SOA factors to the more aged O_x -initiated-SOA
483 under high- O_x condition. However, during the high-RH period, two types of aqueous-phase
484 chemistry were both important pathways for the SOA growth. During nighttime and under high-
485 RH conditions, dark aqueous-phase chemistry played significant roles with rapid aq-SOA
486 formation (up to 45% in total OA), while the aqueous-phase photochemistry was more
487 important by rapid O_x -initiated-SOA formation during daytime (up to 39% in total OA). The
488 primary-related-SOA was evidently linked to the POA originated from coal combustion
489 activities, as indicated by the PAH-like ion peaks. Although it constituted a small fraction of
490 5%, the potential transformation and conversion from primary-related-SOA to aq-SOA could
491 also be an important pathway via hydroxylation of the aromatic ring or ring-breaking oxidation
492 of aromatic POA species through aqueous-phase chemistry. This study highlights the multiple
493 reaction pathways, on top of multiple precursor types, on the SOA formation in industrialized
494 regions, and calls form more in-depth study on the interactive roles of those formation pathways.

495

496 **Data availability.** Raw data used in this study are archived at the Institute of Earth Environment,
497 Chinese Academy of Sciences, and are available on request by contacting the corresponding
498 author.

499 **Supplement.** The Supplement related to this article is available online.

500 **Competing interests.** The authors declare that they have no conflict of interest.

501 **Author contributions.** RJH designed the study. Data analysis and source apportionment were
502 done by YFG and RJH. YFG and RJH wrote the manuscript. YFG and RJH interpreted data
503 and prepared display items. All authors commented on and discussed the manuscript.

739

740 **Figures**

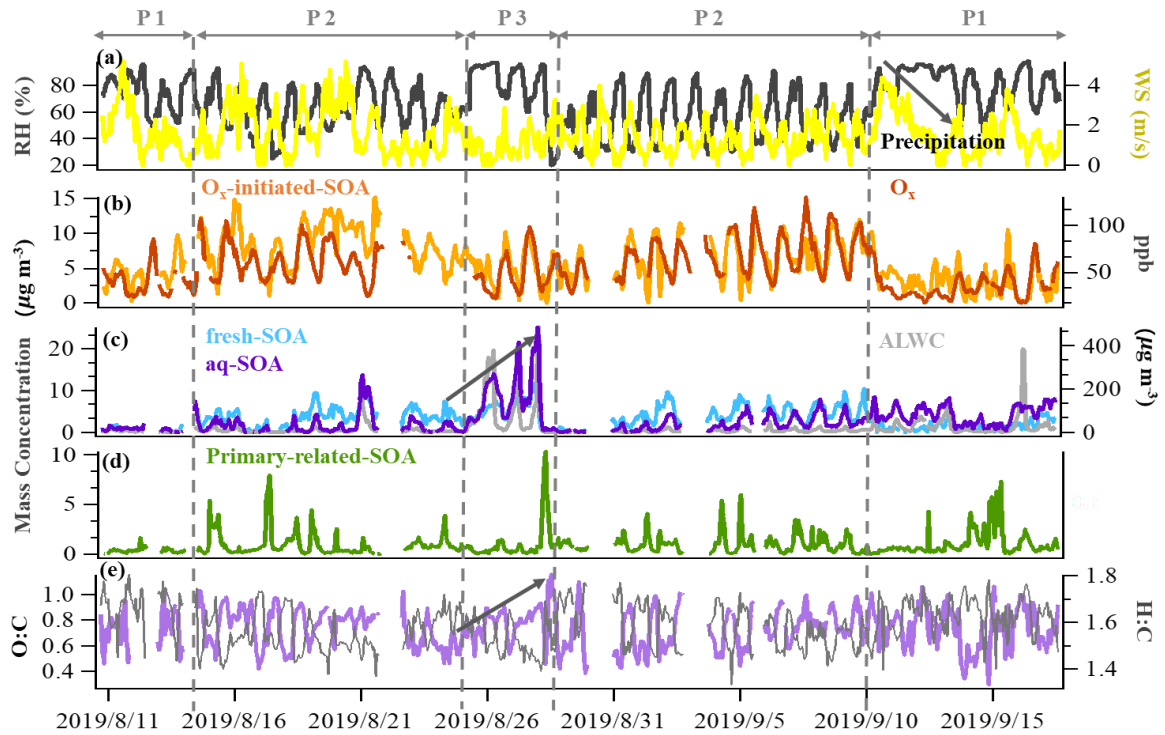

741

742 **Fig. 1** HR and UMR mass spectra of OA factors: (a) HOA; (b) COA; (c) fresh-SOA; (d)
743 primary-related-SOA; (e) O_x-initiated-SOA; (f) aq-SOA. Mass spectra signals less than 120
744 amu are colored by nine ion categories, signals equal to or greater than 120 amu are in unit
745 mass resolution, and polycyclic aromatic hydrocarbons (PAHs) signals are in red on the right
746 panels.

