21	
22	Abstract. In this study, we developed an approach that integrated multiple patterns
23	of time scale for box modeling (MCMv3.3.1) to better understand the O ₃ -precursor
24	relationship through multiple sites and continuous observations. A five-month field
25	campaign was conducted in the summer of 2019 to investigate the ozone formation
26	chemistry at three sites in a major prefecture-level city (Zibo) in Shandong province of
27	northern China. It was found that the relative incremental reactivity (RIR) of major
28	precursor groups (e.g., anthropogenic volatile organic compound (AVOC), NO _x) was
29	overall consistent in the sign along with time scales changed from wider to narrower
30	(four patterns: five-month, monthly, weekly, and daily) at each site, though the
31	magnitudes of RIR varied at different sites. The time series of the photochemical regime
32	(using RIR _{NOx} /RIR _{AVOC} as indicator) in weekly or daily patterns further showed a
33	synchronous temporal trend among the three sites, while the magnitude of
34	RIR _{NOx} /RIR _{AVOC} was site-to-site dependent. The derived RIR ranking (top 10) of
35	individual AVOC species showed consistency at three patterns (i.e., five-month,
36	monthly, and weekly). It was further found that the campaign-averaging photochemical
37	regimes showed overall consistency in the sign but non-negligible variability among

the four patterns of time scale, which was mainly due to the embedded uncertainty in model input dataset when averaging individual daily pattern into different timescales. This implies that utilizing narrower time scale (i.e., daily pattern) is useful to derive reliable and robust O₃-precursor relationship. Our results highlight the importance of quantifying the impact of different time scales to constrain the photochemical regime, which can formulate more accurate policy-relevant guidance for O₃ pollution control.

45 1 Introduction

Since 2013, the ambient PM_{2.5} concentration in China has dramatically declined 46 47 by implementing Clean Air Action (Lu et al., 2018; Wang et al., 2020b; Zhang et al., 48 2019). However, national ground surface ozone concentrations increased over the same 49 period (Xue et al., 2020) and became a major air quality problem that needed to be 50 addressed in China (Li et al., 2019; Wang et al., 2019). It is well-known that ground 51 surface ozone is formed mainly by complex nonlinear photochemical oxidation of 52 volatile organic compounds (VOCs) in the presence of nitrogen oxides (NO_x = NO + 53 NO₂) and sunlight (Blanchard, 2000; Hidy, 2000; Kleinman, 2000), which adversely 54 influences human health, vegetation and corps (Brunekreef and Holgate, 2002; 55 Vingarzan, 2004).

56 Given the complex non-linear relationship between O₃ formation and its 57 precursors (VOCs and NO_x), challenges in mitigating its severity lie primarily in 58 comprehensively understanding of O₃-precursor relationship (Su et al., 2018a; Tan et 59 al., 2018a). It is commonly recognized that regional-scale air quality models and the 0-D box model are two mainstream approaches to investigate the increasingly severe 60 61 ozone problem (Blanchard, 2000; Cardelino and Chameides, 1995; Hidy, 2000; Liu et al., 2019). Unlike the complicated 3-D air quality models, the 0-D box model is an 62 63 observation-based model that implemented with gas-phase chemical mechanism, and 64 has been widely used to diagnose O₃-precursor relationship in various locations (Liu et 65 al., 2021a; Sun et al., 2016; Tan et al., 2019b; Xue et al., 2014a; Yu et al., 2020a). Some previous studies (Li et al., 2021; Lu et al., 2010a; Sicard et al., 2020; Yu et al., 2020b) 66 67 have reported a large variability of O₃-precursor relationship in spatiotemporal scales 68 in many cities of China, which indicates great challenges in current O₃ pollution control 69 (Wang et al., 2017a; Xue et al., 2014b).

Table 1 summarizes the published studies of O_3 -precursor relationship using the 0-D box model (implemented with different gas-phase chemical mechanisms) at diversified patterns of time scale in many places of China. The observational period in most previous studies was short-term (i.e., less than one month), while medium-term (i.e., from one to several months), and long-term (i.e., multiple years) periods were limited. As shown in **Table 1**, we find that model input datasets with different 76 timescales have been employed in previous studies to identify the campaign-averaging O3 formation regime, but there is a lack of comparison among these different timescales. 77 We also find that more than half of the studies using the averaged diurnal patterns as 78 79 box model input, which is particularly common for those medium and long-term 80 measurements. For example, a 10 years long-term observational study by Wang et al., 81 (2017a) adopted monthly pattern of time scale for model simulation with the reason of 82 saving computing resources, and it also revealed a substantial temporal variability of 83 O₃-precursor relationship. In addition, it is believed that long-term (measurements of at least several months) and multiple-site continuous online measurements can provide 84 85 opportunity to develop O₃ control strategy more comprehensively over a wider spatiotemporal scale (Li et al., 2021; Wang et al., 2017b; Wang et al., 2017b). However, 86 87 such measurements have been quite rare in China, limiting the present understanding 88 of O₃-precursor relationship (Lu et al., 2019; Wang et al., 2017b).

89 In this study, a five-month field campaign was conducted in the summer of 2019 90 to investigate the ozone formation chemistry at 3 sites in Zibo, a major prefecture-level 91 Chinese city in Shandong province. According to our measurements at the three sites in Zibo, the averaged O₃ concentration during the whole observational period was around 92 50 ppbv, while the daily maximum of O₃ concentrations for some extremely polluted 93 94 periods were nearly 120-150 ppbv (see details in Section 3.1). Here we developed an 95 approach that integrated multiple patterns of time scale for box model simulation, which 96 aimed at illustrating the non-linearity of O₃-precursor relationship driven by its actual 97 daily / weekly / monthly variability. Our results can be conducive to interpreting 98 variations of O₃-precursor relationship over a wider spatiotemporal scale, and they 99 provide implications for developing more precise and constrained O₃ control strategies 100 in other regions.

