Knowledge of the temperature dependent concentration of ice-nucleating particles (INPs) is crucial to understanding the properties of mixed-phase clouds. However, the sources, transport and removal of INPs around the globe, and particularly in the Arctic region, are poorly understood. In the Arctic winter and spring, when many local sources are covered by ice and snow, it is not clear which INP types are important. In this study, we present a new dataset of aircraft-based immersion mode INP measurements and aerosol size-resolved composition in the western North American Arctic from the 11th – 21st March 2018. Aerosol samples were collected between ~70 and 600 m above the surface on filters that were analysed using both a freezing droplet-based assay and Scanning Electron Microscopy with Energy Dispersive Spectroscopy (SEM-EDS). The measured INP concentrations were at or close to the limit of detection, with concentrations at -20°C of 1 L⁻¹ or below. The size-resolved composition measurements indicates that the aerosol concentrations were low, dominated mostly by sea spray aerosol and mineral dust. Further analysis shows that mineral dust is important for the ice-nucleating properties of our samples, dominating over the sea spray aerosol particles in the four cases we analysed, suggesting that mineral dust is a relevant source of INPs in the Alaskan springtime Arctic. Furthermore, the INP concentrations are more consistent with fertile soil dusts that have an ice active biological component than what would be expected for the ice-active mineral K-feldspar alone. While we cannot rule out local high latitude sources of dust, the relatively small size of the mineral dust implies that the dust was from distant sources.

1. Introduction

Clouds containing both supercooled liquid water and ice are known as mixed-phase clouds and they reflect a substantial amount of the incoming solar shortwave radiation that reaches the Earth (Boucher, 2013). The lifetime, as well as the amount of radiation that these clouds reflect, is strongly affected by the partitioning between liquid and ice (Storelvmo et al., 2015). When above temperatures required for homogeneous freezing (below ~-35°C), ice formation in mixed-phase clouds is initiated by the presence of a small fraction of the aerosol particles known as ice-nucleating particles (INPs) (Murray et al., 2012). Once ice crystals nucleate, they can grow more rapidly than liquid cloud droplets since ice has a lower equilibrium vapour pressure than supercooled water. This process can lead to the precipitation of the ice crystals, removing liquid water from a cloud (Korolev et al., 2017; Vergara-Temprado et al., 2018; Hawker et al., 2021). Ice-related processes in mixed-phase clouds such as the primary production of ice and the link to INP concentration are commonly oversimplified in climate models, which contributes to large discrepancies in the amount of water and ice that the models simulate (Komurcu et al., 2014; McCoy et al., 2016; McCoy et al., 2018). The difficulty of properly representing the current

45 water and ice mixing state of these clouds is responsible for the large uncertainty of the cloud-phase
46 feedback (Storelvmo et al., 2015).

47 As the atmosphere warms, mixed-phase clouds will contain more supercooled water leading to a
48 reduction in shortwave radiation reaching the surface, but also decrease the outgoing longwave radiation
49 flux (Ceppi et al., 2017; Murray et al., 2021). Hence, mixed-phase mid- to high-latitude clouds over the
50 ocean have a negative feedback (Tan et al., 2016), whereas clouds over high albedo ice or snow covered
51 surfaces have a positive feedback (Tan et al., 2016). The strength of these feedbacks depends on the
52 balance between ice and supercooled water in these clouds both in the present and future climate. Hence,
53 better understanding the sources and concentrations of atmospheric INPs, particularly at the mid- to
54 high-latitudes could help to reduce the uncertainty associated with cloud feedbacks.

55 Only a small fraction of aerosol particles have the potential to become INPs. Transported dust from the
56 deserts is one of the most important sources of worldwide atmospheric INPs, especially at temperatures
57 below -15°C (Hoose and Mohler, 2012; Vergara-Temprado et al., 2017; Kanji et al., 2017). Given the
58 fact that substantial amounts of dust are transported from the deserts to the Arctic (Fan, 2013; Huang et
59 al., 2015; Francis et al., 2018), this dust could contribute to the INP population of the region (Irish et al.,
60 2019; Yun et al., 2022). Additionally, local sources of high-latitude dust are known to contribute to the
61 dust budget in the Arctic (Bullard et al., 2016; Groot Zwaaftink et al., 2016; Meinander et al., 2022; Shi
62 et al., 2021). Some of these sources of high-latitude dust have been found to contribute to the Arctic
63 INP population (Tobo et al., 2019; Sanchez-Marroquin et al., 2020; Si et al., 2019). A fraction the INP
64 in the Arctic are also of biogenic origin (Wex et al., 2019; Porter et al., 2022), some of which may be
65 associated with biogenic material in sea spray and some of which may be from terrestrial sources
66 (Wilson et al., 2015; DeMott et al., 2016; Vergara-Temprado et al., 2017; Irish et al., 2017; McCluskey et
67 al., 2018; Bigg and Leck, 2001; Creamean et al., 2019; Hartmann et al., 2020; Creamean et al., 2020).
68 Biogenic material attached to dust particles could be an important part of these terrestrial INPs
69 (O'Sullivan et al., 2014; O'Sullivan et al., 2015; Tobo et al., 2019). Other types of aerosol particles such
70 as volcanic ash or biomass burning particles could also contribute to the INP population in the Arctic
71 (Prenni et al., 2009).

