Abstract

Although many considerable efforts have been done to reveal the driving factors on haze aggravation, however, the roles of aerosol liquid water (ALW) in SIAs formation were mainly focused on the condition of aerosol liquid water content (ALWC)<100 μg/m³. Based on the in-situ high-resolution field observation, this work studied the decisive roles and the shifting of secondary inorganic aerosols formation mechanism during haze aggravation, revealing the different roles of ALWC in a broader scale (~ 500 μg/m³) in nitrate and sulfate formation induced by aqueous chemistry in ammonia-rich atmosphere. The results showed that chemical domains of perturbation gas limiting the generation of secondary particulate matters presented obvious shifts from HNO3 sensitive to HNO3 and NH3 co-sensitive regime with the haze aggravation, indicating the powerful driving effects of ammonia in ammonia-rich atmosphere. When ALWC<75 μg/m³, the sulfate generation was preferentially triggered by the high ammonia utilization, then accelerated by nitrogen oxide oxidation from Clean to Moderate pollution stages, characterizing as nitrogen oxidation ratio (NOR)<0.3, sulfur oxidation ratio (SOR)<0.4, ammonia transition ratio (NTR)<0.7 and the moral ratio of NO₃-/SO₄²-=2:1. While ALWC>75 μg/m³, aqueous-phase chemistry reaction of SO₂ and NH₃ in ALW became the prerequisite for SIAs formation driven by Henry's law in the ammonia-rich atmosphere during Heavy and Serious stages, characterizing as high SOR (0.5-0.9), NOR (0.3-0.5), NTR (>0.7) and the moral ratio of NO₃-/SO₄²-=1:1. A positive feedback of sulfate on nitrate production was also observed in this work due to the shift of ammonia partition induced by the ALWC variation during haze aggravation. It implies the target controlling of haze should not simply focus on SO2 and NO2, more attention should be paid on gaseous precursors (e.g., SO₂, NO₂, NH₃) and aerosol chemical constitution during different haze stages.

Fine particulate matter (PM_{2.5}) presented close link with several environmental issues, such as 36 visibility reduction and climate change (Zhang et al., 2015; Shang et al., 2020; Wang et al., 37 2020; Wang et al., 2016; Nozière et al., 2010). Epidemiological studies have stated the 38 association of PMs with various public health, even adverse birth outcomes (Gwynn et al., 39 40 2000; Lavigne et al., 2016; Zhao et al., 2020). As the most abundant secondary inorganic aerosols (SIAs) in PM_{2.5} during Chinese winter haze episodes (Fu and Chen, 2017; Liu et al., 41 2019), the formations of sulfate and nitrate play the key roles during haze aggravation, as well 42 as the impacting factors of the oxidants in gas and aqueous phases, the characteristics of pre-43 existing aerosols/fog/cloud, and meteorological conditions. Recently, aerosol liquid water 44 content (ALWC) was reported associating with the SIAs formation, especially sulfates and 45 46 nitrates, during the haze periods (Wu et al., 2018; Zheng et al., 2015a; Wang et al., 2016; Cheng et al., 2016; Carlton and Turpin, 2013; Nguyen et al., 2014; Xue et al., 2014; Tan et al., 2017; 47 Liu et al., 2017b). Atmospheric aerosol liquid water (ALW), which determined by ambient 48 relative humidity (RH), has been proposed as a container since it could provide the reaction 49 medium for the multiphase chemistry during the haze process (Ansari and Pandis, 2000; 50 Shiraiwa et al., 2012; Davies and Wilson, 2015). The roles of ALWC on the generations of 51 52 particulate sulfate generations (Wang et al., 2016; Cheng et al., 2016) and global secondary organic aerosols (Hodas et al., 2014; Mcneill, 2015; Wong et al., 2015) were reported. Thus, 53 54 fully understanding ALW and its roles during haze aggravation is fundamentally important on atmospheric physicochemical processes, especially the liquid chemical transformation of SO₂ 55 and NO_x in ALW. 56

Ammonia is the most important alkaline gas, neutralizing with acidic species to form ammonium salts. Due to little attention has been paid to NH₃ emissions by Chinese government, atmospheric NH₃ experienced a significant increasing trend (Ge et al., 2019; Tan et al., 2017). Although the increase in atmospheric NH₃ is beneficial to reduce atmospheric acidity (Liu et al., 2019), its chemical behavior on regional haze formation is still debating. Cheng et al. (2016) indicated that the fast transform of gaseous SO₂ to particle sulfate under polluted conditions is attributed to the neutralization of NH₃, which raises particle pH and thereby facilitated the aqueous oxidation of S (VI) by NO₂. Fang et al. (2017) stated that NH₃ partition significantly modified aerosol pH and thereby adjusting the partition of SO₂ and NO₂. Although the role of NH₃ has been identified from a theoretical perspective, the lack of NH₃ emission control sets barriers for more effective reduction of PM_{2.5}. Therefore, it is urgent to fully understand the reactive gases behavior and the chemical mechanism of SIAs formation during different

pollution stages, which will be helpful to propose reasonable strategies for each stage.