101 **2 Methods**

102 2.1 Study sites and measurements

103 Field measurements were conducted in a major prefecture-level city (Zibo), which is in the middle of Shandong Province, northern China, from 1 May to 30 September, 104 2019. Figure S1 shows the surrounding environment and geographical locations at the 105 three sampling sites; a detailed description of the Tianzhen (TZ), Beijiao (BJ) and 106 107 Xindian (XD) sites can be found in our previous study (Li et al., 2021). Briefly, TZ 108 contains a mixture of crude oil processing and operation stations and farming areas, and 109 is classified as suburban area; XD contains a mixture of residential and heavy industrial 110 zones, and is considered as a suburban area; BJ is in the urban area of Zibo.

Typical inorganic gases of O₃, NO, NO₂, CO and SO₂ were measured using online commercial gas analysers (Thermo Scientific 49i, 42i, 48i and 43i, USA) at the three sites. Following the Chinese meteorological monitoring regulation (GB/T 35221-2017), 114 we continuously monitored the meteorological parameters (i.e., temperature, relative humidity, UV-A solar radiation, precipitation, wind speed, and wind direction) at the 115 three sites (Li et al., 2021). Two online GC systems (gas chromatography-flame 116 ionisation detector, GC-FID, Thermo Scientific GC5900) were deployed at TZ and BJ 117 118 respectively to measure VOC species. For C₂-C₅ VOCs, desorption and separation were 119 performed using a GC with pre-concentration on a combination of two columns, 120 followed by a FID detector. For C₆-C₁₂ VOCs, air sample was pre-concentrated on Tenax GR cartridges and subsequently separated by chromatographic column, then 121 detected by another FID detector. Similarly, one online system (gas chromatography-122 flame ionisation detector/photoionisation detector, GC-FID/PID, Syntech Spectras GC 123 124 955-615/815) was deployed at XD site. For C₂-C₆ VOCs, the hydrocarbons were 125 concentrated on a Tenax GR carrier, then thermally desorbed and separated on a DB-1 column, and finally detected by FID and PID detectors. For C₆-C₁₂ VOCs, the air 126 127 sample was concentrated on a Carbosieves SIII carrier at 5°C, then thermally desorbed 128 and separated on a combination of two columns, and FID and PID detectors were employed for subsequent detection. These systems measured 55 VOC species at a 1-h 129 resolution, and more detailed descriptions can be found elsewhere (Chien, 2007; Jiang 130 131 et al., 2018; Xie et al., 2008).

132 Table S1 summarized the limit of detection, accuracy, precision of the instruments 133 at the three sites, and all the measurement instruments were regularly subjected to the 134 service of checking and maintenance during the whole campaign. Unfortunately, we did not conduct the inter-comparison between the GC-FID and GC-FID/PID instruments at 135 136 the same site due to practical reasons, as these VOC instruments were separately 137 deployed at the three different sites for continuous routine operation. To ensure the 138 quality assurance / quantity control (QA/QC) of online VOC measurement, two five-139 point calibrations (i.e., 2, 4, 6, 8, 10 ppbv, dilution from one cylinder) for standard gases with 55 VOC species (Linde Co., Ltd, USA) were carried out in May and August of 140 141 2019 at the three sites. Table S2 showed that the calibration linearity (R^2) of all 142 measured VOCs were nearly 0.9990. Additionally, a single-point calibration (i.e., 6 143 ppbv) was regularly performed every month during the whole campaign. As shown in 144 Figure S2 (a case from TZ), the retention time, peak fitting and baseline of the 145 chromatogram were manually checked and adjusted on a daily basis.

146 2.2 0-D box model and design of four patterns of time scale

The 0-D box model integrated with the latest Master Chemical Mechanism of MCMv3.3.1 (<u>http://mcm.york.ac.uk/</u>) has been widely utilized in many regions (He et al., 2019; Jenkin et al., 2015; Liu et al., 2019; Whalley et al., 2021). Unlike the lumped chemical mechanisms such as CB05 (Wang et al., 2017a; Yarwood et al., 2005), CB6 (Yarwood et al., 2010), RACM/RACM2 (Goliff et al., 2013; Stockwell et al., 1997,

2020) and SAPRC-07 (Carter, 2010), the MCMv3.3.1 is a near-explicit chemical 152 mechanism consisting of over 5,800 species and 17,000 reactions (Jenkin et al., 2015; 153 Saunders et al., 2003), which can be used to describe the gas-phase chemistry (i.e., in-154 155 situ photochemistry). In this study, the box model (based on the Framework for 0-D Atmospheric Modeling, F0AM) (Wolfe et al., 2016) was applied and constrained by the 156 157 mean diurnal profiles of meteorological data (i.e., temperature, relative humidity, and 158 photolysis rates), 4 inorganic gases (i.e., SO₂, CO, NO, and NO₂), and 45 speciated VOCs (in MCMv3.3.1 species list; see Table S3). Since measured photolysis rates (J 159 values) were not available, the measured UV-A solar radiation was used to scale the 160 161 photolysis rates calculated from the Tropospheric Ultraviolet and Visible Radiation 162 model https://www.acom.ucar.edu/Models/TUV/Interactive TUV/) (TUVv5.2; 163 following the approach of recent studies (Lyu et al., 2019; Lyu et al., 2016). Specifically, 164 the geographical coordinates, date and time were initialized into the TUV model to 165 derive photolysis rates and solar radiation. We obtained the scaling factor by comparing the observed with modeled solar radiation, and used this scaling factor to scale the TUV 166 model derived photolysis rates. A dilution rate of 3/86400 s⁻¹ was applied for all non-167 constraint species and simulation days through a stepwise sensitivity test by adjusting 168 169 it from $1/86400 \text{ s}^{-1}$ to $5/86400 \text{ s}^{-1}$ (see details in Text S1) for the best reproduction of O₃. For each model run (i.e., each daily model simulation), it was performed on a daily 170 171 basis with intervals of 24 hours spanning from 0:00 to 23:00, and each individual model 172 simulation was run to reach one-day diurnal steady state. The detailed descriptions of 173 box model operation were provided in our previous study (Li et al., 2021).