72 The available literature data indicates that the INP concentrations in the Arctic are highly variable,
73 depending on the season and location (Murray et al., 2021). Using samples from land-based sites around
74 the Arctic collected over several years, Wex et al. (2019) found that Arctic INP concentrations reach a
75 minimum during winter, but they increase through spring and reach a maximum around the summer,
76 suggesting that concentrations are highest when the transport of aerosol from the low latitudes is at its
77 weakest (the summer). Similarly, year-round measurements in the central Arctic indicate peak
78 concentrations in the summer months of 2020 (Creamean et al., 2022). Creamean et al. (2022) suggested
79 that local Arctic marine sources might contribute to the elevated INP populations in the summer. Porter
80 et al. (2022) also found elevated summertime INP concentration, during August 2018, while in the pack
81 ice near the North Pole. However, in contrast to Creamean et al. (2022), Porter et al. (2022) concluded
82 that these very active INPs were associated with air masses originating from lower latitude ice-free
83 regions along the Russian coast, whereas air masses that had spent the preceding week or so over ice-
84 covered surfaces (in the central Arctic pack ice) had very low INP particle concentrations. The central
85 Arctic in 2018 and 2020 appear to be rather different, with Porter et al. (2022) reporting up to 2 L^{-1} at
86 -15°C in 2018, whereas Creamean et al. (2022) reported two orders of magnitude lower peak INP
87 concentrations in 2020. Hence, there may simply be a great deal of variability and the contrasting
88 conclusions between Porter et al. (2022) and Creamean et al. (2022) may be appropriate for their
89 respective study periods. Creamean et al. (2018) found a similar trend in INP concentrations to Wex et
90 al. (2019) over spring, with coarse particles being responsible for the higher INP concentration event.
91 However, a recent study did not find strong seasonality of Arctic INPs at Ny-Ålesund, although these
92 measurements were limited to being between April and August 2018 (Rinaldi et al., 2021). Furthermore,
93 there have been very few INP measurements from aircraft. Given there are strong aerosol sinks in the

94 boundary layer, whereas the air above the boundary layer can be stratified with corresponding long
95 aerosol lifetimes (Carslaw, 2022), vertical measurements are required. Hartmann et al. (2020) report
96 INP spectra for late March and early April north of 80° over the Fram Strait and Arctic Ocean and report
97 that the highest INP concentrations ($2 \times 10^{-2} \text{ L}^{-1}$ at -15°C) correspond to the boundary layer, indicating
98 a local marine source even though the region was mostly ice covered. Overall, the picture of INP
99 concentrations in the Arctic is that of high variability, both spatially and temporal (on days to years
100 timescales), with the potential for high variability in local sources, transport from lower latitudes as
101 well as in local INP sinks.

102 In this paper, we present a set of immersion mode INP and aerosol size-resolved composition
103 measurements carried out in the western North American Arctic during March 2018 using an aircraft.
104 Our measurements were carried out at different altitudes up to ~ 600 m above sea level both within and
105 above the boundary layer. INP measurements were combined with aerosol characteristics determined
106 using SEM-EDS to indicate the types of INPs that are were most important during this campaign.

107

108 2. Sampling location and methods

109 Aerosol particles were sampled from the UK's BAe-146 FAAM atmospheric research aircraft during
110 the Measurements of Arctic Cloud, Snow and Sea Ice in the Marginal Ice Zone (MACSSIMIZE)
111 campaign, based in Fairbanks, Alaska (US) in March 2018. The majority of the measurements were
112 carried out close to the northern coast of Alaska and the Canadian territory of Yukon, both over land
113 and over the Arctic Ocean, as shown in Fig. 1, [where the flight track corresponding to each sample has](#)
114 [been presented](#). Measurements were carried out at altitudes between 40 and 600 m above sea level, as
115 detailed in Table 1 along with other pertinent information. Some filters were collected in a single run
116 on a constant heading and height, while others were collected over several runs, with the filters system
117 mostly closed during turns between the runs and altitude changes, although this was not possible for all
118 filters. Filters were collected over 9 to 36 minutes, which at a science speed of $\sim 360 \text{ km hr}^{-1}$
119 corresponded to a horizontal distance of between ~ 50 and ~ 200 km. All the sampling was done outside
120 of cloud and precipitation.

121 Aerosol particles were collected using the filter inlet system on board of the FAAM BAe-146, which
122 has been characterised by Sanchez-Marroquin et al. (2019). Briefly, this inlet is located outside the skin
123 of the FAAM BAe-146 and brings aerosol particles to a filter located inside the cabin with a 45° angle
124 bend. The sampling occurs in sub-isokinetic conditions, which enhances coarse mode aerosol particles.
125 Sampling efficiency for particles with diameters above $20 \mu\text{m}$ becomes very small due to inertial losses
126 in the system (at the bend). No treatment (heat or drying) is applied to the sampled air mass, although
127 the cabin was warmer than the ambient air in this campaign and hence the RH of air passing through
128 the inlet system once inside the aircraft is therefore very low. The system allowed us to collect two
129 aerosol samples in parallel: one on a polycarbonate filter (Whatman Nuclepore polycarbonate track-
130 etched filters, 47 mm diameter with a pore size of $0.4 \mu\text{m}$) and one on a Teflon filter (Sartorius
131 polytetrafluoroethylene, 47 mm diameter with a pore size of $0.45 \mu\text{m}$). For these filter types, the particle
132 collection efficiency is likely to be close to 100 % for the relevant size ranges, as discussed in Sanchez-
133 Marroquin et al. (2019) using the data of Soo et al. (2016) and Lindsley (2016).

