Abstract. Recent developments in atmospheric remote sensing from satellites have made it possible to resolve daily emission plumes from industrial point sources, around the globe. Wind rotation aggregation coupled with statistical fitting is commonly used to extract emission estimates from these observations. These methods are used here to investigate how the Coriolis Effect influences the trajectory of observed emission plumes, and to assess the impact of this influence on satellite derived emission estimates. Of the sixteen industrial sites investigated, nine showed the expected curvature for the hemisphere they reside in, five showed no or negligible curvature, and two showed opposing or unusual curvature. The sites which showed conflicting curvature reside in topographically diverse regions, where strong meso-gamma scale (2 - 20 km) turbulence dominates over larger synoptic circulation patterns. For high curvature cases the assumption that the wind-rotated plume aggregate is symmetrically distributed across the downwind axis breaks down, which impairs the quality of statistical fitting procedures. Using annual NO_x emissions from Matimba power station as a test case, not compensating for Coriolis curvature resulted in an underestimation of $\sim 9\%$ on average for years 2018 to 2021. This study is the first formal observation of the Coriolis Effect and its influence on satellite derived emission estimates, and highlight both the variability of emission calculation methods and the need for a standardised scheme for this data to act as evidence for regulators.

1 Introduction

For the past three decades, national space agencies and private industry have been launching satellite-based instruments to monitor and evaluate atmospheric composition, atmospheric chemistry and anthropogenic emissions around the world. These instruments use absorption-based spectroscopy and interferometry to derive column counts of potentially harmful pollutants, and have enhanced our understanding of the impact these species have on air quality and the environment. New high-resolution instruments, such as the TROPOspheric Monitoring Instrument (TROPOMI), can resolve emission plumes from large industrial point sources such as power generation, industrial fabrication and oil refining processes (Anema, 2021; Goldberg et al., 2019; Ialongo et al., 2021; Wang et al., 2022). A suite of methods have been developed to derive emission estimates from both daily and time aggregated observations of these large sources (Beirle et al., 2011, 2019; de Foy et al., 2015; Fioletov et al., 2015; Hakkarainen et al., 2021), providing a potential avenue for these instruments to assist with regulation and to constrain bottom

up emission estimates (Marais et al., 2021; Pope et al., 2021; Potts et al., 2021). Emissions from these sources are often distinct, thermally buoyant and can extend over 0 - 20 km vertically and 10 - 200 km horizontally, where large scale atmospheric effects may progressively influence the dispersion and trajectory of the plume as it travels downwind. Here we investigate the influence of the Coriolis effect on large industrial emission plumes using observations of Nitrogen Dioxide (NO₂) from TROPOMI, and explore the impact of Coriolis induced curvature, plume geometry and wind fields on satellite-derived emission estimates from large point sources.

2 Data and Methods

2.1 TROPOMI NO₂

TROPOMI was launched by ESA in October 2017 on-board the Sentinel-5 Precursor satellite. TROPOMI is a nadir viewing (downward facing) short wave spectrometer, observing in the UV-Vis (270 – 500 nm), NIR (710 – 770 nm) and SWIR (2314 – 2382 nm) ranges (Veeffkind et al., 2012). It has a spatial resolution of 5.5 × 3.5 km at nadir (7 x 5.5 km for SWIR), and a revisit time of around 13.30 local time each day. TROPOMI data products include, but are not limited to, nitrogen dioxide (NO₂), sulphur dioxide (SO₂), carbon monoxide (CO), methane (CH₄) and ozone (O₃), each with varying sensitivity, resolution and precision. For this study, tropospheric NO₂ from TROPOMI is used as it has a comparatively short photo-chemical lifetime of 2 – 24 hours (Beirle et al., 2011; Shah et al., 2020; Valin et al., 2013), so elevated tropospheric column counts are usually strongly correlated spatially with the emitting point source. This correlation enables more accurate source attribution and plume isolation for emissions from anthropogenic sources such as large industry and populous urban environments (Goldberg et al., 2020), compared to other longer lived pollutants. The TROPOMI processor upgraded to version 2.2.0 in July 2021, which resulted in a 10-15% increase in tropospheric column NO₂, particularly over polluted scenes with small cloud fractions (Eskes et al., 2019). Here the S5P-PAL product has been used, where older observations have been reprocessed with the updated processor to achieve a better retrieval and to ensure consistency across the time frame, harmonising the dataset. For this study, data from May 2018 to November 2021 was used, and observations have been over-sampled onto a 0.01 x 0.01° regular grid, following the sub-pixel sampling approach of Pope et al. (2018). A quality flag of 0.75 was used as per the S5P-NO₂ user manual (Eskes et al., 2019), which filters out cloud contaminated pixels and poor quality retrievals. Furthermore, at least 75% of the possible pixels within a region around the source were required to pass the quality filter for that daily observation to be included in the aggregate. This region was defined as ± 20 km from the site perpendicular to the wind direction and from –20 km to +60 km along the wind direction, for each observation, which discards observations where there is not sufficient coverage over the downwind region. The number of observations included in each aggregate is annotated on the figures as "n".