So far, the SIAs formation has been extensively studied during short-term, continuous, or persistent haze episodes, proposing several heterogeneous and homogeneous oxidation pathways on sulfate and nitrate formation (Guo et al., 2014; Guo et al., 2017; Zheng et al., 2015b; Huang et al., 2014; Liu et al., 2021; Yao et al., 2020; Zhou et al., 2018; Liu et al., 2019). In ammonia-rich atmosphere, NH₃ partition significantly modified aerosol pH, adjusted the partition of SO₂ and NO₂ (Fang et al., 2017) and promotes the aqueous oxidation of S (VI) by NO₂ (Wang et al., 2016; Cheng et al., 2016). Although many considerable efforts have been done to reveal the driving factors on haze aggravation, however, the roles of ALW in SIAs formation were mainly focused on the condition of ALWC<100 µg/m³ (Nenes et al., 2020; Wu et al., 2018; Bian et al., 2014; Jin et al., 2020). Therefore, the roles of ALWC in a broader scale and the mechanism shifting of secondary inorganic aerosols formation during haze aggravation in ammonia-rich atmosphere need to be understood in depth. Based on a continuous observation with 1-hour resolution from December 2019 to January 2020, this work discussed the shift of dominant mechanism with ALWC variation during the time window of haze aggravation processes, which will be helpful to propose more effective PM_{2.5} control strategies for each pollution stage.

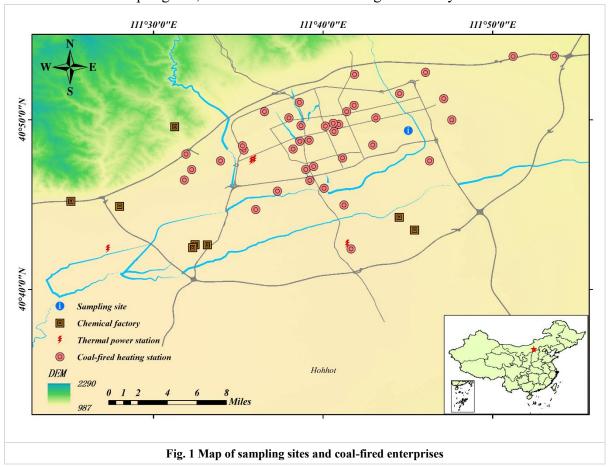

2 Sampling and Experiment Methods

2.1 Description of Sampling Site

Hohhot, the capital city of Inner Mongolia Autonomous Region, is the central city of Hohhot-Baotou-Ordos group, as well as an important northern China city with a population of more than 3.126 million and an area of 17224 km² (Fig. 1). This region is featured as continental climate with marked seasonality changes, which characterized as long-lasting cold humid winter and short-time other seasons. Thereby, to survive the cold season, approximately half year of coal-fired heating events (Oct. 15-the following Apr. 15) were introduced, which emitting gaseous pollutants as well as PMs around-the-clock. The main industries include thermal power plants, coal-energy based biochemical industry, dairy industry and petrochemical industry, etc., which also emit atmospheric pollutants ceaselessly. Thus, high concentrations of PMs pollution cases dominated the major contamination cases during winter season (data obtained from Department of Ecology and Environment of Inner Mongolia Autonomous Region, https://sthjt.nmg.gov.cn/) and gradually emerging as the limiting factor on regional ambient air quality and human health.

In this study, the observation was conducted at the Inner Mongolia Environmental

Monitoring Center (40°49′22″N, 111°45′2″E) on a top of a sixteen-story building (~40m above the ground level) located at the eastern part of the downtown near the People's Government of Inner Mongolia Autonomous Region near the 2nd ring road from December 1, 2019 to January 31, 2020. Residential and administrative regions were characterized as the major functional domain near the sampling site, with no direct industrial regions nearby.

2.2 Data acquisition and analysis methods

2.2.1 Data acquisition

On-line ion-chromatograph instrument (MARGA ADI 2080, Metrohm Applikon, Switzerland) was employed to simultaneously determine the water-soluble inorganic ions (Na⁺, NH₄⁺, Mg²⁺, Ca²⁺, K⁺, Cl⁻, F⁻, SO₄²⁻, NO₃⁻) in PM_{2.5} and corresponding trace gases (SO₂, HNO₂, HNO₃, HCl, NH₃). This instrument has been widely used in previous work (Rumsey et al., 2014; Nie et al., 2015; Huang et al., 2020) and the details were listed in Supplement (S1.1). Correspondingly, gaseous pollutants (e.g., NO_x, CO, PM₁, PM_{2.5}, PM₁₀) and meteorological datasets (e.g., wind speed, wind direction, RH, temperature, etc.), as well as the adopted models could be found in our previous work (Xie et al., 2021). In addition, peroxyacetyl nitrates (PANs), nitrous oxide (N₂O) and solar spectrophotometry were measured by PANs-100 (Focused Photonics Inc.),

120 N₂O Monitor (LSE, Monitors) and CE-318T (CIMEL), respectively.

121

122

2.2.2 Analysis methods

- Generally, sulfur oxidation ratio (SOR) and nitrogen oxidation ratio (NOR) were calculated as
- follows, which were used to indicate the contribution of secondary transformation during the
- 125 haze events (Song et al., 2007; Zhou et al., 2018).

126
$$SOR = \frac{n(SO_4^{2-})}{n(SO_2) + n(SO_4^{2-})}$$

127
$$NOR = \frac{n(HNO_3) + n(NO_3^-)}{n(NO_2) + n(HNO_3) + n(NO_3^-)}$$

- Meanwhile, as an indicator of ammonia conversion efficient, ammonia transition ratio
- (NTR), was calculated as the following equation (All units were $\mu g/m^3$).

$$NTR = \frac{NH_4^+/18}{NH_4^+/18 + NH_3/22.4}$$

- In addition, as the fractions of ammonia, nitrate and sulfate in deliquesced aerosol, ε
- 132 (NO₃⁻), ε (NH₄⁺) and ε (SO₄²⁻) were expressed as follows.