134 The ice-nucleating particle assay was conducted in a temporary laboratory set up in a hotel room near
135 the aircraft base in Fairbanks, Alaska, with minimum time between sampling and analysis. Most filters
136 were analysed a matter of hours after collection, however where this was not possible they were stored
137 at $\sim -18^\circ\text{C}$ for a few days prior to analysis. This approach has a number of advantages compared to the
138 commonly used strategy of bringing filters back to a laboratory for latter analysis. Firstly, analysis of
139 field blanks can reveal sources of contamination that can be reduced by making adjustments to the
140 experimental protocol; secondly, we can try to adjust the sampling methodology (such as sampling
141 time) to fit the INP concentration and thirdly, we can minimise storage and transport of filters thus
142 reducing potential biases. Teflon filters were used to perform a droplet-on-filter freezing assay to
143 quantify the INP concentration, as described in detail in Price et al. (2018) and also used by Sanchez-
144 Marroquin et al. (2020) and (Sanchez-Marroquin et al., 2021). The technique was first described by
145 Schnell (1982) and our version of this assay makes use of the Asymptote EF600 Stirling cooler
146 described in Whale et al. (2015). For the present study we pipetted $2 \mu\text{L}$ pure water droplets on top of
147 each filter that had been exposed to aerosol particles (or handling blanks). On average, we pipetted 54
148 (with and standard deviation of 5) droplets per filter. The filters were placed on top of a cold stage,
149 within a chamber that is flushed with dry nitrogen gas to prevent water condensation, that is cooled at a
150 constant rate of 1°C min^{-1} until temperatures of $\sim -35^\circ\text{C}$. Droplet freezing was recorded and the resulting
151 videos were manually analysed to determine the fraction of droplets frozen at each temperature and
152 then the INP concentration. At least one handling blank experiment was performed for every flight.
153 Handling blank filters were prepared and transported in the same way as the measurement filters
154 including loading the filters into the sampling system on the aircraft and briefly opening (for a second
155 or so) and closing the inlet valves that allow air to pass through the filters. Hence, the handling blank
156 should provide information on sources of contamination throughout the handling of the filter. A

157 disadvantage of the droplet-on-filter technique is that each sample can only be analysed once, which
158 makes it incompatible with standard heat tests such as the ones described by Daily et al. (2022).
159 However, the great advantage of the droplet-on-filter technique over techniques where particles are
160 washed off a filter into a volume of water is that it is around 20 times more sensitive than a typical
161 wash-off assay employing 1 μL droplets (depending on the details of the freezing assays). This
162 enhanced sensitivity is very important given that aerosol sampling durations are typically only a few
163 tens of minutes long.

164 The droplet fraction frozen (the fraction of droplet that were frozen as a function of temperature)
165 produced by our samples, along with those produced by the handling blank filters, is shown in Fig 2a.
166 While the fraction frozen for the sample filters were generally shifted to warmer temperatures than the
167 handling blanks, many of the samples overlapped with the range defined by the handling blanks. Hence
168 it was necessary to account for influence of the background from the measurements. The background
169 subtraction procedure and the INP concentration calculations are detailed in Appendix A. Briefly, we
170 converted our cumulative fraction frozen values for the samples and handling blanks into the differential
171 INP spectrum, $k(T)$, in units of INP per unit temperature (Vali, 1971;Vali, 2019). k is the number of
172 INP that become active in a temperature interval. This allowed us to define a limit of detection then
173 apply a criterion to separate samples that show a significant signal above this from the ones that do not.
174 Data points whose error bars did not overlap with the error bars associated to the handling blank were
175 considered to be above the limit of detection. The error bars of the differential concentrations of the
176 samples represent a confidence level of 68 % while the error bars of the background represents the
177 standard deviation of all the measured handling blanks. Background-subtraction was applied to data
178 points above the limit of detection ($k_{\text{sample}} - k_{\text{background}}$) using a similar approach to Vali (2019). The
179 cumulative INP spectrum, the common way of presenting INP data, was then derived using the
180 background corrected values of k .

181 A subset of the polycarbonate filters was analysed using Scanning Electron Microscopy with Energy
182 Dispersive Spectroscopy (SEM-EDS) to study aerosol size-resolved composition. The analysis was
183 carried out in the Leeds Electron Microscopy And Spectroscopy centre (LEMAS), at the University of
184 Leeds. Filters were transported to the University of Leeds and then stored at $\sim -18\text{ }^{\circ}\text{C}$ until its analysis.
185 This technique can be used to obtain the morphological and chemical properties of individual aerosol
186 particles within the sample. The subset of samples was coated with a 30 nm layer of Iridium and the
187 SEM-EDS analysis was performed using an accelerating voltage of 20 KeV. The scanning and
188 acquisition of EDS spectrums is done using a semi-automatic method with the Aztec Feature Software
189 by Oxford Instruments. Our method captures the morphology and chemical signature of particles down
190 to 0.2 or 0.3 μm , depending on the sample. Particles are detected based on their contrast in the secondary
191 electron images, although some artefacts were removed manually. Each particle is then classified into
192 a defined composition category based on its chemical composition. The morphological and composition
193 category of each particles is used to obtain statistics about the size-resolved composition of the aerosol
194 samples. A more detailed description of the technique can be found in Sanchez-Marroquin et al. (2019).

195 In parallel with the filters sampling, we make use of FAAM's underwing optical particle counters. One
196 of these counters is the Passive Cavity Aerosol Spectrometer Probe 100-X (PCASP), manufactured by
197 Particle Measurement Systems, and measures aerosol particles in the 0.1 to $\sim 3\text{ }\mu\text{m}$ range. The second
198 counter is the Cloud Droplet Probe (CDP) by Droplet Measurement Technologies and it measures
199 aerosol particles and droplets with sizes from ~ 3 to 50 μm . A detailed description of these instruments
200 and its calibration and can be found in Rosenberg et al. (2012).

201 The Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) model was used to calculate
202 five day back trajectories of sampled air masses (Stein et al., 2015;Rolph et al., 2017) and shown in
203 Sect S1. The back trajectories show that in many cases air masses remained near or over Alaska and
204 northern Canada before sampling. However, the backtrajectories corresponding to the C085 flight

205 arrived mostly from the south west. Most of the trajectories suggest that the air mostly stayed at altitudes
206 below 1000 m above sea level in the five days prior to sampling. At the time of sampling, most of the
207 sea and land surfaces were covered by sea ice or snow (Fig. 1), which most likely suppressed any local
208 aerosol sources. However, local sources of marine aerosol particles may still occur due to open leads
209 (May et al., 2016; Kirpes et al., 2019; Chen et al., 2022).