2.2 Site selection

In order to explore the impact of the Coriolis Effect on wind rotation aggregation, several sites were investigated. Selection was based on latitude and three additional criteria: (i) 50 km from any large urban or industrial source, to avoid overlap of

55 multiple plumes. (ii) Site of considerable size to produce a plume that can be detected by TROPOMI, generally > 1000 MW
 capacity for a power station. Note higher capacity does not equate directly to higher emissions. (iii) In operation during the
 2018 – present operational lifetime of TROPOMI. Sites were identified from the Global Power Plant Database (2018) and the
 point source emission catalogue developed by (Beirle et al., 2021). In total sixteen sites were investigated, and their details are
 outlined in Table 1. Fifteen sites were coal/oil fired power stations, to allow for more direct comparisons. The remaining site is
 60 a large copper mining/smelting operation.

2.3 Wind Rotation Aggregation

Wind rotation aggregation is a well-established method for combining multiple observations whilst preserving the structure of an emission plume. Pioneered by Pommier et al. (2013), this approach has been used for various satellite based studies of point source emissions, such as cities (Goldberg et al., 2019), power stations (Fioletov et al., 2015; Hakkarainen et al., 2021), fertiliser plants (Clarisse et al., 2019; Dammers et al., 2019) and oil refineries (Potts et al., 2021). Each observation that passes quality filtering requirements (Fig. 2a) is rotated so that the wind vector is aligned to a pre-determined axis, in this case to the West-East direction (Fig. 2b). This process is repeated for every observation that passes quality filtering requirements to produce the wind rotated aggregate (Fig. 2c). The angle of rotation is found from the angle the wind vector at the origin/industrial site makes with the chosen axis of rotation. The entire observation is rotated through this angle to achieve alignment. This is done using Equation 1, where lon_i and lat_i are the coordinates of each pixel corner in the observation and the angle between the wind vector and the East direction is θ_{wind} . This allows for all quality data to be used, and preserves the upwind-downwind profile of the emission plume (de Foy et al., 2015; Fioletov et al., 2015).

$$\frac{lon'_i}{lat'_i} = \begin{pmatrix} \cos\theta_{wind} & -\sin\theta_{wind} \\ \sin\theta_{wind} & \cos\theta_{wind} \end{pmatrix} \frac{lon_i}{lat_i} \quad (1)$$

2.4 Wind data

To perform the analysis, information on the daily wind field for each observation at each site is required. As there are often no meteorological measurement stations within a reasonable distance to the sites, we therefore used modelled meteorology. Similar studies use ERA-5 reanalysis/interim wind fields, typically averaged from 0 - 500m (1000 - 950 hPa, Goldberg et al. (2019); Beirle et al. (2011)) or 0 - 800m in altitude (1000 - 900 hPa, Fioletov et al. (2015)). However, all sources investigated in this study; (a) emit from an elevated point, e.g. a 200-300 m tall chimney or stack, (b) are thermally buoyant and (c) are

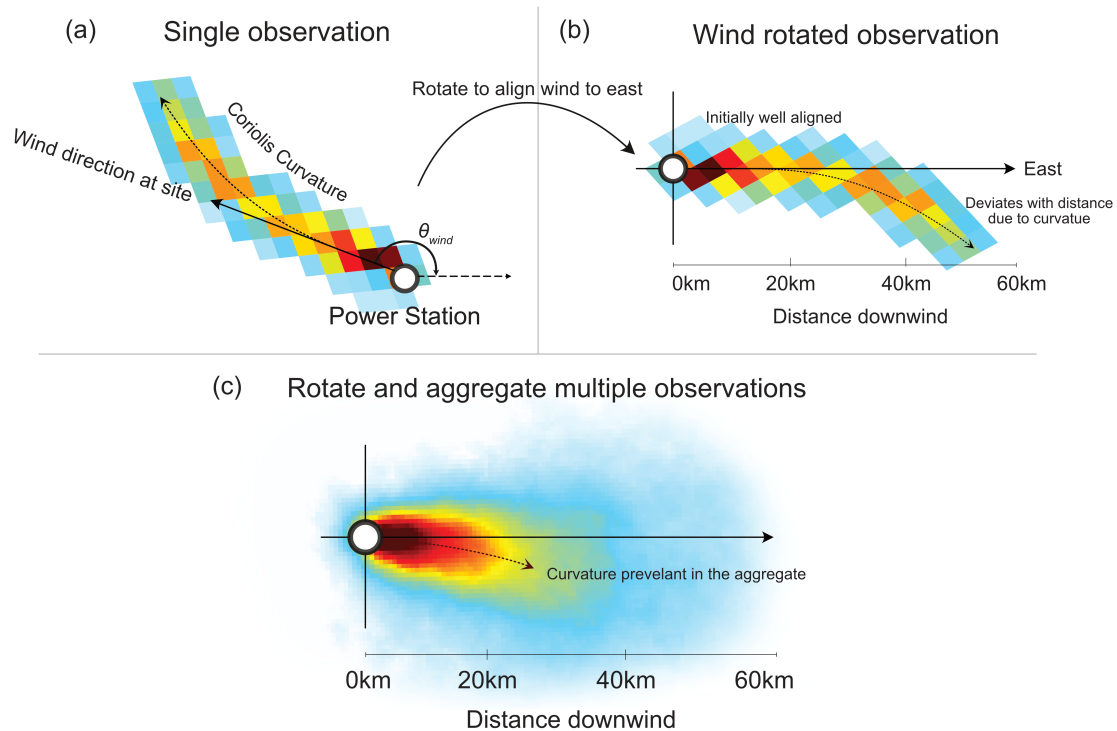

Figure 2. Illustration of the wind rotation method. (a) A single overpass from TROPOMI for Belchatow power station, on 03/06/2019, (b) plume is rotated so that its wind vector now points Eastwards. This initial stage of the plume is well aligned, but Coriolis curvature causes the latter parts of the plume to deviate from the downwind x-axis. (c) This rotational process is repeated for all quality observations and aggregated into a wind rotated average. On average the Coriolis Effect causes a clockwise deflection of the aggregate plume, increasing magnitude with distance.