133
$$\varepsilon(NO_3^-) = \frac{n(NO_3^-)}{n(HNO_3) + n(NO_3^-)}$$

134
$$\varepsilon(NH_4^+) = \frac{n(NH_4^+)}{n(NH_3) + n(NH_4^+)}$$

135
$$\varepsilon(SO_4^{2-}) = \frac{n(SO_4^{2-})}{n(SO_2) + n(SO_4^{2-})}$$

- 136 **2.2.3** *Aerosol pH*
- In this work, a widely used thermodynamic model, ISORROPIA-II (Song et al., 2018; Gao et
- al., 2020), was employed to establish aerosol acidity. Including the concentrations of WSIs in
- PM_{2.5} and gaseous pollutions (e.g., NH₃, HCl), the simultaneously measured temperature and
- RH data were imported into its Na⁺-K⁺-Ca²⁺-Mg²⁺-NH₄⁺-SO₄²⁻-NO₃⁻-Cl⁻-H₂O aerosol system.
- 141 According to previous study (Song et al., 2018) and our data profiles, "Forward Mode" and
- "Metastable State" were selected in the model of ISORROPIA-II to calculate aerosol acidity
- 143 $(H_{air}^+, H^+ \text{ loading per volume air } (\mu g/m^3))$ and aerosol liquid water content (ALWC). Then the
- aerosol pH was calculated by the following equation.

$$pH = -\log_{10} \frac{1000H_{air}^{+}}{ALWC}$$

The concentrations of NH₃, NH₄⁺, NO₃⁻ and SO₄²⁻ modeled by this model significantly

- 147 correlated with their measured values with correlation coefficients of 0.971-0.999, indicating
- the accuracy and acceptability of the model in this work (Fig. S1).
- 149 2.2.4 Heterogeneous sulfate production
- Due to the necessity of precise SO₄²⁻ generation, heterogeneous sulfate production (P_{het}) was
- parameterized and calculated according to the following equation(Jacob, 2000; Zheng et al.,
- 152 2015a),

153
$$P_{het} = \frac{3600sh^{-1} \times 96gmol^{-1} \times P}{R \times T} \left(\frac{R_p}{D_q} + \frac{4}{v\gamma}\right)^{-1} S_p[SO_2(g)]$$

- Where P_{het} was presented in μg·m⁻³·h⁻¹, 3600sh⁻¹ is time conversion factor, 96 g/mol is the
- molar mass of SO₄²-, P is atmospheric pressure in kPa, R is the gas constant with the value of
- 8.31 Pa·m³·mol⁻¹·K⁻¹·, T is the temperature with the unit of K, R_p represented the radius of
- aerosol particles (m), D_g is the SO_2 molecular diffusion coefficient and v is the mean molecular
- speed of SO₂ with the typical tropospheric value of 2×10^{-5} m²·s⁻¹ and 300 m·s⁻¹, respectively. γ
- is the uptake coefficient of SO₂ on aerosols, S_p is the aerosol surface area per unit volume of
- air (m²·m⁻³) (Jacob, 2000). PM_{2.5} mass concentrations (μg·m⁻³) and mean radius (m) during
- campaign were roughly calculated utilizing the following empirical formula published by Guo
- 162 et al. (2014):

163
$$R_p = (0.254 \times C_{(PM_{25})} + 10.259) \times 10^{-9}$$

- mean density of particles ρ was calculated and showed as 1.5×10^6 g·m⁻³ using the volume
- and surface area formulas of a sphere (Guo et al., 2014). Sp was estimated from the following
- 166 formula:

170

172

$$S_p = \frac{C_{(PM_{2.5})} \times 10^{-6} g \cdot \mu g^{-1}}{4/3 \cdot \pi R_p^3 \cdot \rho} \cdot 4\pi R_p^2$$

- relative humidity-dependent γ were derived according to Zheng et al. (2015a) during the
- campaign in this work and showed as the following formular:

$$\gamma = \begin{cases} 2 \times 10^{-5}, & \Psi \le 50\%, \\ 2 \times 10^{-5} + \frac{5 \times 10^{-5} - 2 \times 10^{-5}}{100 - 50\%} \times (\Psi - 50\%), & 50\% \le \Psi \le 100\% \end{cases}$$

where ψ referred to RH with the unit of %.

3 Results and Discussion

- 173 Based on National Ambient Air Quality Standards of China (HJ633-2012)
- 174 (https://www.mee.gov.cn/ywgz/fgbz/bz/bzwb/jcffbz/201203/t20120302 224166.shtml), air
- quality index (AQI) was introduced in this work to classify pollution levels (Wang et al., 2015;

- 176 Kanchan et al., 2015; Xu et al., 2017) and discuss the characteristics of atmospheric pollutants.
- Briefly, daily concentrations of PM_{2.5} ranged from 0-75, 75-115, 115-150, 150-250 and >250
- 178 μg/m³ were classified as clean (C), light polluted (L), moderate polluted (M), heavy polluted
- 179 (H) and serious polluted (S) periods, respectively.