174 Since the box model simulations are conducted with intervals of 24 hours spanning 175 from 0:00 to 23:00 local standard time (Wang et al., 2018), the entire campaign 176 observations were taken into four patterns of time scale (i.e., five-month, monthly, 177 weekly, and daily) as diurnal average format for model input (Figure 1). Note that some days or weeks were not modeled due to some missing data in the measurements. 178 179 Nevertheless, the total simulation number at the daily (i.e., 100, 81, and 114 days for 180 TZ, BJ and XD respectively) or weekly (i.e., 21, 20, and 19 weeks for TZ, BJ, and XD 181 respectively) scale was representative of the five-month campaign. Specifically, the 182 entire campaign data classified as four patterns of time scale were modeled as base runs. 183 Then we performed the sensitivity modeling to calculate the relative incremental 184 reactivity (RIR) of precursors by adjusting the input concentrations in the base runs (see 185 next section) (Lu et al., 2010a).

186 2.3 Calculation of net O_x production rate P(O_x) and Relative incremental 187 reactivity (RIR)

188 Considering the rapid chemical titration of NO to NO_2 in the presence of O_3 , the 189 concept of 'total oxidant' ($O_x = O_3 + NO_2$) has been widely used to represent the actual photochemical production of O_3 (Lu et al., 2010). Similar to those described in previous studies using the 0-D box model (He et al., 2019; Lyu et al., 2016), the net or in-situ O_x production rate ($P(O_x)$) is defined as the difference between the O_x gross production rate ($G(O_x)$) and the O_x destruction rate ($D(O_x)$), which is formulated in accordance with Eq. (1):

195

$$P(0_x) = G(0_x) - D(0_x)$$
(1)

196 The O_x gross production rate ($G(O_x)$), or the total chemical production of O_x , is 197 calculated by summing the rates of oxidation of NO by HO₂ and RO₂ radicals in 198 accordance with Eq. (2):

$$G(O_x) = k_{\text{HO}_2 + \text{NO}}[\text{HO}_2][\text{NO}] + \sum k_{\text{RO}_{2,i} + \text{NO}}[\text{RO}_{2,i}][\text{NO}]$$
(2)

The O_x destruction rate ($D(O_x)$), or total chemical loss of O_x , is calculated by summing O_3 photolysis, the reaction of O_3 with OH, HO₂ and alkenes, as well as the reaction between NO₂ and OH, as described by Eq. (3):

203 $D(O_x) = k_{O^1D+H_2O}[O^1D][H_2O] + k_{OH+O_3}[OH][O_3] + k_{HO_2+O_3}[HO_2][O_3] +$ $204 k_{alkenes+O_3}[alkenes][O_3] + k_{OH+NO_2}[OH][NO_2]$ (3)

Concentrations of radicals and intermediates are obtained from the outputs of the O-D box model. The k values in Eq. (2) and (3) represent the rate constants of the corresponding reactions, respectively. The subscript '*i*' in Eq. (2) represents the individual RO₂ species.

Additionally, relative incremental reactivity (RIR) has been widely used as a metric to quantify the O₃-precursor relationship, and it can be derived from the 0-D box model (MCMv3.3.1) by changing the input mixing ratios of its precursors (Sillman, 2010; Xue et al., 2014a). The RIR is defined as the ratio of percentage change in net O_x (O_x = O₃ + NO₂) production rate $P(O_x)$ (Li et al., 2021) to percentage change of concentration of precursor X. The RIR of a specific precursor X is described in Eq. (4):

215 $\operatorname{RIR}(X) = \frac{[PO_{X}(CX) - PO_{X}(CX - \Delta CX)]/PO_{X}(CX)}{\Delta CX/CX}$ (4)

Here, X is a specific precursor (i.e., NO_x, CO or grouped / individual VOC species), 216 217 CX is the measured concentration of precursor X, and ΔCX is the hypothetical 218 concentration change ($\Delta CX/CX = 10\%$ in this study in accordance with the previous 219 studies (Lyu et al., 2016; Wang et al., 2018)). PO_x(CX) represents the simulated O_x 220 production rate in a base run, whereas $PO_x(CX-\Delta CX)$ is the simulated O_x production 221 in a second run with a hypothetical concentration change of species X. Obviously, a 222 higher positive value of RIR(X) suggests a more effective way of reducing the ambient 223 O₃ production rate by reducing X (Ling et al., 2011; Zhang et al., 2008a).

In this study, the O₃ precursors were divided into four major categories, including anthropogenic VOC (AVOC), biogenic VOC (BVOC, only isoprene in this study), CO and NO_x (Tan et al., 2019b). AVOC was further divided into three subcategories: alkanes, aromatics and alkenes* (the asterisk denotes anthropogenic alkenes, excluding isoprene in this study) (Yu et al., 2020a). As mentioned, RIR method was applied mainly to evaluate the O_3 -NO_x-VOC sensitivity and determine the photochemical regimes among four patterns of time scale. Thus, we calculated the RIR values of major precursor groups (i.e., AVOC, BVOC, CO, NO_x, alkanes, alkenes* and aromatics) to further quantify the O₃-precursor relationship.