210

211 3. INP concentrations in the western North American Arctic

212 The background corrected cumulative INP concentrations are shown in Fig 2b. Hollow markers indicate
213 measurements consistent with the limit of detection, where the lower error bar goes to zero, while filled
214 markers correspond to a cumulative INP concentration above the limit of detection. Using a 68 %
215 confidence interval, approximately 70 % of the differential spectra binned data was not significantly
216 above the limit of detection and around half of the data points in the cumulative INP spectra shown in
217 Fig. 2b show INP concentrations consistent with zero (i.e. not above the detection limit). The reported
218 INP concentrations are always below 0.1 and 1 L⁻¹ at -15 °C and -20 °C, respectively. However, given
219 the fact that a substantial percentage of the data is not above the detection limit, the real values of some
220 of these samples may be well below these values. A daily, more detailed representation of the INP
221 concentrations is shown in Fig. B3.

222 INP concentrations across the Arctic vary significantly depending on the time of the year and location
223 (Creamean et al., 2018; Si et al., 2019; Wex et al., 2019). Hence, in order to compare to the pertinent
224 data we show our INP concentrations alongside literature data collected in a similar location and time
225 of the year in Fig. 3a (we restricted the literature datasets from February to April). Some of our reported
226 INP concentrations are above some of the values measured using a droplet freezing assay on filters
227 collected the surface by Creamean et al. (2018) and Wex et al. (2019) as well as filters collected on an
228 aircraft and processed using a dynamic developing chamber at water saturation by Borys (1989).
229 Creamean et al. (2018) reported INP concentrations at -25 °C up to 0.1 L⁻¹ on the north coast of Alaska
230 in March. Measurements performed by Wex et al. (2019) in a close location (Utqiagvik) indicate that
231 INP concentrations ranging from ~10⁻⁴ to 10⁻² L⁻¹ at -10 °C in March. The more active samples reported
232 by Wex et al. (2019) form a consistent INP spectrum with our more active samples, but unfortunately
233 there is no direct overlap. Borys (1989) reported INP concentrations of 0.001 L⁻¹ to 0.3 L⁻¹ at -25 °C
234 measured from an aircraft at a similar location and time of the year. These values are of course consistent
235 with our samples where we report upper limits, but some of our samples clearly had substantially higher
236 INP concentrations than the range reported by Borys (1989). Hiranuma et al. (2013) also report INP
237 measurements using an airborne continuous flow diffusion chamber (CFDC) during the Indirect and
238 Semi-Direct Aerosol Campaign (ISDAC) in a very similar study region to ours, but in April rather than
239 March. We have only compared our measurements with theirs at water saturation, which happened to
240 be during a relatively high INP period. This INP value of 5.6 ± 3.5 L⁻¹ at -22°C is consistent with our
241 highest recorded INP concentrations. Overall, this comparison with measurements in previous years at
242 a similar location and time of year indicates that the INP concentrations are rather variable, ranging
243 over at least three orders of magnitude at -20°C.

244 Our measurements have also been presented alongside a compilation of INP measurements from across
245 the Arctic carried out throughout the year (Fig 3b). Our dataset is well within the range of literature INP
246 measurements from across the Arctic. Around 50% of our data points were below detection limit (and
247 not shown in Fig. 3), hence we are only able to report INP concentrations when their values are
248 relatively high. The picture that emerges in the Arctic is a region of highly variable INP concentrations,
249 where INP concentrations vary spatially as well as temporally (seasonally as well as on shorter time
250 scales). This variability is likely related to a combination of transport from local and remote sources of
251 INP as well as sinks both locally and along those transport routes. This high variability in INP
252 concentrations will affect primary ice production in clouds, with more INP leading to greater ice

253 concentrations that may or may not be amplified by secondary production processes. Intriguingly,
254 several authors report that greater INP concentrations leads to more ice in Arctic cloud and vice versa
255 (Rogers et al., 2001;Hiranuma et al., 2013).

256 A handful of measurements of INP have been made from aircraft (Hartmann et al., 2020;Sanchez-
257 Marroquin et al., 2020;Prenni et al., 2009;Hiranuma et al., 2013) and it is these measurements that
258 produce many of the highest observed Arctic INP concentrations, rather than those made on the ground.
259 However, aircraft sampling is often limited by the volume of air that can be sampled due to restrictions
260 in flight lengths and other technical limitations. This necessarily biases the results to relatively high INP
261 concentrations. For example, (Rogers et al., 2001) report that 50% of the 10 s averaged data was zero
262 (i.e. below detection limit). Given the Arctic atmosphere is highly stratified, it would be interesting to
263 perform simultaneous measurements at the surface and from an aircraft to explore how or if INP at the
264 surface are related to those higher in the boundary layer and those in the free troposphere.

265

266 **4. SEM-EDS size-resolved composition analysis**

267 The equivalent circular diameter size distributions obtained with the SEM-EDS technique were
268 compared with the average size distributions for the same sampling periods measured using the
269 underwing optical particle counters on-board of the FAAM BAe-146. The analysis is shown in Fig. 4
270 alongside the size-resolved chemical composition of the analysed samples. The number size distribution
271 is multiplied by the fraction of particles in each category and binned to calculate the number size
272 distribution of each category. Then these number size distributions are turned into surface area size
273 distributions and integrated to obtain the surface area of each category, as shown in Table 2.