3.1 The observed evidence for ammonia-rich atmosphere

The characteristics of atmospheric pollutants and meteorological parameters during the studied

period were summarized in Supplement (S2.1). In this work, molar ratios of NH₄⁺ vs. anions

was used to identify the chemical species of ammonium salts (Zhou et al., 2018; Wang et al.,

2021; Liu et al., 2017b; Shi et al., 2019). The calculated results (Supplement, S2.2) showed the

predominant chemical species of ammonium gradually varied from the coexistence of

ammonium sulfate ((NH₄)₂SO₄) and ammonium nitrate (NH₄NO₃) to the coexistence of

((NH₄)₂SO₄), NH₄NO₃ and ammonium chloride (NH₄Cl) with haze aggravation (Fig. S5).

Further, the slope of fitted equation between excess-NH₄⁺ and anions were still lower than 1:1

line after neutralized all the measured anions, indicating the ammonia-rich atmosphere (Fig.

S5c). To meet the national demand of ultra-low emissions activities (nearly two times lower

than former national standard) on gaseous pollutants, heavy usage of ammonia-containing

compounds in the process of desulfurization and denitrification (Solera García et al., 2017; Tan

et al., 2017) at broadly distributed thermal power plants (>300,000kWh) and the close-set coal-

fired heating stations (Fig. 1) resulted ammonia fugitive provided a reasonable explanation on

this ammonia-rich atmosphere. Although the retrofit of national demand of ultra-low emissions

activities on gaseous pollutants (nearly two times lower than former national standard) has

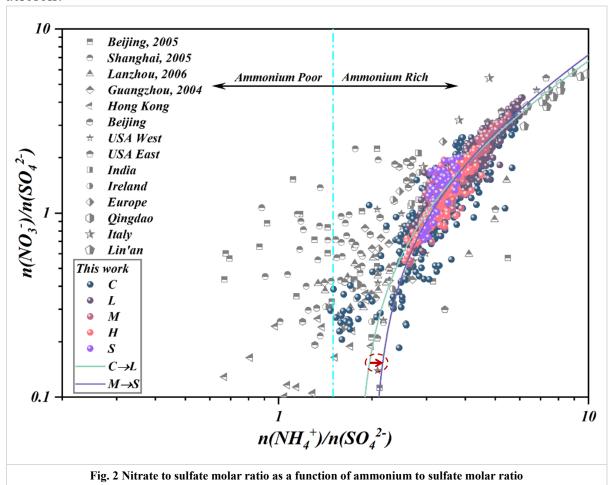

been completed, distributed coal-based enterprises could also emit substantial SO₂ and NO₂

and subjecting to heterogeneous reactions to further generate sulfate and nitrate and aggravated

the haze events (Fig. S7a, S7b).

To show the reaction between ammonia and nitric acid and the other formation processes of nitrate in different (relative) concentrations of sulfate, the data of previous studies and different pollution levels (C, L, M, H, S) in this work were plotted in Fig. 2. When $[NH_4^+]/[SO_4^{2^-}] \le 1.5$, the nitrate formation associated with crustal elements rather than ammonium; while $[NH_4^+]/[SO_4^{2^-}] > 1.5$, the homogeneous gas-phase reactions between NH₃ and HNO₃ became the major pathway for atmospheric ammonia to form NH₄NO₃ (Pathak et al., 2009; Liu et al., 2019). The results illustrated that the ammonia-rich regimes were not only found in Hohhot, but also observed in Guangzhou (Huang et al., 2011), Chengdu (Huang et al., 2018), Lanzhou USA West and East, India, Ireland, Europe, Qingdao, Italy, Lin'an (Pathak et al., 2009) in recent decades (Fig. 2). It suggested that atmospheric oxidative modifications in

ammonia-rich atmosphere should be a widespread atmospheric issue with significant contributions on SIA generation. It was worth noting that the slopes of our data were becoming steeper, coupling with the $NO_3^{-}/SO_4^{2^{-}}$ ratios change from ~4 to about 1, as the increasing pollution levels. The high $PM_{2.5}$ nitrate concentration during Heavy and Serious stages cannot be explained by the homogeneous gas-phase reaction involving ammonia and nitric acid, which may be associating with the heterogeneous reaction in ALW on the surface of the preexisting aerosols.

3.2 Driving mechanism of SIAs formation

3.2.1 Aerosol liquid water

Our results showed that SOR, NOR and SIAs in PM_{2.5} presented increasing trends with the increasing ALWC during the five pollution levels. The variation of predominant chemical species of ammonium (Fig. 2) indicated more SIAs will be generated on particles with the simultaneous increase of ALWC and PM_{2.5} (Fig.3b). Theoretically, the inorganic compounds conversion was enhanced via aqueous phase chemistry on moist particles owing to the continuous partition of gaseous pollutants (e.g., SO₂, NO₂, N₂O₅) in ALW, then disrupted the equilibrium between the gaseous and condensed phases, resulting in the aggravation of haze