In general, O_3 formation chemistry is usually classified into three regimes (i.e., VOC-limited, transitional and NO_x-limited) (He et al., 2019; Wang et al., 2018). In this study, RIR_{NOx}/RIR_{AVOC} (the ratio of two RIR values) was used as a metric to classify the photochemical regimes (Li et al., 2021). Specifically, RIR_{NOx}/RIR_{AVOC} value of less than 0.5 was defined as VOC-limited regime, greater than 2 as NO_x-limited regime, and from 0.5 to 2 as transitional regime (see **Text S2** and **Table S4**) (Li et al., 2021).

239 **3 Results and discussion**

240 **3.1 Overview of the field campaign**

241 Figure 2 shows the time series of measured meteorological parameters and O_3 as 242 well as its precursors at the three sites during the whole campaign. In general, the 243 temperature (T) and relative humidity (RH) were basically consistent at the three sites, 244 while the wind speeds were different, which suggests that the three sites had an overall consistent meteorological condition. In addition, the time series of UV-A radiation was 245 246 shown in Figure 2d, which was only available from one urban site of Zibo but expected 247 to represent the whole Zibo city in this study. Following the protocol of the previous 248 studies (Lyu et al., 2019; Wang et al., 2017b; Xue et al., 2014), the time series of 249 photolysis rates (e.g., J_{NO2} (Figure 2e) and J_{O1D} (Figure 2f)) were calculated from 250 TUVv5.2 model and further scaled from UV-A radiation measurement.

251 As shown in Figure 2g, we found that severe O_3 pollution was observed at the 252 three sites throughout the whole campaign. According to our measurements at the three 253 sites in Zibo, the averaged O₃ concentration during the whole observational period was 254 around 50 ppby, while the daily maximum of O₃ concentrations for some extremely 255 polluted periods were nearly 120-150 ppbv (Figure 2g). Interestingly, the O₃ 256 concentrations at the three sites were generally consistent, while the levels of its 257 precursors (e.g., VOC, NO_x) were obviously different (Figure 2h-k), which implies the 258 site-to-site variation of O₃ formation chemistry for the whole Zibo city.

Generally, OH reactivity (or OH loss rate, k_{OH}) is widely applied to quantify the capacity of OH consumption by VOCs (Tan et al., 2019a). According to **Table S3**, the BVOC reactivity (k_{BVOC} , $3.5 \pm 4.1 \text{ s}^{-1}$) in TZ were highest among the three sites. As BJ was mainly influenced by the emission from urban region, it showed the highest AVOC reactivity (k_{AVOC} , $6.8 \pm 6.3 \text{ s}^{-1}$) and NO_x level ($31.1 \pm 28.6 \text{ ppbv}$). In addition, XD showed the highest level of alkenes* reactivity of $4.0 \pm 3.2 \text{ s}^{-1}$ within the three sites, and the local petrochemical industry nearby XD area may explain such characteristic

266 (Li et al., 2021).

267 **3.2 Evaluation of box model performance**

268 The measured O₃ concentrations were not constrained in our MCMv3.3.1 box 269 model calculation, thus the model performance could be quantitatively assessed by 270 comparing the modeled O₃ (from base runs) with the measured O₃. Figure S3-S8 show 271 the time series of simulated and observed O₃ concentrations at four patterns of time 272 scale. In most cases, the box model simulation could accurately capture the level and 273 variation trend of the observed O3. However, on some days the modeling results 274 underestimated or overestimated the O₃ concentrations, particularly the 275 underestimation of nocturnal O₃ concentrations. Such discrepancies between the 276 simulated and observed O₃ were likely due to limitations in explicit representations of 277 atmospheric and transport processes (i.e., the horizontal and vertical transport process 278 of ground ozone) by 0-D modeling approach (Lyu et al., 2019; Yu et al., 2020b). 279 Specifically, ozone simulated by the 0-D box model is considered as in-situ 280 photochemical processes from its precursors. Unlike the 3-D air quality model, 0-D box 281 model usually simplifies the representation of the physical processes (i.e., deposition 282 and advection) (Lu et al., 2010a; Sillman, 2010). Note that some adjustable parameters 283 (e.g., radiation scheme, dilution rate) were remained consistent in all of our model 284 calculations, which ensured the comparability of model results to the greatest extent.

285 The index of agreement (IOA) (Li et al., 2021; Lyu et al., 2016), Pearson's correlation coefficient (r) and root mean square error (*RMSE*) were jointly used as 286 287 statistical metrics to quantify the goodness-of-fit between the simulated and observed 288 O₃ concentrations. Table S5 summarizes these statistical metrics for each site at various 289 patterns of time scale. Because any single statistical metric has its own limitations, 290 using these three indicators conjointly provided a more comprehensive evaluation of the model performance (Su et al., 2018b). Generally, higher IOA and r as well as lower 291 292 RMSE indicate better agreement between the simulated and observed values (Wang et 293 al., 2018; Willmott, 1982). As shown in Table S5, slightly reduced correlation was 294 observed as the time scale changed from the wider (i.e., five-month scale) to the 295 narrower (i.e., daily scale) pattern, which is understandable because of the enlarged 296 statistical samples in the narrower pattern of time scale.

In summary, TZ showed the best performance of the box model simulation, followed by XD and BJ, regardless of any statistical metrics or different patterns of time scale, which may be associated with the optimized dilution rate for non-constraint species in model configuration. The overall model performance in this study (i.e., a dayto-day *IOA* of approximately 0.90 for TZ) was close to or slightly better than those reported in previous studies, such as IOA = 0.74 in Hong Kong (Liu et al., 2019), *IOA* 303 = 0.74 in Wuhan (Lyu et al., 2016) and IOA = 0.90 in Jiangmen (He et al., 2019). 304 According to the above evaluation of base runs, our modeled results were acceptable 305 for the subsequent O₃-precursor relationship analysis described in the following 306 sections.