80 often in higher altitude regions with lower surface pressures than 1000hPa. For this study we find the average surface pressure at each site for the study period from the ERA-5 reanalysis, and then take the average of the wind fields from this surface pressure to a decrease of 100hPa (equating to 700-1000m altitude depending on location), in an attempt to better describe winds in the lowest kilometre of the atmosphere relative to each site. Wind speeds will vary day to day, and so the plumes included in the aggregate will each experience different ventilation/dispersion rates, and the density distribution of pollutants

85 will vary. Furthermore, the wind speed experienced by each individual plume will vary with downwind distance and as the plume ascends vertically due to plume rise. These variations in wind speed between and within observations make it necessary to evaluate an “average” wind speed in order to infer emissions. The average needs to be both: (i) temporal (covering plumes on different days) and (ii) spatial (covering the same plume at different positions/heights within its trajectory). Only observations with wind speeds greater than 2 ms^{-1} were used to calculate emissions, as NO_2 decay under this condition is dominated by

90 chemical removal rather than by wind variability, which is not the case for calmer conditions (de Foy et al., 2014).

2.5 Coriolis Effect

Described mathematically by Gaspard-Gustave de Coriolis in 1835, the Coriolis force is an inertial force which acts on an object moving within a rotating coordinate system. The deflection caused by this force is known as the Coriolis Effect, which manifests in the atmosphere as large-scale clockwise deflections in the Northern Hemisphere (NH), and anticlockwise deflections in the Southern Hemisphere (SH) (Figure 3). The effect is greatest at the poles and negligible at the equator, and is greater for higher velocity wind speeds.

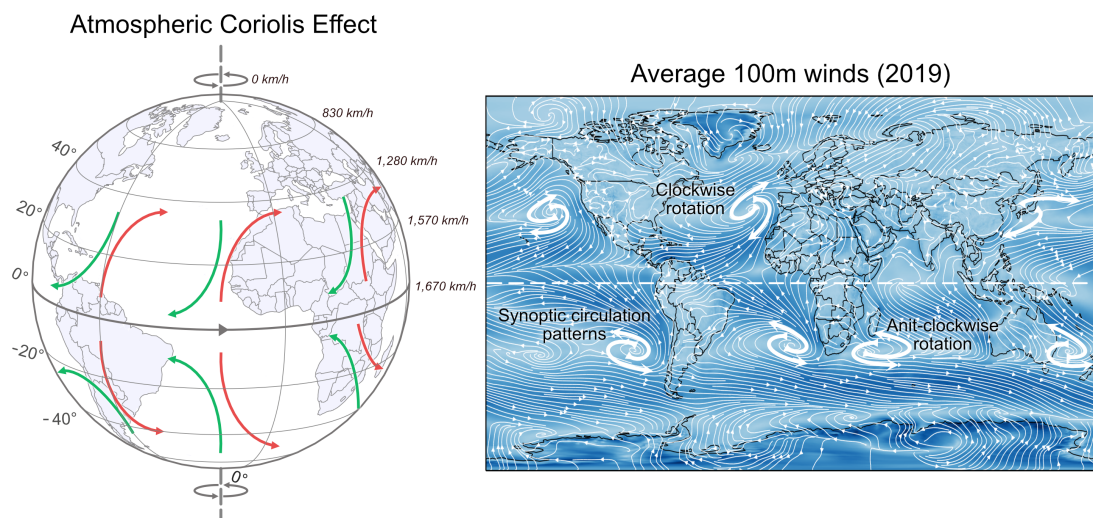

Figure 3. Illustration of the Coriolis Effect on atmospheric circulation patterns. The right hand plot is produced using an average of the ERA-5 100m winds for 2019 at 12pm

NO₂ emissions from large industrial sources can extend tens of kilometres, and can rise quickly due to their thermal buoyancy. Emission plumes do not move independently or freely within the atmosphere, but instead follow the given wind field. This wind field is influenced in part by the Coriolis Effect, and so it follows that observed emission plumes of significant magnitude will be deflected due to the Coriolis Effect as they move with the air mass. Furthermore, as the plume ascends due to its thermal buoyancy and the wind fields inherent vertical velocity, the plume may undergo an Ekman Spiral, which itself is a consequence of the Coriolis Effect. An Ekman Spiral occurs due to the differing wind speeds in the vertical column, illustrated in Figure 4a and 4b. As altitude increases, so does wind speed, and greater wind speeds experience greater curvature due to the Coriolis force, which leads to a deflection effect as altitude increases. This also introduces variability in the magnitude of deflection, as magnitude is dependent on altitude, and the altitude the plume reaches is dependent on its exit velocity, temperature and most importantly the meteorology, which will vary day by day. Some examples of strong emission plume curvature are given in Figure 4c. Plume curvature becomes an issue when observations are rotated into an upwind-downwind aggregate to derive emissions, as the averaged plume may exhibit strong curvature and be unevenly distributed to one side

of the common downwind axis. This deflection can be seen in some previous wind rotated averages in other works, such as
 110 Figure 4 of Hakkarainen et al. (2021), though its presence is not discussed. Coriolis effects are just one of many influences
 on the movement of the atmosphere, and various micro/meso/synoptic scale processes all contribute with variable intensity.
 Consequently, wind fields are not always dominated by the Coriolis effect, and can circulate in the opposing direction to the
 Coriolis Effect, or not at all, and so not every observation will show the "expected" curvature for that hemisphere. However, on
 average we expect emission plumes to curve in favour of the direction of the Coriolis force for that hemisphere.