events (Xue et al., 2014; Wu et al., 2018; Zheng et al., 2015b; Wang et al., 2016). Considering seasonal heating characteristics, the shift of the equilibrium between gaseous and condensed phases was enhanced with the increasing atmospheric pollutants concentrations due to the coalfired combustion events in winter. Detailly, owing to hygroscopic nature, the particles must increase their water contents via ALW along with RH (Fig. S8a) to maintain thermodynamic equilibrium and water vapor and simultaneously enhance the oxidation and dissolution of precursors in the micro-solution (ALW) of the particulates. This process elevated the inorganic mass fraction as well as particulate mass concentrations during different pollution stages (Fig. S8b) (Bertram et al., 2009; Wang et al., 2016; Zheng et al., 2015a; Cheng et al., 2016). Due to the larger affinity of H₂SO₄ for NH₃ (aq), sulfate was preferentially and fully neutralized by ammonium in the ammonia-rich atmosphere to generate non-volatile nature of (NH₄)₂SO₄ (Liu et al., 2017b; Zhou et al., 2018; Wang et al., 2021). Thus, SOR presented higher exponential growth with the elevated AWLC coupling with more sulfate production (Fig. 3b). Concomitantly, the preferentially generated (NH₄)₂SO₄ further enhanced the hygroscopicity of particulate matter, in turn, helped more ammonia partitioning into moist particulate matter and generating ammonium salts accelerating haze aggravation (Supplement, Fig. S6, Fig. S8c). Thus, most important of all, the sharp increase of inorganic compounds associating with the elevated ALWC significantly modified the specific surface area of particulates and further accelerated the hygroscopic aerosol growth, which simultaneously provided a substrate for the ensuing heterogenous reaction and accelerated the evolution of haze events. Previous work reported that particles of different modes made different contributions to ALWC with the contributions of nuclear, Aitken, accumulation and coarse modes assessed at <1%, 3%, 85% and 12%, respectively, indicating that the contribution of accumulation mode particles to ALWC dominated among all the aerosol particle modes (Tan et al., 2017). It indicated that secondary aerosol formation mainly happens on these fine particles as the surface area and volume of the fine particles are much larger than those of the coarse particles. Thus, the observed significant correlations of ALWC with the ratios (PM_{1.0}/PM_{2.5} and PM_{2.5}/PM₁₀) in this work also indicated that the hygroscopic growth of fine particulate matter ($D_p \le 2.5$ um) strongly associated with ALWC (Fig. 3a). Both the previous work and our monitoring results suggested that the ratios of PM_{1.0}/PM_{2.5} and PM_{2.5}/PM₁₀ presented the potential possibility to index the hygroscopic growth of particulate matter.

3.2.2 Perturbation gases

Due to the strict control of SO₂, atmospheric concentrations of NO₂ and NH₃ gradually became as the decisive reactive precursors on regional atmospheric secondary particulate matter generation. Thus, the state-of-the-art flamework proposed by Nenes et al. (2020) was carried out to exam the chemical domain classifications and the decisive precursor based on the data sets of previous studies (Nenes et al., 2020) and this work (Fig. 4). Due to the thermodynamically stable property of the preferentially generated (NH₄)₂SO₄, the semi-volatile NH₄NO₃ dominate the partitioning of NH₃^T (sum of NH₃ and NH₄⁺, same to NO₃^T) and NO₃^T. Although aqueous NO₃⁻ concentrations varied with haze processes, the calculated ε (NO₃^T) (detailed calculated method could be found in S1.2), which was an equilibrium parameter between gaseous HNO₃ and particle-phase NO₃⁻ (Guo et al., 2016; Fang et al., 2017), presented consistently full loadings of nitrate on the existing particulates during the studied period (Fig. S9a, Fig. S9b). This could provide clear evidence for the initial HNO₃ sensitive area and continuous control of HNO₃ during the studied periods. However, with haze aggravation, significant elevated ALWC resulted in more precursors partitioned in microdroplets to maintain water vapor. This process induced a positive shift of HNO₃ dissolution

equilibrium and leading more HNO₃ partitioned on particles driven by the Henry's law (e.g., 275 $HNO_{3(g)} \leftrightarrow HNO_{3(aq)}$, $K_H = 2.07 \text{mol/}(\text{L-Pa})$). Meanwhile, HNO_3 and HONO could also produce 276 through the reactions of $NO_2 + H_2O \xrightarrow{Het} HNO_3 + HONO$) (Huang et al., 2018). Accordingly, 277 the OH radicals generated by HONO photolysis also contributed to this oxidation processes 278 (Yue et al., 2020; Zhu et al., 2020). These aqueous oxidations processes were evidenced by the 279 280 observation of significantly elevated HONO and PANs during the haze aggravation (Supplement, Fig. S7c, Fig. S7d). Accordingly, the equations of $NH_4^+ + NO_3^- + H^+ + OH^- \rightleftharpoons$ 281 $NH_4NO_3 + H_2O$ and $NH_4^+ + SO_4^{2-} + H^+ + OH^- \rightarrow (NH_4)_2SO_4 + H_2O$ were shifted to 282 generate more NH₄NO₃ and (NH₄)₂SO₄ (Nenes et al., 2020; Xie et al., 2020) due to the driving 283 force of more ammonia partitioned in elevated ALWC (NH₃+H₂O ≠ NH₃·H₂O, NH₃·H₂O ≠ 284 NH₄⁺+OH⁻). Therefore, NH₃ and NO_x became as the decisive factors on regional atmospheric 285 oxidability in the ammonia-rich regime (Zhai et al., 2021; Tan et al., 2017; Liu et al., 2019; Li 286 et al., 2019). 287 288