307 3.3 Month-to-month

308 Figure 3a-b presents the monthly RIR values of the major precursor groups at 309 each site, and the large variability of O₃-precursor relationship at spatiotemporal scale 310 (i.e., site-to-site and month-to-month) was observed. Specifically, in most months, XD generally showed the highest RIRAVOC among the three sites, followed by BJ and TZ. 311 312 In addition, RIR_{BVOC} showed similar level to RIR_{AVOC} in TZ, but much less than 313 RIR_{AVOC} in BJ and XD, which can be explained by the observed higher BVOC 314 reactivity in TZ than the other two sites (see Figure S9 and Table S3). Also, almost all the precursor groups showed positive RIR values, except negative RIR_{NOx} appeared in 315 316 BJ and XD in September. In addition, the RIR_{CO} values at the three sites suggested its limited role in O₃ formation at the three sites, compared with other major categories of 317 O3 precursors. Among the three subcategories of AVOC, alkenes* always had the 318 319 highest RIR values, followed by aromatics, while the contribution of alkanes to O₃ 320 formation can be ignored due to their near-zero RIR values. That sequence of O3-AVOC 321 sensitivity (alkenes* > aromatics > alkanes) indicated by the RIR analysis was 322 consistent with previous studies in some other Chinese cities (Su et al., 2018b; Tan et 323 al., 2019b). Significant monthly variations of O₃, NO_x, CO, VOC reactivity and 324 TVOC/NO_x ratios (in ppbC/ppbv, as a widely used simple metric to determine the 325 photochemical regime) (National Research Council, 1991) were also observed from 326 May to September (see Figure S9 and Table S3) at the three sites. For example, the 327 BVOC reactivity in TZ showed highest level among the three sites during the whole 328 campaign, and the AVOC reactivity in BJ showed more considerable variations in 329 different months, which indicated spatial and temporal variations of local primary 330 emission for O₃ precursors in Zibo city.

331 Figure 3c shows monthly RIR_{NOx}/RIR_{AVOC} at each site, which clearly reveals the 332 spatial and temporal variations in photochemical regimes. For instance, the 333 photochemical regime at the TZ site was considered to be transitional regime in May, 334 NOx-limited regime in June and July, and VOC-limited regime in August and September; whereas for a specific month like June, NOx-limited, VOC-limited, and 335 transitional regimes were generally identified for TZ, BJ, and XD respectively. Figure 336 337 5b shows good consistency between monthly TVOC/NO_x and RIR_{NOx}/RIR_{AVOC}, 338 suggesting that the changes of local emissions for O₃ precursors may partially explain 339 the considerable variation of O₃ formation chemistry in different months.

340 **3.4 Week-to-week**

341 Figure 4 shows the time series of week-to-week RIR values of major precursor 342 groups and RIR_{NOx}/RIR_{AVOC} at three sites in Zibo. Compared with month-to-month 343 results, Figure 4 further reveals the O₃-precursor relationship with more information in 344 temporal trends. The temporal variations in weekly RIRAVOC at the three sites generally 345 decreased and then increased, whereas weekly RIR_{NOx} represented an opposite temporal variation during the entire campaign. Additionally, weekly RIR_{BVOC} showed a trend of 346 347 first decrease and then increase at TZ, while it did not show clear temporal variation at 348 BJ and XD due to low values (Figure 4a-c). In general, RIR_{alkanes}, RIR_{alkenes*} and 349 RIR_{aromatics} showed a tendency consistent with that of the RIR_{AVOC} at three sites (Figure 350 4d-f). Overall, these phenomena were consistent among the three sites, though the 351 magnitude of RIR values varied site-to-site. In parallel, the temporal changing of O₃ 352 precursor (e.g., AVOC, NO_x) was also observed at the three sites during the entire 353 campaign (see Figure S10). For example, the weekly NO_x concentration showed an 354 overall trend of first decrease and then increase, while the AVOC reactivity showed a different temporal variation. Given the moderate correlation between weekly 355 356 TVOC/NO_x and RIR_{AVOC}/RIR_{NOx} (Figure 5c), the temporal variations of RIR values 357 and O₃ formation chemistry at the three sites may be partially elucidated by the emission 358 changes of O₃ precursors.

359 As shown in Figure 4g-i, all the three sites showed similar temporal trends of 360 RIR_{NOx}/RIR_{AVOC}, as it increased first and then decreased, though the magnitude of RIR_{NOx}/RIR_{AVOC} varied largely at each site. Such site-to-site variability of 361 RIR_{NOx}/RIR_{AVOC} suggests that the photochemical regime in a local scale was mainly 362 363 influenced by local emissions. By contrast, the site-to-site synchronization in temporal trend of RIR_{NOx}/RIR_{AVOC} suggests that the photochemical regime in a local scale may 364 365 also be influenced by the emissions in a regional area. Therefore, the long-term, week-366 to-week RIR_{NOx}/RIR_{AVOC} of multiple sites can further reflect the variability of ozone 367 formation regime at a large geographic scale.

368 3.5 Day-to-day

In this section, O₃-precursor relationship at the narrowest pattern of time scale was 369 identified in detail. Figure S11-S12 shows the time series of daily RIR values at three 370 371 sites in Zibo, where the temporal trend of RIR values was consistent with that at weekly 372 scale (Figure 4). Additionally, the time series of daily RIR_{NOx}/RIR_{AVOC} (Figure S13) 373 showed more irregular variations in temporal trends during the entire campaign, though 374 such temporal trends were overall consistent with that of weekly scale in Figure 4 g-i. 375 In summary, the time series of RIR values from the daily scale can provide more 376 informative variations and characteristics of O3-precursor relationship in temporal 377 trends.