274 The analysed samples exhibited low aerosol concentrations relative to other locations where we have
275 used this technique, especially for the coarse mode. In this study, almost no particles above 10 μm were
276 detected, in contrast to samples from around Iceland, the eastern tropical Atlantic and the south east of
277 the United Kingdom analysed using the same or similar technique, where significant amounts of
278 aerosols in between 10 and 20 μm were detected (Price et al., 2018;Sanchez-Marroquin et al.,
279 2019;Sanchez-Marroquin et al., 2020;Sanchez-Marroquin et al., 2021). Most of the detected particles
280 were below $\sim 2 \mu\text{m}$. At sizes below $\sim 3 \mu\text{m}$, the comparison between the optical probes and the SEM-
281 EDS size distributions are consistent in most cases, with an undercounting at the lower end of the SEM-
282 EDS technique ($\sim 0.3 \mu\text{m}$). This undercounting is related to the difficulty in observing small organic rich
283 particles and has been discussed in Sanchez-Marroquin et al. (2019). At sizes above $\sim 3 \mu\text{m}$, the optical
284 probes and SEM-EDS size distributions showed a comparable amount of detected particles in samples
285 C089_3 and C090_1. However, for samples C087_1 and C091_2, the optical counters detected a larger
286 concentration of particles with sizes ~ 5 to 10 μm than the SEM analysis of the filters. Similar
287 discrepancies have been observed previously with these instruments in another low aerosol environment
288 (Young et al., 2016), and were attributed to regions of high humidity even if the average humidity in a
289 run should not have led to substantial hygroscopic growth. In dust plumes near Iceland and in aerosol
290 around the UK where there was a significant coarse mode the agreement between CDP and SEM tended
291 to be good. We note CDP is designed for cloud droplets, and we are using it at the edge of its capability
292 for larger aerosol particles, hence there may be some biases which seem more significant in low aerosol
293 environments.

294 In terms of chemical composition, the samples were mainly dominated by sea spray (Na rich) and
295 mineral dust (Si rich, Si only, Al-Si rich and Ca rich) particles. There were some smaller contributions
296 of S rich particles (likely sulphates) and Carbonaceous particles (likely black carbon or organic
297 material). This is consistent with other SEM-EDS studies of the aerosol samples collected on the
298 Alaskan Arctic from the ground (Chen et al., 2022;Creamean et al., 2018;Kirpes et al., 2018;Gunsch et
299 al., 2017) or during a ship campaign (Kirpes et al., 2020). However, we tend to observe larger fractions

300 of dust aerosol particles, particularly in the sample C090_1, where this type of aerosol constituted ~65
301 % of the surface area of the sample.

302 In this dataset, nearly all particles in the Na rich category were dominated by the presence of Na and
303 Cl, having traces of other elements (such as S in some occasions), consistent with sea spray particles.
304 As a consequence, we will refer to particles in this category as sea spray aerosol particles. Some
305 carbonaceous particles were also detected through most sizes and there were significant contributions
306 of S rich aerosol, particularly in the accumulation mode. As shown in Fig. 4 and Table 2, the surface
307 area of samples C087_1 and C091_2 were dominated by sea spray aerosol particles with sizes around
308 ~ 1 μm . In Sect. S1 it is shown that most of the air masses associated with these samples had been
309 circulating above the Arctic Ocean at relatively low altitude (below 1000 m) before sampling took place.
310 This is consistent with the fact that sea spray aerosol particles are normally emitted by bubble bursting
311 in the surface of the oceans (Lewis and Schwartz, 2004). It is possible that the detected sea spray aerosol
312 in our study was transported from ice free oceans. However, Sect. S1 indicates that the closest ocean
313 masses were almost fully covered by sea ice (with some open leads) during the campaign and the
314 majority of the sampled air masses did not pass by the open oceans prior to sampling. Hence, it is
315 possible that the sea spray particles had been emitted from open leads in the sea ice, as this is thought
316 to be a source of sea spray aerosol in the region (May et al., 2016;Kirpes et al., 2019;Chen et al., 2022).
317 It is also possible that some of the sea spray aerosol has been directly emitted from the sea ice through
318 blowing snow events (Yang et al., 2008;Huang and Jaeglé, 2017;Frey et al., 2020).

319 Particles in the categories Si rich, Si only, Al-Si rich and Ca rich have a chemical composition consistent
320 with mineral dust particles so we will refer to them collectively as mineral dust. However, it should be
321 borne in mind that the composition of particles in these categories is also consistent with some types of
322 combustion ashes or volcanic ash. Mineral dust particles were present in all the samples, particularly
323 with sizes between 1 and 5 μm , constituting a substantial percentage of its surface area, as shown in
324 Table 2. This was particularly the case in the sample C090_1, where 65 % of the surface area was given
325 by mineral dust particles. Although we cannot fully determine the relative contribution of different
326 sources to the detected mineral dust, several arguments suggest that the sampled mineral dust originated
327 from the low latitude deserts. The back trajectory analysis shown in Sect. S1 suggests that most of the
328 air masses had been circulating around the sampling location prior to sampling for ~5 days. However,
329 the majority of the potential high-latitude dust sources were covered by snow at this time, so it seems
330 unlikely that this mineral dust is related to natural emissions, although we cannot rule out sources
331 associated with human activities along the coast (e.g. Purdue Bay oil fields). Mineral dust originating
332 from the Sahara and Central Asia is known to be transported to the Arctic, especially in late winter and
333 early spring, when this study took place (VanCuren et al., 2012;Fan, 2013;Huang et al., 2015;Francis
334 et al., 2018;Shi et al., 2022;Zhao et al., 2022). This is consistent with the some of the backtrajectories
335 associated to the samples collected on the C085 flight, which originate from Asia. Almost all the mineral
336 dust particles found in this study had sizes below 5 μm and it is known that dust particles have a lifetime
337 of many days so can conceivably be transported to Alaska from distant sources (Huneeus et al.,
338 2011;Ménégoz et al., 2012). Once in the Arctic, accumulation mode aerosol has a lifetime extending to
339 months during winter and spring, when removal processes are weak (Carslaw, 2022). The small sizes
340 of dust particles found in this campaign contrast with results obtained using similar techniques on
341 samples collected closer to dust sources, where dust particles with sizes above 10 μm are frequent (Price
342 et al., 2018;Ryder et al., 2018;Sanchez-Marroquin et al., 2020). Although this evidence suggests that
343 most of our dust likely originated in arid lower-latitude deserts, high-latitude dust could still contribute
344 to the dust budget or even dominate it during other times of the year such as autumn (Groot Zwaafink
345 et al., 2016;Shi et al., 2022).