308

Generally, both NH₃ and HNO₃ were the limiting factors governing the aerosol generations for cities of North China due to high loadings of atmospheric ammonia, while NH₃ governed PM formation for the southeast US (SAS) (Zhao et al., 2020). Thanks to the raw data of Shenzhen (SZ) (Wang et al., 2022), we also calculated the ALWC and aerosol pH using ISORROPIA-II and the scatters of SZ suggested obvious chemical transition from HNO₃-NH₃ regime to NH₃ sensitive regime due to the differently originated air masses. Although both cities located in US, the findings in California (CNX) were quite interesting and distributed in the insensitive region and the combined NH₃-HNO₃ sensitive region due to the moderate NH₃ levels and the complicated atmospheric conditions during the observation (Nenes et al., 2020). In our work, the data points (541/744) in summer (pH= 3.47 ± 1.29) mostly lied in HNO₃ sensitive region, while chemical domains of perturbation gas limiting the generation of secondary particulate matters presented obvious shifts from HNO₃ sensitive to HNO₃ and NH₃ co-sensitive regime with the haze aggravation in winter. Some data points of this work lied in the combined NH₃-HNO₃ region in winter owing to the more acidic condition. Under the stable pH of aerosols in winter at Hohhot (pH=4-5), the more important is that a fraction of points will distribute in the combined NH₃-HNO₃ region when ALWC>75 μg/m³, which may be attributed to the aqueous chemical transformation driven by Henry's law mentioned above due to the elevating ALWC. Comparatively, the aerosols pH in summer was significantly lower than those in winter in Hohhot. Compared to TJ and SZ, the aerosols pH of Hohhot in winter was also significantly higher (Fig. 4) due to the acidity of atmospheric PM is largely depended on the alkaline material in surface soils in arid and semi-arid region and the elevated

atmospheric ammonia. In terms of seasonal characteristics, the higher temperature in summer elevates the volatility of NH₄NO₃ and dominates the partitioning of NH₃^T in atmospheric phase to decrease the pH of aerosols. Therefore, as can be seen from Fig. 4, the data points measured in winter Hohhot characterized as higher pH and low ALWC than those in summer (Hohhot, SAS, CNX, SZ). According to the framework of Nenes et al. (2020), the transition points of Hohhot (whether winter or summer) between NH₃-dominated and HNO₃-dominated sensitivity also occurs at a pH around 2 but at lower levels of ALWC. Theoretically, it should be associated with the more aridity of Hohhot locating in the arid and semi-arid region of China. Our results provided the evidence for "the additional insight" proposed by Nenes et al. (2020) that the transition ALWC varies with season change and the aridity of sites, in response to seasonal variability and climate change. Although this effort could provide sound explanation for limiting gaseous pollutants on PM formation, mechanisms on their chemical domains, especially the roles of ALW in different locations with various conditions need further study in the future.

3.2.3 The shifting of SIAs formation mechanism driven by ALW

It's worth noting that two independent correlations were found between SOR and odd oxygen $(O_x, O_x=NO_2+O_3)$ during the aggravating processes of haze events, indicating the differential

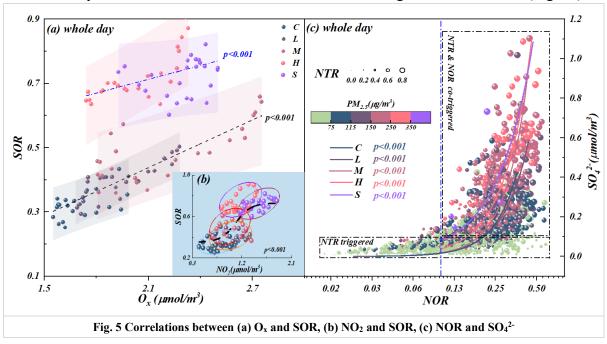

mechanisms of atmospheric oxidability on sulfate generations at different stages (Fig. 5a). Different to inefficient homogeneous sulfate oxidation efficiency (Supplement, Fig. S10), significant correlations pairs of NO₂ with SOR (Fig.5b) and NOR with SO₄²⁻ (Fig.5c) suggested the haze aggravation was largely related to the regional NO₂ levels due to the regulating effects on atmospheric oxidizability. Thus, the aqueous-phase oxidation of S(IV) by NO₂ (aq) was triggered and accelerated by the increasing ALWC and the following equation (Yao et al., 2020; Wang et al., 2016) (Supplement, Fig. S11a):

$$S(IV) + NO_2(aq) + H_2O \rightarrow S(VI) + H^+ + NO_2^-$$
 (R1)

Meanwhile, sharp logarithmic increase between SOR and NH₄⁺ were also observed from Clean to Moderate pollution stages (Supplement, Fig. S12). Due to the joint effects of ammonia-rich atmosphere and ammonia's extremely water-soluble property, sufficient hydroxide generated by ammonia dissolution forced the NO₂ partitioned in ALW to maintain pH through neutralization and producing sulfate via R1. Thus, the following equation (R2) was derived with considering the processes of ammonia hydrolysis, which was evidenced by Fig. S11b.

$$S(IV) + NO_2(aq) + NH_3(aq) + H_2O \rightarrow S(VI) + NH_4^+ + NO_2^- + H^+ + NO_3^-$$
 (R2)

Generally, NOR<0.1 means insignificant nitrogen oxide oxidation, therefore the observed regime shift of nitrate and ammonia chemical behavior on sulfate generation suggested the sulfate generation was preferentially triggered by the high ammonia utilization, then accelerated by the co-effects of ammonia utilization and nitrogen oxide oxidation (Fig. 5c).