378 Table 2 summarizes the number of days and proportions that were classified into the three photochemical regimes across each site and each pattern of time scale. Near-379 consistent proportions of O₃ formation regimes (using RIR_{NOx}/RIR_{AVOC} as a metric) 380 381 were shown among multiple patterns of time scale, whereas a variability of proportion 382 occurred among the three sites. The proportions of photochemical regimes changed 383 accordingly along with the time scale varied from wider to narrower pattern. Taking TZ 384 as an example, 20% (monthly) and 26% (daily) of the time was considered as VOClimited regime. The number of days and proportions for photochemical regimes 385 summarized at four patterns of time scales can reveal a more plausible and 386 387 comprehensive variation in ozone formation chemistry. Compared with patterns of 388 monthly and weekly scales, the results derived at a daily scale can reveal the temporal 389 variability of photochemical regimes more comprehensively. Note that the 390 photochemical regime proportion obtained from the day-to-day scale has an advantage 391 due to the large number of statistical samples.

392 **3.6 Comparison among different patterns of time scale**

393 This section gives a more comprehensive understanding of the campaignaveraging O₃-precursor relationship by comparing the similarities and differences of 394 395 the results from various patterns of time scale. The overall O₃-precursor relationship for 396 the entire campaign can be quantified by averaging the RIR values from the individual simulation runs depending on the chosen time scale (e.g., five simulation runs for 397 398 monthly scale in this study). Therefore, four sets of logical and comparable results can 399 be derived to represent the campaign-averaging O₃-precursor relationship, as four 400 patterns of time scale (i.e., five-month, monthly, weekly, and daily) were treated in this 401 study.

402 Figure 6 shows the averaged RIR values of the major precursor groups at different 403 patterns of time scale. As the time scale changed from wider (i.e., five-month scale) to 404 narrower (i.e., daily scale) pattern, all three sites showed increases in the means of 405 RIR_{AVOC} and RIR_{alkenes*} as well as decreases in averaged RIR_{NOx}, whereas the averaged 406 RIR of other precursors (i.e., BVOC, CO, alkanes and aromatics) did not vary obviously 407 (see Table S6). Comparing with the O_3 -VOC-NO_x sensitivity at the daily scale, the results obtained at the five-month scale underestimated O₃-AVOC sensitivity (indicated 408 409 by averaged RIR values) by 48% (TZ), 66% (BJ), and 49% (XD), and overestimated O₃-NO_x sensitivity by 37% (TZ), 142% (BJ), and 144% (XD). We performed 410 411 comprehensive uncertainty analysis for model input and output results, which was 412 assessed through statistical methods (see details in Section 3.7). We found that the 413 model-derived RIR values may become more uncertain when the input dataset was 414 averaged into a wider diurnal pattern (i.e., five-month scale), which may explain the discrepancy of RIR values between five-month scale and daily scale. We expect that 415

416 such discrepancies derived from different patterns of time scale could widely exist in 417 many other world areas. Note that the mean RIR values were generally consistent 418 among the four patterns of time scale within a reasonable range (within 25-75th quantile 419 and standard deviation, see **Figure 6** and **Table S4**), suggesting that any selected pattern 420 of time scale could reasonably derive the campaign-averaging O₃-precursor relationship.

421 Figure 7 further shows the variations in photochemical regimes (defined by 422 RIR_{NOx}/RIR_{AVOC}; see Text S2 and Table S4 for details) for each pattern of time scale. Specifically, TZ was mainly considered as transitional regime for the entire campaign 423 424 period, whereas its variations covered three photochemical regimes, which was consistent with the results from Table S6. BJ was generally identified as VOC-limited 425 426 regime, whereas some days were also grouped into transitional regime. XD was 427 considered as primarily between VOC-limited and transitional regime, and its 428 variations also spanned three photochemical regimes. Compared with the five-month 429 pattern, it was further found that the averaged RIR_{NOx}/RIR_{AVOC} from other time scale 430 patterns (i.e., monthly, weekly, and daily) were higher (12% to 20% for TZ; 38% to 431 153% for XD) or lower (21% to 65% for BJ) than that from five-month scale. Note that 432 the above discrepancies in photochemical regime derived from multiple patterns of time 433 scale may influence the development of targeted O₃ control strategies. In summary, the 434 photochemical regime derived by averaging RIR_{NOx}/RIR_{AVOC} from the daily scale (see 435 Table S6) suggests that the three sites mainly followed the sequence of TZ (1.34 \pm 436 1.39 > XD (0.67 ± 1.49) > BJ (0.16 ± 0.65).

437 In addition, the temporal variations of $TVOC/NO_x$ in different timescales were 438 identified during the whole campaign, and good correlations between observed 439 $TVOC/NO_x$ and model derived RIR_{NOx}/RIR_{AVOC} at four patterns of time scale were also 440 found (see **Figure 5**). Such consistency suggests that both metrics can reasonably 441 reflect the variation of photochemical regimes, which can also improve the reliability 442 of our box model simulation.

443 The consistency and difference of model output (summarized in Table S7) are quantified by the statistical methods of Pearson's correlation coefficient (Hu et al., 2018) 444 445 and paired-samples t-test analysis (Wang et al., 2016). In particular, we assess and compare the degree of significance of differences among multiple patterns of time scale 446 by the p values (a statistical significance assuming at p < 0.05) through paired-samples 447 448 t-test and Wilcoxon matched-paired signed-rank test (non-parametric statistics) 449 (Chiclana et al., 2013). Figure 8a shows high Pearson's correlation coefficients (with values all above 0.85, p < 0.01) were found among four patterns of time scale, and the 450 higher correlation coefficient was identified between the two closer patterns. Figure 451 452 8b-c shows that the differences among multiple patterns of time scale were nonsignificant using Paired-samples t-test analysis and Wilcoxon matched-pair signed-rank 453 454 test respectively. Furthermore, their results indicate that more significant difference was

recognized between the two distant patterns (e.g., daily and five-month), which is consistent with the results of Pearson's correlation analysis. Noted that the discrepancy between the two distant patterns was not significant but non-negligible (e.g., p = 0.092of Wilcoxon matched-paired signed-rank test between five-month and daily patterns).