346 As shown in Table 2, C087_1 and C091_2 samples have a larger surface area of sea spray aerosol
347 particles (Na rich) than mineral dust, whereas sample C090_1 is dominated by the presence of mineral
348 dust. Hence, it is reasonable to ask if the mineral dust or organic material associated with sea spray is

349 the more important INP type in these samples. To estimate the relative contribution of mineral dust and
350 sea spray aerosol to the INP population, we present the expected INP concentrations based on the SEM-
351 EDS surface areas in Fig. 5, in comparison with the measured INP concentrations. The INP
352 concentrations expected from the SEM-EDS analysis were calculated assuming a dust containing 10 %
353 of K-feldspar (Harrison et al., 2019) (the ice active component of desert dust) and the parametrization
354 of fertile soils given by O'Sullivan et al. (2014). Note that the latter is very similar to the desert dust
355 parameterization given by Ullrich et al. (2017). For the pristine sea spray INP, the parametrization given
356 by McCluskey et al. (2018) that links INP concentration and aerosol surface area has been used. As
357 shown, even in the cases where there is more sea spray aerosol than mineral dust (C087_1 and C091_2),
358 the minimum contribution of mineral dust INP is orders of magnitude above the INPs produced by the
359 pristine sea spray aerosol particles. It is possible that the sea spray in this location was more active than
360 defined by McCluskey et al. (2018), however, the INP concentrations calculated based on the presence
361 of dusts better explains the observed INP concentrations measured using the droplet freezing assay at
362 the lower end of the temperature spectrum. At the higher end of the temperature spectrum, the measured
363 INP concentrations are above those expected from a 10 % K-feldspar dust, but are consistent with the
364 fertile soil dust parameterisation. It is known that fertile soil dusts contain biological ice nucleating
365 material (O'Sullivan et al., 2014), hence this suggests that the samples from Alaska contained some
366 biological ice nucleating material (either from marine or terrestrial sources). Although our INP
367 concentrations would also be comparable with those predicted using the desert dust parameterization
368 by Ullrich et al. (2017), the latter is usually higher than the activity of samples of airborne desert dust
369 at temperatures greater than about -20°C from other studies (Boose et al., 2016; Price et al.,
370 2018; Harrison et al., 2022; Reicher et al., 2018; Gong et al., 2020). It has been suggested that dust that
371 has been transported far from its source regions is less active than arid soil dusts that have been recently
372 aerosolised and also there appears to be substantial differences in activity of dust from different source
373 regions (Boose et al., 2016; Harrison et al., 2022). Hence, we suggest that the enhanced ice-nucleation
374 ability of our samples is perhaps due to the presence of biological material. This is consistent with other
375 studies that also provided evidence that Arctic INP samples have a substantial biological component
376 (Wex et al., 2019; Creamean et al., 2019; Santl-Temkiv et al., 2019; Porter et al., 2022).

377

378 5. Conclusions

379 In this study, we present a new dataset of INP and SEM-EDS aerosol size-resolved composition
380 measurements in the western North American Arctic in March 2018. Back trajectory analysis suggests
381 that most of these air masses spend the preceding five days circulating over or near Alaska and Northern
382 Canada where local sources of primary aerosol were suppressed by snow and ice cover. Observed INP
383 concentrations were at or close to the limit of detection of the measuring technique, being always below
384 0.1 and 1 L^{-1} at -15°C and -20°C respectively. SEM-EDS analysis revealed that samples are mostly
385 dominated by the presence of mineral dust and sea spray aerosol particles, with some contributions of
386 sulphur rich and carbonaceous particles. The mineral dust is most likely sourced from the low-latitudes,
387 rather than local high-latitude dust sources. Our analysis shows that mineral dust contributes more to
388 the INP population than sea spray, despite sea spray being more abundant in some samples. However,
389 it appears that the ice-active mineral K-Feldspar cannot account for all of the observed INPs, especially
390 above $\sim -22^{\circ}\text{C}$. This suggests that there is another INP type that controls the INP spectrum above -22°C ;
391 these particles may be biogenic in origin, but where this biogenic ice nucleating material might be
392 derived from is unclear. More work is clearly required to understand the sources and nature of INP in
393 the winter and early springtime Arctic.

394 **Acknowledgments**

395 We are grateful to all the people involved in the MACSSIMIZE campaign, led by Chawn Harlow (UK
396 Met Office). The samples were collected using the FAAM BAe-146-301 Atmospheric Research
397 Aircraft, flown by Airtask Ltd., maintained by Avalon Aero Ltd., and managed by FAAM Airborne
398 Laboratory, jointly operated by UKRI and the University of Leeds. We acknowledge the Centre for
399 Environmental Data Analysis for the access to the FAAM datasets used here. We would also like to
400 thank Duncan Hedges and Richard Walshlaw at the Leeds Electron Microscopy and Spectroscopy
401 Centre.

402

403 **Author contributions**

404 Aerosol measurements during the MACSSIMIZE campaign were organised by ASM, JBM, and BJM.
405 ASM and BJM worked on the manuscript with contributions from all authors. The field work was
406 carried out by ASM and JBM. ASM performed all the experimental measurements (INP analysis and
407 SEM-EDS). The SEM-EDS technique was developed by ASM and ITB. The back-trajectory analysis
408 was carried out by SLB and ASM. All the authors contributed to the discussion.

409

410 **Financial support**

411 This research has been supported by the European Research Council (MarineIce (grant no. 648661))
412 and the Natural Environment Research Council (NE/R006687/1, NE/T00648X/1).