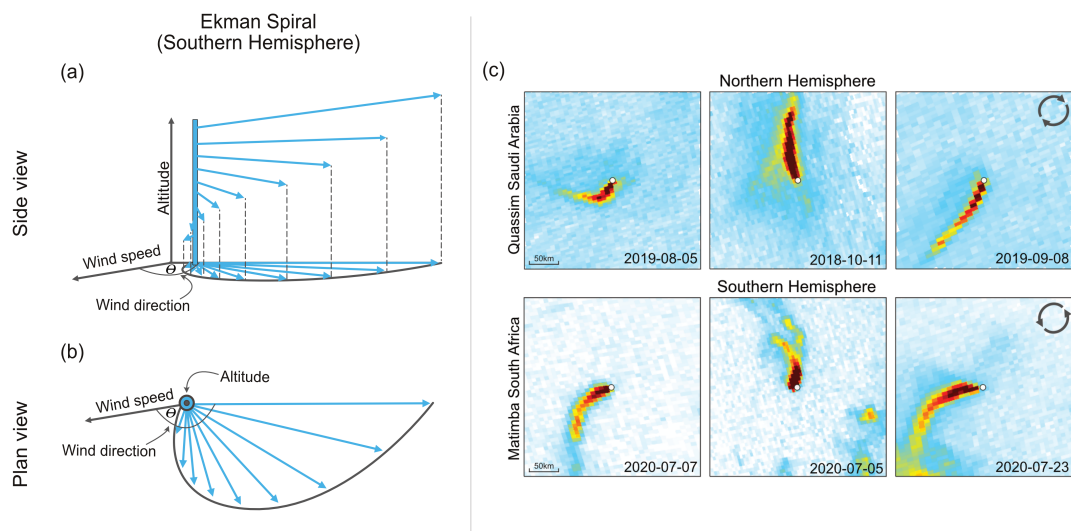

Figure 4. Example of Coriolis influence on NO₂ emission plumes from daily TROPOMI NO₂ observations above Quassim, Saudi Arabia and Matimba, South Africa. Power stations are shown as the central white dot of each observation.

115 2.6 Curvature fitting

In order to evaluate the curvature of the wind rotated plume, a “spine” was fitted to the aggregate. Firstly, the across-wind
 line density at 1 km transects perpendicular to the downwind axis were taken, as shown in Figure 5a. These profiles show a
 characteristic normal distribution, with the maxima transect located near the origin. The origin here corresponds to the west-east
 “downwind” axis used for the wind rotated aggregate. At greater distances downwind, the maximum of each transect laterally
 120 deviates with increasing distance from the origin, due to the curvature introduced by the Coriolis Effect. These profiles contain
 a degree of noise, and so a Gaussian smoothing procedure is applied, displayed in Figure 5b. This allows for the maxima
 of each transect to be more readily identified above the per-pixel variability. These peaks are then fitted with a second order
 polynomial to identify the “spine” of the plume and the degree of deviation from the origin, shown in Figure 5b as a dashed
 red line. This “spine” is shown in later figures as a dashed black line.

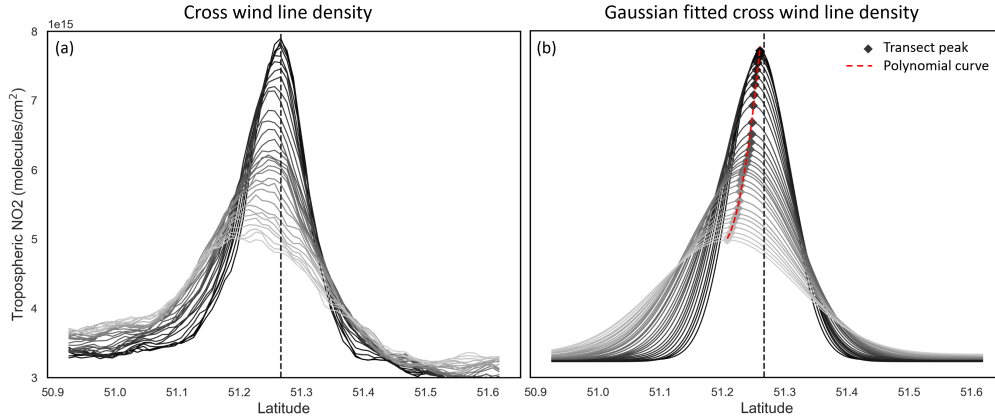

Figure 5. Across wind line density profiles (a) and Gaussian fitted line density profiles (b) taken at regular 1 km transects for the wind rotated average of Belchatow Power station in Poland. The transect at the origin is given by the black line, with the gradient getting lighter as distance increases from the origin. Produced using data from May 2018 – November 2021.