747

748

749

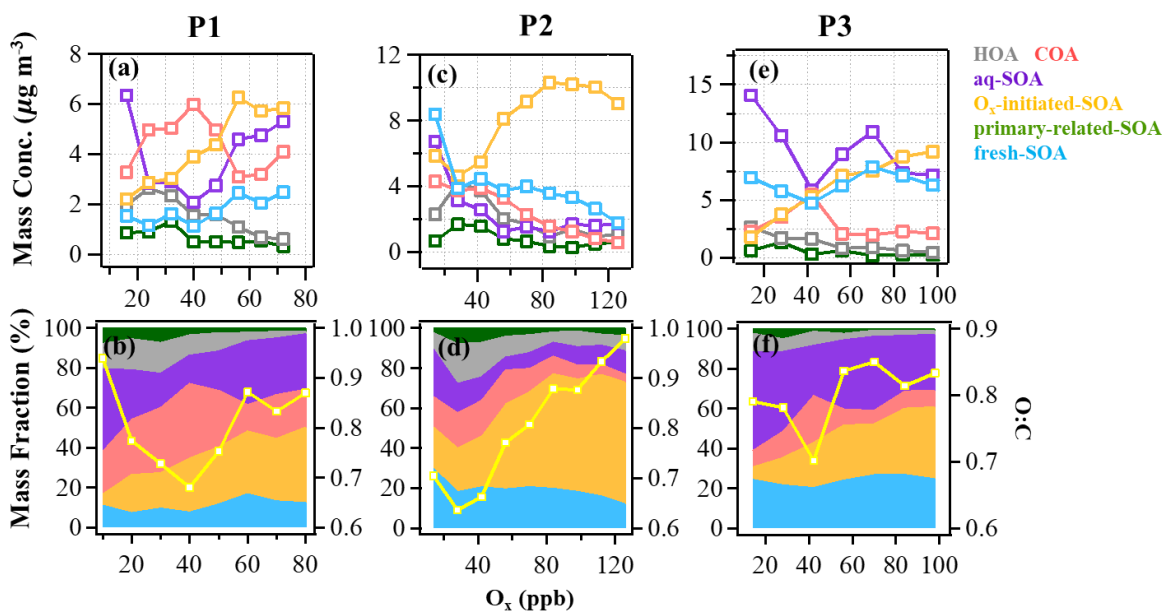

750 **Fig. 2** Time series of (a) relative humidity (RH) and wind speed (WS), (b) O_x and O_x -initiated-
 751 SOA, (c) fresh-SOA, aq-SOA and ALWC, (d) primary-related-SOA, (e) the O:C ratio and H:C
 752 ratio. The time series were categorized to be three typical periods based on total SOA mass
 753 concentrations and meteorology conditions: reference period (P1), high O_x period (P2) and high
 754 RH period (P3).