413

414 **Competing interests**

415 The authors declare that they have no competing interests.

416

417 **Data and materials availability**

418 All data needed to evaluate the conclusions in the paper are present in the paper and/or the
419 Supplementary Materials. The digitalized data are available from Alberto Sanchez-Marroquin and
420 Benjamin J. Murray (2023): Data for 'Aircraft ice-nucleating particle and aerosol composition
421 measurements in the western North American Arctic'. [Dataset]. <https://doi.org/10.5518/1401>. FAAM
422 data associated to each of the flights can be found in: Facility for Airborne Atmospheric Measurements;
423 Natural Environment Research Council; Met Office (2018): FAAM C085 MACSSIMIZE flight:
424 Airborne atmospheric measurements from core and non-core instrument suites on board the BAE-146
425 aircraft. Centre for Environmental Data Analysis.
426 <https://catalogue.ceda.ac.uk/uuid/b04281cc10c44d9dab1eb2e4eb19d5b8> (and similar for the other

430 Table 1. Details of the samples collected during the MACSSIMIZE campaign. PTFE position
431 refers to which inlet was used to collect the PTFE sample in each run. The other line was used
432 to collect the polycarbonate sample. In order to determine if the sample was collected within
433 the boundary layer (BL) or in the Free Troposphere (FT), we looked at the temperature and
434 potential temperature profiles. (*) For all the runs in the C089, C090 and C091, the flight did
435 not descend low enough to determine the exact depth of the BL. Hence, it was assumed that
436 the runs occurred above the BL. Stored filters were kept for a few hours or days at -18 °C,
437 while the rest of them were analysed immediately after collection without any long-term
438 storage. The given altitude values correspond to the average of each run. The mean values of
439 the air temperature across the run was derived from the Rosemount de-iced temperature
440 sensor, while the dew temperature is given by the Buck CR2 Hygrometer of the BAe-146.
441 Dew temperature could not be calculated for all runs due to technical problems. The aerosol
442 number concentration corresponds to the range of ~0.1 to ~3 µm and it has been calculated
443 using the PCASP instrument. Blank entries correspond to a filter that was not collected or the
444 instruments not working.

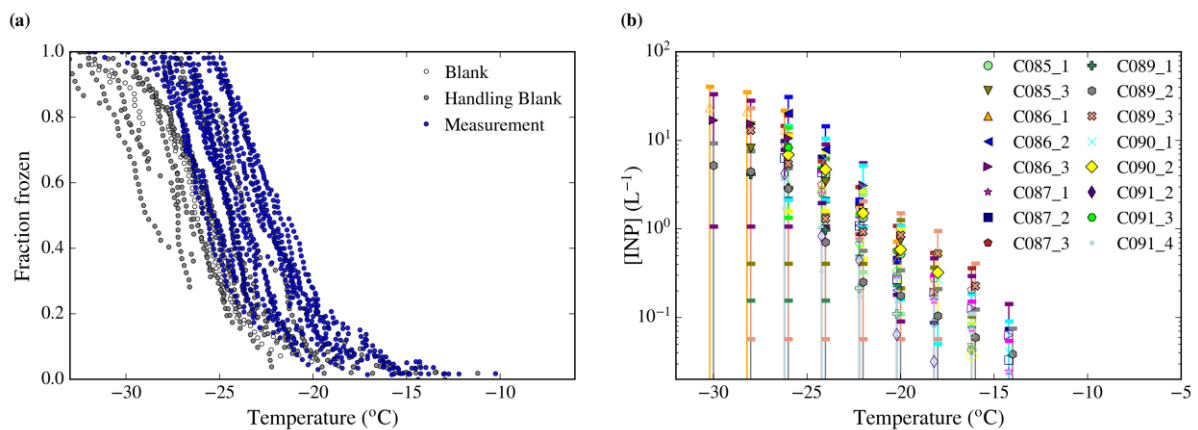

445

446

447 Figure 1. Flight tracks of the samples collected in this study and described in Table 1 (top panel). GPS
 448 altitude at which the samples were collected (lower panel). The altitude is presented against the GTM
 449 time at which the samples were collected (although they were collected across several days).

450

451

452 Figure 2. (a) Fraction of droplets frozen for all filter samples as well as blanks and handling blanks. (b)
 453 INP particle concentrations for each filter sample. Data points corresponding to the upper limits (open
 454 symbols) have been shifted 0.2 °C along the x-axis for clarity. The way in which the INP concentrations,
 455 upper limits and its uncertainties have been calculated are shown in Appendix A. The criteria to
 456 determine if a measurement is above the limit of detection is based on 68% confidence intervals.

457

459

460

461 Figure 3. INP concentrations from the present study compared with literature data. We only show our
 462 data that was above the background (limiting values are included in Figure 2). Note that this data is
 463 above the limit of detection based on 68% confidence intervals. The left panel is limited to a comparison
 464 with previous measurements at nearby locations at a similar time of year (February, March and April)
 465 (Borys, 1989;Creamean et al., 2018;Wex et al., 2019;Hiranuma et al., 2013). We also limit this
 466 comparison to data recorded at or above water saturation, which limits the data from Hiranuma et al.
 467 (2013) to a single point during what they describe as a relatively high INP concentration event. Note
 468 that for the dataset of Wex et al. (2019), the concentrations increased through this period with the two
 469 highest INP spectra from April. The right hand figure is a comparison with Arctic data in general, from
 470 any time of the year and any location (Flyger and Heidam, 1978;Borys, 1989;Bigg, 1996;Rogers et al.,
 471 2001;Bigg and Leck, 2001;Prezzi et al., 2007;Hiranuma et al., 2013;Conen et al., 2016;DeMott et al.,
 472 2016;Mason et al., 2016;Creamean et al., 2018;Wex et al., 2019;Creamean et al., 2019;Irish et al.,
 473 2019;Si et al., 2019;Porter et al., 2020;Sanchez-Marroquin et al., 2020;Welti et al., 2020;Hartmann et
 474 al., 2020;Hartmann et al., 2021;Porter et al., 2022). The mid-latitude data range given by Petters and
 475 Wright (2015) is also shown.

 484 composition fractions (right).