125 2.7 Emission estimation via an Exponentially Modified Gaussian (EMG)

To derive emissions from a wind rotated aggregate, an Exponentially Modified Gaussian (EMG) (Beirle et al., 2011; de Foy et al., 2015; Fioletov et al., 2015; Goldberg et al., 2019) is fitted to the integral of the across-wind line densities in Figure 5, the form of which is given in Equation 2.

$$NO_2 \text{ Line Density} = \alpha \left[\frac{1}{x_o} \exp\left(\frac{\mu}{x_o} + \frac{\sigma^2}{2x_o^2} - \frac{x}{x_o}\right) \Phi\left(\frac{x - \mu}{\sigma} - \frac{\sigma}{x_o}\right) \right] + \beta \quad (2)$$

$$130 \quad NO_x \text{ Emissions} = 1.33 \left(\frac{\alpha}{\tau_{eff}} \right), \quad \text{where } \tau_{eff} = \frac{x_o}{\omega} \quad (3)$$

Where α is the total number of NO_2 molecules minus the background, β . x_o is the e-folding distance downwind from the source, μ is the displacement of the apparent source relative to the assumed source center, σ is the standard deviation of the Gaussian function and Φ is the cumulative distribution function. Using a non-linear iterative least squares fitting approach, α , x_o , σ , μ , and β are determined. This process is illustrated in Figure 6. From these fitted parameters we can then calculate an effective lifetime, τ_{eff} , using the mean wind speed, w . Equation 3 is then used to calculate NO_x from the TROPOMI derived NO_2 , using τ_{eff} and a scaling factor of 1.33 to convert from NO_2 to NO_x . This scaling factor describes the typical NO_2/NO ratio under polluted conditions at noon (Seinfeld and Pandis, 2016).

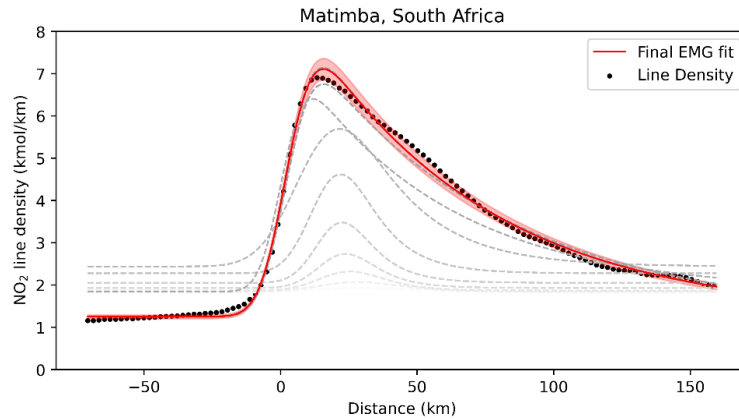

Figure 6. Demonstration of the Curvefit process of fitting the Exponentially Modified Gaussian (EMG) to the NO₂ line density. Produced using wind rotated NO₂ from Matimba power station for May 2018 – Nov 2021. The red line shows the final EMG fit, and the grey lines illustrate the iterative fitting procedure, changing from light grey to black as it converges to the final EMG fit.

3 Results and Discussion

140 3.1 Wind rotation aggregates of selected sites

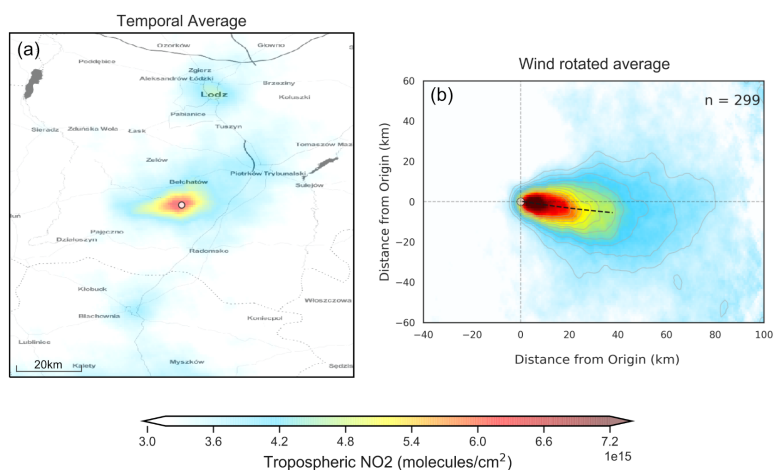

Figure 7 shows both the unrotated and wind rotated aggregates for Belchatow power station in Poland (a-b) and Matimba power station in South Africa (c-d), as examples of a Northern and a Southern site. The black dashed line shows the “spine” of the plume and the value of “n” shows the number of observations included in the aggregate. Both sites are strong emitters, well isolated from other sources and the surrounding area consists of relatively simple topography. Both of these sites show

145 strong curvature in their wind rotated aggregates, and whilst the plume’s structure is successfully preserved, there is a clear distinguishable curvature in favour of the Coriolis force direction. As these two example sites are non coastal and in regions with simple topography, there are minimal micro/meso scale processes influencing the wind field, and so the effect of the Coriolis force is easily identified, as it more frequently prevails over other influences. The remaining sites are shown the appendix (Figures A1-A3), grouped by their hemisphere. Of the sixteen sites investigated, nine showed the expected curvature for the