755

756

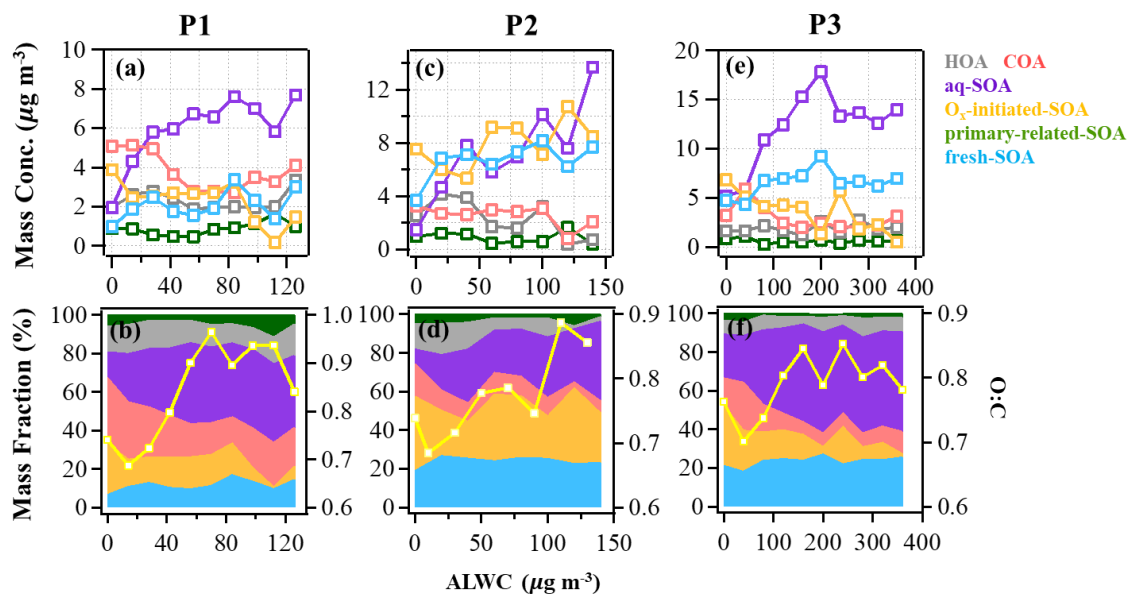

757 **Fig.3** Van Krevelen plot for OA of urban and suburban sites in China and other nations. Data
 758 points are colored by RH (%). P1, P2 and P3 in red circles represents the different periods in
 759 this study. All the data and related references can be found in Table S3.