Accordingly, the reaction R2 was activated due to the increased ALWC forced more ammonia to partition into moist particulate matter driven by the Henry's law in the ammonia-rich atmosphere ($NH_{3(g)} \rightarrow NH_{3(aq)}$) (Supplement, Fig. S9c) (Clegg et al., 1998; Wu et al., 2018;

Xie et al., 2020). Meanwhile, our calculated aqueous generated NO₃- nicely matched theoretical nitrate aqueous generation curve (the solid blue line in Fig. S9b) proposed by Guo et al. (2017), suggesting the pathway of fast sulfate formation from oxidation of S(IV) by NO₂ to generate HONO (Wang et al., 2020) (Supplement, Fig. S11) via the reaction R2. As a result, the thermodynamically stable (NH₄)₂SO₄ would be preferentially formed to maintain its water vapor pressure and thermodynamic equilibrium, then trigged the haze formation. Thus, the mentioned effects resulted in a pronounced increase of NH₃ partitioning with the haze aggravation, suggesting the importance of ammonia partition on sulfate generations, namely, NTR-controlled regime with ALWC<75 μg/m³. In summary, when ALWC<75 μg/m³, the sulfate generation was preferentially triggered by high ammonia utilization, then accelerated by nitrogen oxide oxidation from Clean to Light pollution stages (Fig. 5c) with NOR<0.3, SOR<0.4 and NTR<0.7. In this period, the chemical composition of SIAs characterized as the moral ratio of NO₃-:SO₄²-=2:1 (Fig. 6).

381

When ALWC>75µg/m³, the haze was aggravated from Moderate to Serious stages along with the increasing ALWC. As a result of increase in ALW, large amount of H⁺ was dissociated during the generation of ammonium sulfate (Supplement, Fig. S13a). From Light to Moderate pollution stages, the solubility SO₂ driven by Henry's law was self-limiting due to the acidity effect in low ALWC (with ALWC<75 µg/m³). Therefore, low sulfate concentrations coupled with low ALWC at the beginning of haze event (Supplement, Fig. S13a). However, due to the co-effects of elevated ALWC and hygroscopic nature of pre-generated ammonia sulfate, H⁺ concentrations were diluted and nearly constant in-situ pH with the increase of ALWC during Heavy and Serious pollution stages (Supplement, Fig. S14) (Wang et al., 2016; Clifton et al., 1988; Huie and Neta, 1986; Lee and Schwartz, 1982). Hence, the significantly elevated ALWC provided more chance for the partition of SO₂, NO₂ and NH₃ in ALW from Moderate to Serious pollution stages. Theoretically, Henry's constants of NO₂ (9.74×10⁻⁸ mol·(L·Pa)⁻¹) is 3-4 orders of magnitude lower than those of SO_2 $(1.22 \times 10^{-5} \text{ mol} \cdot (\text{L} \cdot \text{Pa})^{-1})$ and NH_3 $(6.12 \times 10^{-4}$ mol·(L·Pa)⁻¹), however, it is worth noting that the aqueous generated NO₃⁻ from Moderate to Serious stages rapidly increased 2-5 times higher than Clean and Light stages (Supplement, Fig. S9b). Meanwhile, according to our monitoring results, the solar spectrophotometry at 380nm during Moderate to Serious stages was significantly lower than that in Clean stage (Supplement, Fig. S15), suggesting the aqueous oxidation of NO₂ was the predominant compared to chain photolysis (Huang et al., 2018). Accordingly, it could be deduced that aqueous-phase chemistry reaction of SO₂ and NH₃ in ALW, driven by Henry law, became the dominant mechanism for sulfate formation due to more NO₂ was required to take part in the

fast sulfate formation with the increase of ALWC in the ammonia-rich atmosphere by the reaction R2. Thus, with the increasing of ALWC, high concentrations of sulfate and nitrate with high SOR (0.5-0.9), NOR (0.3-0.5) and NTR (>0.7) induced the haze events becoming Heavy and Serious levels (Fig. 5c). Simultaneously, the calculated heterogeneous sulfate production rate (Jacob, 2000; Mcneill, 2015) (Supplement, Fig. S16) presented similar trends with the impacts of ammonia on sulfate production during different pollution stages (Xue et al., 2016; Cheng et al., 2016; Liu et al., 2020). It further stated the environmental significance of the partitioning of SO₂ and NH₃ between gas and aqueous (ALW) phases for SIAs formation and haze aggravation. Our results provided the evidence of significant negative correlations between HONO and N₂O (Supplement, Fig. S17) from Moderate to Serious stages and positive correlations between HONO and SOR (Supplement, Fig.S11a), highlighting the recent reported secondary aqueous-phase oxidation pathway of SO₂ by HONO from moderate pollution period $(2N(III) + 2S(IV) \rightarrow N_2O \uparrow + 2S(VI) + other products)$ (Wang et al., 2020). In summary, when ALWC>75 μg/m³, aqueous-phase chemistry reaction of SO₂ and NH₃ in ALW became the prerequisite for SIAs formation driven by Henry's law in the ammonia-rich atmosphere during Heavy and Serious stages with high SOR (0.5-0.9), NOR (0.3-0.5), NTR (>0.7). In this period, the chemical composition of SIAs characterized as the moral ratio of NO₃⁻:SO₄²=1:1 (Fig. 6).