150 hemisphere they reside in, varying in magnitude. Five showed no or negligible curvature, and two showed opposing or unusual curvature. These latter two sites are located in areas with steep and highly variable topography which may “steer” plumes locally, and such “steering” may dominate over larger-scale Coriolis curvature. A good example of this is given in Figure 8. The Jorge Lacerda power station is located in Brazil at a latitude of -28.45 in the Southern hemisphere, yet we observe clockwise, Northern hemisphere curvature. This can be explained by the topographical surroundings of Jorge Lacerda, as the

155 power station sits between the South Atlantic and the Serra do Mar coastal mountain range, where there is an abrupt +1200m increase in altitude over a short distance. Onshore synoptic-scale winds and sea breeze penetrate inland and are “steered” by

Belchatow, Poland

Matimba, South Africa

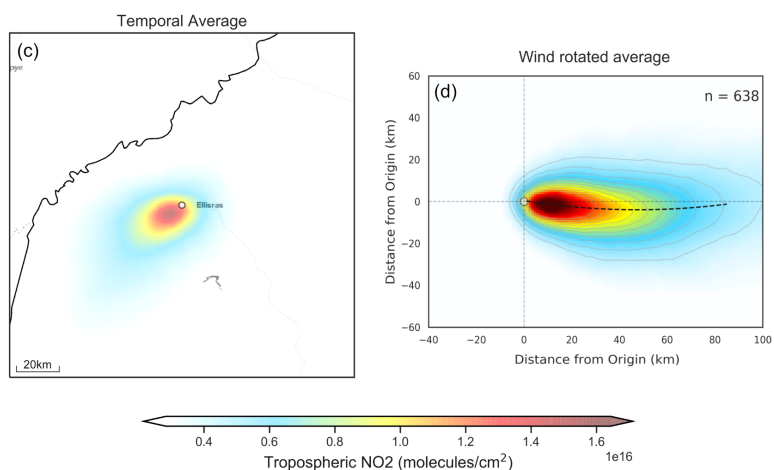

Figure 7. Unrotated and wind rotation averaged tropospheric NO₂ columns from TROPOMI, using data from May 2018 to December 2021 for (a-b) Belchatow power station in Poland and (c-d) Matimba power station in South Africa.

the topography. These local effects, over tens of kilometers, dominate over larger synoptic weather patterns, and therefore outweigh the influence of the Coriolis Effect, leading to this unexpected display of Northern hemisphere curvature.

3.2 Impact of selected wind level on quality of aggregate

160 To investigate the influence of the chosen wind field on the final aggregate and emission value, emissions were derived for Matimba using wind fields corresponding to pressure levels: 900 hPa (~100m), 875 hPa (~250m), 850 hPa (~450m), 825 hPa (~700m) and 800 hPa (~1000m), as well as an average of all six levels. As seen in Figure 9, with increasing altitude the plume migrates anticlockwise, e.g. the plume spine is below the aggregate x-axis at 900 hPa (~100 m) but above it at 800

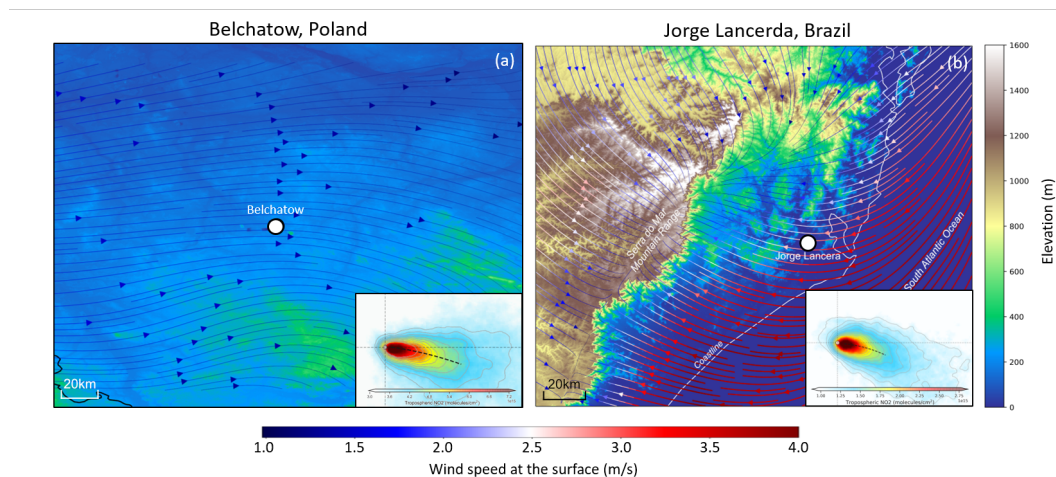

Figure 8. (a) Average 2018 surface wind fields from ERA-5 Reanalysis, including topography from the Copernicus GLO-30 digital elevation model for (a) Belchatow in Poland and (b) Jorge Lacerda in Brazil. Included in the bottom right of (a) and (b) is the wind rotated tropospheric NO₂ columns from TROPOMI, using data from May 2018 to December 2021.