760

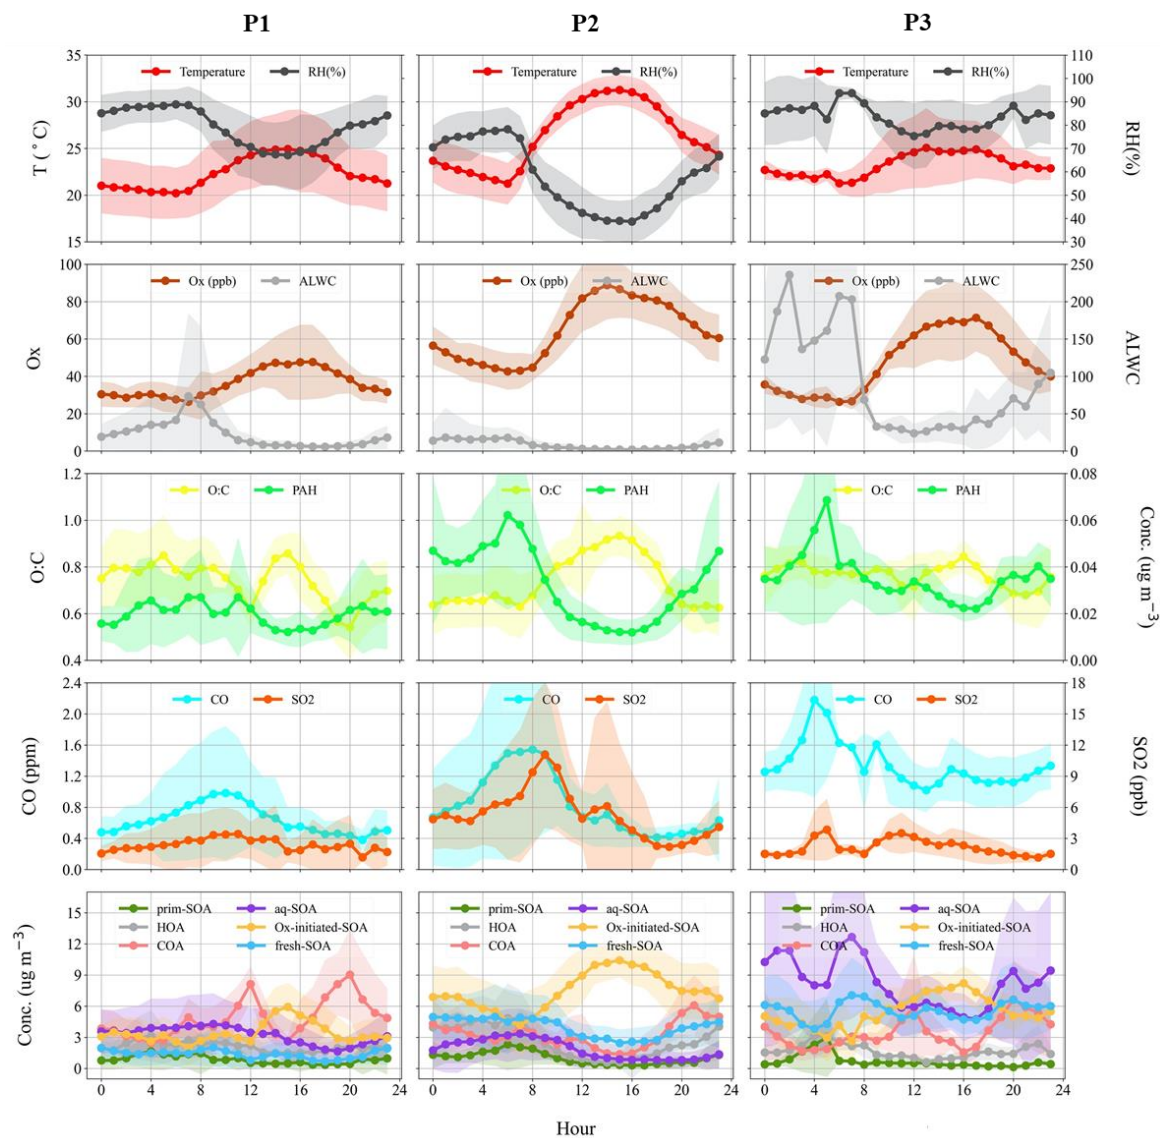

761 **Fig. 4** The mass concentration and contribution of OA factors as functions of O_x in reference
 762 period (P1: a & b), high O_x period (P2: c & d) and high RH period (P3: e & f) during this

763 campaign. The yellow curves represent the O:C ratio vs. O_x . The data were binned according
 764 to O_x concentration (10 ppb increment in P1, 14 ppb increment in P2 and P3).

765

766 **Fig. 5** The mass concentration and contribution of OA factors as functions of ALWC in
 767 reference period (P1: a & b), high O_x period (P2: c & d) and high RH period (P3: e & f) during
 768 this campaign. The yellow curves represent the O:C ratio v.s. ALWC. The data were binned
 769 according to the ALWC concentration ($14 \mu\text{g m}^{-3}$, $20 \mu\text{g m}^{-3}$ and $40 \mu\text{g m}^{-3}$ increment in P1 P2
 770 and in P3).

771

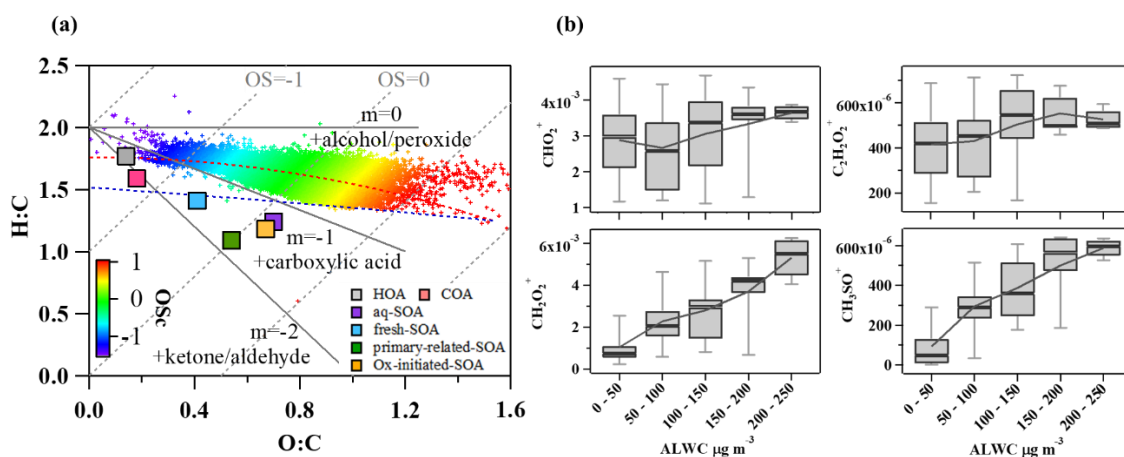

772 **Fig. 6** Diurnal patterns of meteorological parameters (T, RH), gaseous species (O_x, CO, SO₂),
 773 ALWC (liquid water content), O:C (oxygen-to-carbon elemental ratio), polycyclic aromatic
 774 hydrocarbons (PAHs) fragments and OA factors in reference period (P1), high O_x period (P2)
 775 and high RH period (P3) in this campaign.

776

777 **Fig. 7** Evolution of high-resolution organic mass spectra on changes in relative intensities (mass
 778 fraction) of oxygen-containing ions: $C_2H_3O^+$ (m/z 43) and CO_2^+ (m/z 44) in reference period
 779 (P1:a), high O_x period (P2: b) and high RH period (P3: c) in this campaign.

780

781

782 **Fig. 8** (a) Van Krevelen diagram for the O:C and H:C ratios of different OA factors (marked
 783 with squares) and bulk of OA during summer (marked with plus signs and colored by
 784 Oscarbon oxidation state (OSc)); (b) Mass fractions of ion fragments indicative of aqueous-
 785 phase processing and oxygenated functional groups (alcohols, carboxylic acids) as a function
 786 of ALWC.