485

Sample	Dust area ($\mu\text{m}^2/\text{cm}^3$)	Dust limit of detection ($\mu\text{m}^2/\text{cm}^3$)	Dust area percentage	Sea spray aerosol area ($\mu\text{m}^2/\text{cm}^3$)	Sea spray area percentage
C087_1	0.75	0.042	13.9	3.97	73.4
C089_3	0.57	0.15	38.1	0.26	17.1
C090_1	1.21	0.083	65.5	0.16	8.9
C091_2	0.53	0.051	11.3	2.79	59.5

486

487 Table 2. Surface area of dust and sea spray aerosol from SEM-EDS analysis. The dust limit of detection
 488 corresponds to the upper limit of the dust concentration detected on the handling blank filter based on
 489 one standard deviation. Note that the given dust and sea spray aerosol percentages refer to surface area
 490 percentages. The limit of detection of sea spray aerosol particles has not been indicated because the
 491 presence of this type of particles in the handling blank is negligible. Further information on the size-
 492 resolved composition of the handling blanks and a discussion about it can be found in (Sanchez-
 493 Marroquin et al., 2019).

494

495

496 Figure 5. Predicted INP concentration of the SEM-EDS samples compared with the INP measurements
 497 at $-20\text{ }^{\circ}\text{C}$. The dust INP prediction has been calculated by applying different ice-nucleation
 498 parametrizations to the surface area of dust calculated from the SEM-EDS analysis. The O'Sullivan et
 499 al. (2014) for fertile soils and a dust containing 10 % of K-Feldspar (Harrison et al., 2019) have been
 500 used. The NaCl INP prediction has been obtained by applying the sea spray aerosol parametrization

501 from McCluskey et al. (2018) to the SEM-EDS sea spray aerosol surface area. The purple points
502 correspond to our INP measurements or upper limits, based on 68% confidence intervals (Appendix A).

503

504 **Appendix A: Upper limit determination and background subtraction of the ice-nucleation** 505 **experiments**

506 As shown in Fig. 2a, most of the fraction of droplets frozen produced by the collected samples were
507 comparable or only slightly above to the ones produced by the handling blanks. Hence, we established
508 criteria to separate data points of the INP spectrum that are not significantly above the limit of detection
509 of the instrument. The analysis is performed using the differential spectrum of ice-nucleus rather than
510 the cumulative spectrum, which is normally used to display and compare ice-nucleation data such as
511 INP concentrations and densities of active sites (Vali, 1971;Vali, 2019). First, we create a histogram
512 with the number of freezing events per temperature interval per sample. This is done for all the samples
513 and handling blanks, with temperature intervals of 2 °C. We transform the number of freezing events
514 per interval of each sample into the differential INP spectrum, $k(T)$, using Eq. 1 (Vali, 2019).

$$k(T) = -\frac{1}{V\Delta T} \ln\left(1 - \frac{\Delta N}{N(T)}\right) \quad \text{Eq. 1}$$

515 In Eq. 1, V is the droplet volume, ΔT is the temperature interval, ΔN is the number of frozen droplets
516 between T and $(T-\Delta T)$, and $N(T)$ is the number of unfrozen droplets at T . The $k(T)$ values of the handling
517 blanks is shown in Fig B1, alongside the mean value of each interval and its standard deviation. Note
518 that many of the temperature intervals had zero freezing events, corresponding to k equal to zero. These
519 zero values cannot be seen in Fig. B1 but they have been included in the means and standard deviations.
520 The mean and standard deviation of the k values produced by each handling blank has been compared
521 with the k values corresponding to each sample. The uncertainty in the k values associated with each
522 sample has been calculated using a very similar Monte Carlo simulation as used previously (Vali, 2019)
523 using a 68 % interval. The k values associated to each sample were individually compared with the
524 mean and standard deviation of the k values of the handling blanks. A data point was considered above
525 the limit of detection when its lower error yields above the mean plus standard deviation of the blanks.
526 Background subtraction was applied to data points significantly above the limit of detection. This was
527 done by subtracting the mean of the k values of the handling blanks. The error of the background-
528 subtracted point was calculated by square rooting the quadratic sum of the error of the k_{sample} and
529 $k_{\text{background}}$. Two examples of the comparisons between samples and the handling blanks are shown in
530 Fig. B2. (a) corresponds to a case where no data point was higher than the limit of detection, while (b)
531 corresponds to a case where most of the data points were significantly above the limit of detection. Note
532 that all the data measured on the 16th of March (flight C087) has been flagged as an upper limit. This is
533 because the handling blank experiment carried out on that day was unusually high, being compatible
534 with all the measurements.

535 The background corrected $k(T)$ was integrated into the cumulative spectrum of active sites, $K(T)$, using
536 Eq. 2 (Vali, 1971;Vali, 2019).

$$K(T) = \sum_{T=0}^T k(T) \Delta T \quad \text{Eq. 2}$$

537 INP concentrations were calculated from , $K(T)$ using Eq. 3, where V_d is the droplet volume, A_{fit} is the
538 area of the filter, V_a is the sampled air volume and α is the contact surface of the droplets. For this study,
539 we used the same values than Sanchez-Marroquin et al. (2021).

$$INP(T) = \frac{K(T)V_D A_{fil}}{V_a \alpha} \quad \text{Eq. 3}$$

540 A k value which was not significantly above the limit of detection has been represented with lower bars
 541 going to zero in the INP spectrum (meaning upper limit to the INP concentration). However, if a k value
 542 not significantly above the limit of detection was preceded by a value which was above the limit of
 543 detection, then as a result of the cumulative nature of the reported INP concentration the corresponding
 544 value is reported with a filled symbol, but the lower bound of the error bar does not change since it is
 545 possible that no new INP were present in that temperature interval. In Fig B3 one can see the INP
 546 concentration of all the samples collected in this study per each day.

547

548

549 Figure B1. Differential spectrum of ice-nucleus of all the handling blanks performed during this
 550 campaign. Data is shown in blue, while the mean and standard deviation of the data of each bin
 551 show in green.

552

553

554

555 Figure B2. Examples of a comparison between the handling blank mean with two samples. None of the
 556 data points of sample C086_1 is significantly above the background. However, most of the data points
 557 associated with sample C090_2 are more than one error bar above the data produced by the handling
 558 blanks and they have been background-subtracted.