3.2.4 The positive feedback of sulfate on nitrate production

Previous works suggested that the homogeneous reaction of NO₂ with OH radicals during daylight and heterogeneous hydrolysis of N₂O₅ at night were the main routes on nitrate formation during haze episodes (He et al., 2018; Liu et al., 2020; Liu et al., 2019). Unsurprising, higher nitrate production rates (Δ NO₃⁻, the difference of hour concentrations and matrixing afterwards) were frequently observed in ammonia-rich conditions due to that ammonia-rich regime was more conducive on nitrate generation. However, the high level of nitrate production rates (Δ NO₃⁻) were found in the area characterizing as high ammonium and low sulfate levels, suggesting that highly utilizing ammonium and pre-generated sulfate promoting particle-phase nitrate generations (Fig. 7).

Here, we proposed a hypothesis about the hydrogen ion concentration to respond the above observations. As is known to all, apart from the extremely low levels of crustal elements, ammonia is the only alkaline gas to neutralize the acidic gases in the atmosphere and generate ammonium ions (Xie et al., 2020). Thus, the concentrations of particulate sulfate and nitrate are affected by the partitioning of NH_4^+/NH_3 . Thereby, higher values of ΔNO_3^- and ΔSO_4^{2-}

always occurred in the regions with higher ammonium ions were not confused (Fig. 7, Fig. S18). According to both our results and published laboratory work (Wang et al., 2016), the acidity of the particulate matter could be significantly modified by the bulk aqueous reaction between NO₂ and SO₂, in which this reaction could be further enhanced due to in the presence of NH₃. As a result of the increase in RH, the partitioning of atmospheric ammonia was broken in a deep extent, which enhanced the neutralization of S(VI) by ammonia at the particle surface to generate ammonium sulfate and dissociate huge H⁺ (Fig. S13b, red part). Simultaneously, the ALWC did not raised significantly (Fig. S14b) at the beginning of haze event with relative low sulfate concentrations. Thus, hydrogen ions generated from sulfate dissociation absorb ammonia more effectively from the ammonia-rich atmosphere at low relative humidity during the early pollution stages, which significantly promotes the net nitrate production. However, due to the co-effects of elevated RH and hygroscopic nature of pre-generated ammonia sulfate, H⁺ concentrations were diluted and shown as nearly constant in-situ pH (Fig. S14a). According to previous works, the reaction between firstly generated sulfate and bisulfate with ammonia were treated as the determination reaction on particle acidity (Weber et al., 2016; Liu et al., 2017a). This reaction is self-limiting due to the acidity effect, namely that it increases the acidity of aqueous phase and in turn reduces the efficiency of Henry's constant for SO₂ solubility and reaction rate and reduced the H⁺ formation rates from moderate periods, compared with clean periods (Fig. S13b, blue) (Wang et al., 2016; Clifton et al., 1988; Huie and Neta, 1986; Lee and Schwartz, 1982). Due to the co-effects of RH increase and hygroscopic of sulfate, the ALWC was significantly elevated with the worsen of haze. Although more H⁺ was generated in this process, no significant decrease in pH was found with the haze aggravation due to the dilution effect of ALWC on H⁺. Previous works suggested that in the case of ALWC increase, nitrate production is controlled by elevated H⁺ associating with the increase of sulfate, namely, NO₃ presented elevating trend with the increases of H⁺ concentration (Xie et al., 2020). Thus, although H⁺ from the dissociation of sulfuric acid and full-loaded particle nitrate in conjunction with the haze aggravation generate particle HNO₃ (Fig. S19a) could forcing more ammonia partitioned on the particles to generate ammonium nitrate (Fig. S19b), net nitrate production (ΔNO_3^-) was nearly consistent.

The formation of SIAs, especially sulfates and nitrates, was inherently associated with ALWC during the haze aggravation, in which the roles of ALWC should be more significant in ammonia-rich atmosphere. The novelty of our work is to find the shifting of secondary inorganic aerosols formation mechanism during haze aggravation and explain the different

roles of ALWC in a broader scale (~500 ug/m³) in ammonia-rich atmosphere based on the insitu high-resolution on-line monitoring data sets. The results showed that chemical domains of perturbation gas limiting the generation of secondary particulate matters presented obvious shifts from HNO₃ sensitive to HNO₃ and NH₃ co-sensitive regime with the haze aggravation, indicating the powerful driving effects of ammonia in ammonia-rich atmosphere. When ALWC<75 ug/m³, the sulfate generation was preferentially triggered by the high ammonia utilization, then accelerated by nitrogen oxide oxidation from Clean to Moderate pollution stages, characterizing as NOR<0.3, SOR<0.4, NTR<0.7 and the moral ratio of NO₃⁻:SO₄²-=2:1. While ALWC>75 ug/m³, aqueous-phase chemistry reaction of SO₂ and NH₃ in ALW became the prerequisite for SIAs formation driven by Henry's law in the ammonia-rich atmosphere during Heavy and Serious stages, characterizing as high SOR (0.5-0.9), NOR (0.3-0.5), NTR (>0.7) and the moral ratio of NO₃-:SO₄²-=1:1. A positive feedback of sulfate on nitrate production was also observed in this work. Our work provides a potential explanation for the interactive mechanism and feedback between nitric aqueous chemistry and sulfate formation in ammonia-rich atmosphere based on high-resolution field observation. It implies the target controlling of haze should not simply focus on SO₂ and NO₂, more attention should be paid on gaseous precursors (e.g., SO₂, NO₂, NH₃) and aerosol chemical constitution during different haze stages.