hPa (~1000m). Winds near the surface are orientated clockwise from winds at higher altitude, and so rotational alignment
 165 using winds at lower altitude results in a clockwise deviation compared to alignment using winds at higher altitude, which
 is to be expected. The initial stages (first 10km downwind) of each plume align with the aggregated x-axis and are laterally
 symmetric around it. This confirms that rotations based on the wind vector near the source produce well-aligned and symmetric
 aggregate plumes in the near field. However, at greater distances the Coriolis curvature becomes distinguishable from the initial
 alignment, and as the plume progresses down-wind it is increasingly deviated and asymmetric relative to the common axis.
 170 Aggregates using winds at 900hPa – 850hPa are very similar, with 825-800hPa showing better initial alignment with the axis
 of aggregation, within the first 10km. This initial agreement may be due to the wind direction at these levels being the most
 representative, or due to an inherent bias in the ERA-5 model, as there may be small but consistent differences between the
 wind at the site compared to the coarse $0.25^\circ \times 0.25^\circ$ modelled fields. All exhibit comparably strong curvature, which shows
 that curvature is not an artefact of the wind product but an inherent feature of the observations. Furthermore, wind speed
 175 increases with altitude, and as wind speed factors into the emission calculation it is important that representative wind fields
 are used. For the purposes of this study the average wind field is used, as in most cases it results in good plume alignment whilst
 also reasonably describing the wind speeds experienced as the plume travels downwind both vertically and horizontally from
 the source. Although the 800hPa aggregate has the best initial alignment, these higher wind speeds would not be experienced
 by the plume for the majority of its lifetime, and would lead to an overestimate in the emission, as demonstrated by Figure A4.
 180 There must be a trade off between the geometric alignment of the aggregated plumes and ensuring the wind field reasonably
 describes the wind speeds experienced.

Wind rotation using different pressure levels

Figure 9. Demonstration of the difference in aggregate when using wind products from different pressure levels, using data from Matimba power station for May 2018–November 2021

3.3 Impact of Coriolis curvature on emission estimates

From the wind rotated aggregate, the typical next step is to take the integral of evenly spaced (1 km) across-wind (± 30 km) segments perpendicular to the x-axis, as shown in Figure 10(a). This approach assumes the wind rotated plume is distributed evenly either side of the common axis. Occasionally this assumption holds, as the curvature is often minor/negligible and so emission estimates are marginally impacted. However, as evident with sources such as Matimba, this is not always the case, and the plume can deviate considerably from the x-axis due to the plume's inherent curvature. Using the EMG emission estimation

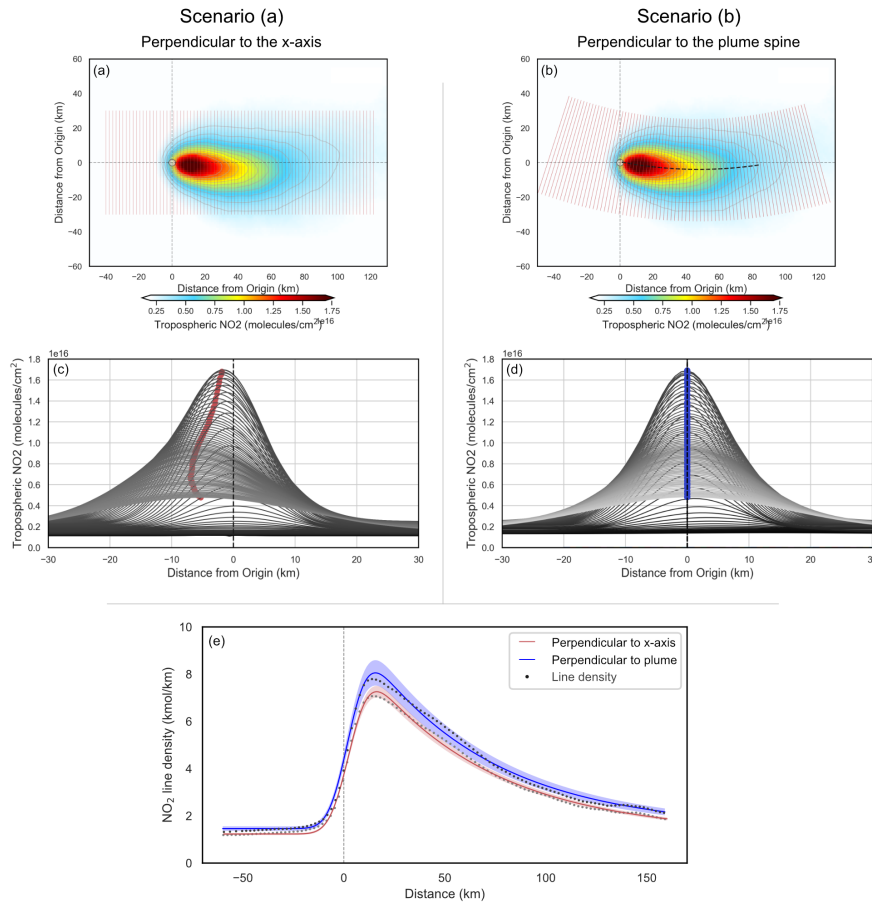

Figure 10. Demonstration of the impact the Coriolis Effect has on the resulting emission estimate. (a) & (c) show the results using cross sections perpendicular to the x-axis, whereas (b) & (d) show cross sections perpendicular to the plume of the spine. (e) Shows the EMG fit for each scenario with the shaded region showing the quality of each fit.