459 The influence of different patterns of time scale on deriving RIR values from 460 individual AVOC species was further investigated. Briefly, quantifying the relative 461 contribution of individual AVOC on O₃ formation based on RIR calculation is beneficial to the development of cost-effective AVOC control strategies (Zhang et al., 2021). 462 463 Figure 9 shows the averaged RIR values of individual AVOC species (i.e., top 10) at 464 different patterns of time scale (i.e., five-month, month-to-month, week-to-week) at 465 three sites in Zibo. As shown in Figure 9, the 10 individual AVOC species at the three sites were selected according to the top 10 highest RIR from five-month pattern. All 466 467 three sites showed that the RIR of individual AVOC species increased gradually as the 468 time scale changed from the wider (i.e., five-month) to narrower (i.e., weekly) pattern, 469 which was consistent with the earlier discussion (see Figure 6 and Table S6) of O₃-470 AVOC sensitivity derived from four patterns of time scale. The results also indicate that 471 the choice of time scale pattern has a limited effect on deriving high-ranking AVOC species (i.e., top 10) based on RIR calculations. 472

473 **3.7 Uncertainty analysis**

474 The uncertainty of model input was quantified in this section, which is embedded 475 in pre-processed dataset with multiple patterns of time scale. As showed in Figure 1, the daily simulation used the individual daily pattern to constrain model, while the input 476 477 dataset of averaged diurnal patterns (i.e., weekly, monthly, and five-month) is treated 478 by averaging individual daily pattern into different timescales. This averaging approach 479 will conceal the temporal variations of O₃ precursors and meteorological factors, 480 particularly for a long-term observational campaign. Figure S14 shows the distributions of the standard deviations for OH reactivity (k_{OH}) or concentration of O₃ 481 482 precursor groups at three averaged patterns of time scale at the three sites. As the time 483 scale changed from wider (i.e., five-month scale) to narrower (i.e., weekly scale) pattern, 484 the uncertainty (indicated by the average, median and 25%-75% quantile) decreased 485 accordingly. In addition, meteorological factors such as temperature and irradiation also 486 play an important role on O₃ formation, especially these meteorological parameters can 487 vary greatly over a long observational period (Boleti et al., 2020; Liu et al., 2019b; 488 Weng et al., 2022). Therefore, the masked temporal variation of these meteorological 489 factors behind the averaged input dataset would also result in model uncertainty.

490 Moreover, it has been widely recognized that the uncertainty for 0-D box model 491 simulation mainly arises from the constraint of observation dataset and the 492 configuration of model scheme. Note that constraints with more species from 493 measurements (or including as many species as possible) would lower its uncertainty 494 from the chemical box model simulation (Wolfe et al., 2011, 2016). Nevertheless, due to the measurement limitation in our field campaign, we are unable to measure some 495 496 important atmospheric species (i.e., HONO and oxygenated VOC (OVOC)), and these may arise uncertainty in box model simulation. For instance, Xue et al., (2021) 497 498 performed a sensitivity test for HONO constraint in their box model simulation, and 499 they showed that without HONO constraint would lead to O₃ photochemical production rate decreasing by 42%. More recently, Wang et al., (2022) obtained a comprehensive 500 501 VOC dataset at Guangzhou, and their results showed that box model simulation without 502 OVOCs constraints would underestimate the productions of ROx and O₃. Besides, both 503 gaseous HNO₃ and organic nitrates can result in interferences on NO_x measurement by 504 chemiluminescence technique, which may arise uncertainty in our box modelling (Ge et al., 2022; Uno et al., 2017; Xu et al., 2013). Since the accurate NO_x measurement is 505 506 essential in determining the photochemical regime, more in-depth studies on NO_x 507 measurement uncertainty in box model simulation are required in the future. In addition, 508 the parameter configuration of model scheme is essential to derive a reliable and valid model output, such as dilution rate as an important model technical parameter. We 509 510 performed a stepwise sensitivity test for this parameter to obtain an optimized dilution 511 rate, and assigned it to all non-constraint species, which can reduce uncertainty in box model simulation (see details in Text S1). Also, the dry and/or wet deposition of 512 513 pollutants is an important atmospheric physical process, which has been mostly 514 parameterized in emission-based chemical transport modeling but very limited in box 515 model, as most of the primarily emitted species are already constrained from 516 measurements. Xue et al., (2014) considered O₃ deposition into box model simulation, 517 and their result showed negligible contribution of O₃ deposition to total O₃ destruction 518 rates. As for this work, we are unable to consider the deposition due to the difficulty in 519 representing and parameterizing this term in the 0-D box model. Nevertheless, 520 deposition of O₃ and other species may be one of the uncertainties during box model 521 simulation, which is worth further study in the future.

522 4 Summary and implications

523 Our present results suggest that comprehensively understanding of multiple 524 patterns of time scale is conductive to formulating a more accurate and robust O₃ control 525 strategy. Specifically, as identified from the narrower patterns of time scale (i.e., weekly 526 and daily), the site-to-site photochemical regime indicated by RIR_{NOx}/RIR_{AVOC} showed 527 various magnitudes but a synchronous temporal trend. This indicates that the O₃ 528 formation regime in a city area can be influenced by local and regional emissions jointly. 529 The reason behind this phenomenon is not clear at present, and we believe that further 530 investigation on the synergetic effect of local and regional emission reduction for O₃

531 control would help elucidating this observation. It was also found that the campaign-532 averaging photochemical regimes showed overall consistency but non-negligible 533 variability among the four patterns of time scale, which was mainly due to the 534 embedded uncertainty in model input dataset with averaged diurnal patterns. This 535 implies that comparison among multiple patterns of time scale based on RIR analysis 536 is useful to derive the O₃-precursor relationship more accurately and reliably.

537 Moreover, the high-ranking AVOC species (i.e., top 10) based on RIR calculations were overall consistent from the narrow to wide patterns of time scale. Table S8 538 539 summarizes the total run number of box model for different patterns of time scale. It is 540 known that large-scale computing capacity and computational efficiency were required 541 in the narrower pattern of time scale (e.g., 2760 simulation runs in weekly scale in this 542 study). Considering the difficulties of performing long-term and continuous online 543 measurements in some environments, it is also advisable to identify the high-ranking 544 VOC species from the campaign-averaging diurnal pattern in box model simulation.

545 In this study, we explored the non-linearity of O₃-precursor relationship in a way driven by the actual daily / weekly / monthly variability around the distribution. Our 546 results highlight the importance to quantitatively test the impact of different timescales 547 on photochemical regime determination, as there is uncertainty embedded in model 548 549 input dataset when averaging individual daily pattern into different timescales. Such 550 understanding would be complementary in developing more accurate O₃ pollution 551 control strategy, particularly as the long-term O₃-precursor observations (e.g., from 552 several months to years) are becoming more available than before in many places of 553 China. In addition, site-to-site differences of model-derived photochemical regimes 554 also underlines the importance of developing target O₃ control strategy for different 555 areas in a city scale. Specifically, according to the averaged RIR_{NOx}/RIR_{AVOC} at daily 556 pattern, the derived photochemical regime was transitional for TZ (suburban) and XD (suburban), while VOC-limited for BJ (urban). This implies that for mitigating ozone 557 558 pollution in Zibo city, more endeavors should be devoted to the anthropogenic VOC 559 reduction in urban areas, while strengthening the synergetic mitigation of VOC and NO_x emissions at the same time in other suburban areas. Although the above 560 561 implications for O₃ control were derived from a case study in a major prefecture-level 562 city (Zibo) of northern China, the developed approach by integrating multiple patterns 563 of time scale in the present work can be used to other regions, particularly the on-going 564 "One City One Policy" campaign (2021-2023) for O₃ control in many cities in China.

905 Table 2. Summary of the number of days (for model calculation) and proportions that
906 were classified into the three photochemical regimes across each site and multiple
907 patterns of time scale.

	Site	Photochemical regime: RIR _{NOx} /RIR _{AVOC}							
Patterns of Time scale		NO _x -1	imited: >2	Transit	tion: 0.5~2	VOC-limited: <0.5			
		No. of days	Proportion	No. of days	Proportion	No. of days	Proportion		
	ΤZ	2	40%	2	40%	1	20%		
Month-to-month	BJ	0	0%	3	60%	2	40%		
	XD	0	0%	2	40%	3	60%		
	ΤZ	7	33%	8	38%	6	29%		
Week-to-week	BJ	0	0%	10	50%	10	50%		
	XD	3	16%	6	32%	10	53%		
	ΤZ	29	29%	45	45%	26	26%		
Day-to-day	BJ	0	0%	21	26%	60	74%		
	XD	20	18%	23	20%	71	62%		

910 Figure 1. Schematic diagram of the dataset treatment to derive four patterns of time scale for 0-D box

911 model input. Note that the four patterns (i.e., five-month, monthly, weekly, and daily) were the diurnal

912 average of the initial dataset. This diagram takes one site and several input measurements (temperature,

913 toluene, and NO₂) as examples.

915 Figure 2. Time series of meteorological parameters, O₃ and its precursors (i.e., CO, NO_x, VOCs)

⁹¹⁶ throughout the whole campaign at the three sites in Zibo.

919 Figure 3. Time series of month-to-month RIR values of major precursor groups and RIR_{NOx}/RIR_{AVOC} at

923

Figure 4. Time series of week-to-week RIR values of major precursor groups and RIR_{NOx}/RIR_{AVOC} at three sites (TZ, BJ, and XD) in Zibo. The blue lines in (g)-(i) are the three points moving average of RIR_{NOx}/RIR_{AVOC} value.

927 Figure 5. The correlations of TVOC/NO_x with RIR_{NOx}/RIR_{AVOC} at multiple patterns of time scale at the 928 three sites in Zibo.

931 Figure 6. Distribution of RIR values of major precursor groups in multiple patterns of time scale at three

sites (TZ, BJ, and XD) in Zibo.

934 Figure 7. Distribution of RIR_{NOx}/RIR_{AVOC} (indicator of photochemical regime) in multiple patterns of

935 time scale at three sites (TZ, BJ, and XD) in Zibo.

936

937 Figure 8. The statistical analysis results of RIR values (from Table S6) at multiple patterns of time scale:

938 (a) Pearson's r correlation analysis (all the results have passed statistical significance assumed at p < 939 0.01), (b) Paired-samples t-test analysis (*p values refer to differences with a statistical significance

assumes at p < 0.05), (c) Wilcoxon matched-pair signed-rank test (* p values refer to differences with a

941 statistical significance assumes at p < 0.05).

943 Figure 9. Averaged RIR values of individual AVOC species (top 10) at different patterns of time scale at

944 three sites (TZ, BJ, and XD) in Zibo. The error bars represent the standard deviations of the mean.