method discussed in Section 2.7, we calculated NO_x emissions for Matimba under two scenarios; (a) using cross wind segments perpendicular to the common downwind axis, and (b) using cross wind segments perpendicular to the curved spine of the plume. Scenario (b) aims to counteract the influence of the plume's geometry on the emission estimate, by re-centring the integral along the curved spine of the plume. Uncertainties are determined using a bootstrapping approach, whereby observations are randomly selected, with replacement, to be included in the aggregate. Each scene has both measurement and numerical error, and so by assuming these errors are randomly distributed, the random selection and replacement of scenes in the bootstrapping algorithm allows for the estimation of the impact that all these errors have on the emission estimate (de Foy et al., 2015, 2014). Uncertainty introduced by the selection of wind field is evaluated through sensitivity tests, where emissions are calculated using each pressure level, shown in Figure A4. This approach does not account for uncertainty introduced due to the clear sky bias, caused by only using cloud-free observations. Figure 11 shows annual NO_x emission estimates for Matimba power station

from; (i) a similar study of Matimba using TROPOMI NO₂ and EMG before S5P-PAL released (Hakkarainen et al., 2021), (ii) scenario (a), (iii) scenario (b) and finally (iv) reported values from the site operator, Eskom, derived from Continuous Emission Monitoring Systems (CEMS) (<https://www.eskom.co.za/dataportal/emissions/ael/matimba-c2/>). The reported emissions are not provided with an uncertainty, and so conclusive statements about the accuracy of the TROPOMI based estimate are not possible.

Figure 11. Comparison of emission estimates from TROPOMI NO_x using different applications of with the EMG method, compared to values obtained by Hakkarainen et al. (2021) for the same site, and emissions reported from estimates by the operator, Eskom (<https://www.eskom.co.za/dataportal/emissions/ael/matimba-c2/>).

The use of S5P-PAL explains the increase in emissions between Hakkarainen et al. (2021) and scenario (a), as S5P-PAL can lead to a 10-15% increase in tropospheric columns for polluted cloud free scenes (Eskes et al., 2019). This translated to a 5-10% increase in the emission estimate for Matimba power station. Between scenarios (a) and (b) there is a substantive 9.1% ±1.92% increase in emissions annually on average, for the years 2018-2021, when the curved geometry of the wind rotated plume is taken into account. Scenario (b) yields an emission value closer to the reported value and its uncertainty is within range of the reported emissions for 3 out of the four years investigated. This strongly suggests an improved satellite derived emission estimate can be achieved by considering the curvature of the wind rotated aggregate. This approach is not constrained to the Coriolis effect, as any consistent misalignment of the aggregated plume, such as the topographic deviation seen at Jorge Lacerda, could be accounted for when calculating emissions by following the method discussed here. This approach is rather generalised, and could be easily applied autonomously to a given source. We suggest that the spine fitting and along-spine integration steps should be incorporated into a regulatory wind rotation aggregation approach, in order to minimise the influence of plume curvature on the emission estimate.

This study demonstrates the Coriolis Effect's varying influence over the trajectory of point source emission plumes observed by TROPOMI, and has shown how strong curvature can lead to substantive underestimations in the emission estimate if it is not accounted for. Of the 16 locations investigated, nine showed the expected curvature for the hemisphere they reside in, varying in magnitude. Five showed no or negligible curvature, and two showed opposing or unusual curvature. The sites which showed conflicting curvature are all within regions with complex terrain where air flows are steered by local topography in ways that dominate over larger-scale influences such as the Coriolis Effect. Emissions of NO_x were estimated for Matimba power station in South Africa, chosen as a demonstration due to its strong curvature and good data coverage. Conducting the emission calculation in a way that accounted for the inherent curvature of the plume resulted in an average $\sim 9\%$ increase in yearly emitted NO_x over the regular approach, and was more comparable to and within the uncertainty range of the emission value reported by the operator. As demonstrated, the wind rotated aggregate of a source is not always aligned and distributed along the common downwind axis, and so site specific considerations need to be included. This study formally identifies, for the first time, Coriolis curvature in the satellite record, and suggests how it can be accounted for during emission analysis of high curvature cases, such as Matimba power station. For satellite evidence to be used by regulators and operators, there needs to be a standardised data processing routine in place for emission calculation and uncertainty analysis, as there is with air quality modelling, so that satellite observations can be used to generate consistent and auditable evidence of emissions for regulatory purposes. The rapid development of satellite instruments over the next decade offers a unique opportunity for air quality regulators and industrial operators to begin to monitor emission performance remotely and persistently, and so a greater understanding of the role atmospheric dynamics has on satellite derived emission estimates is vital.

Data availability. The TROPOMI data used in the findings of this study are freely available at the following: <https://s5phub.copernicus.eu/dhus/#/home> (accessed on 1 February 2022). Site selection information was obtained from the Global Power Plant Database publicly available at <https://datasets.wri.org/dataset/globalpowerplantdatabase> (accessed 1 July 2022) and from the public database produced in Beirle et al. (2021). ERA5 Reanalysis products (Hersbach et al., 2020) was downloaded from the Copernicus Climate Change Service (C3S) Climate Data Store, and are publicly available at <https://cds.climate.copernicus.eu/cdsapp#!/dataset/reanalysis-era5-pressure-levels> (accessed on 1 July 2022). Emissions data for Matimba power station were obtained from the operator's website, available at <https://www.eskom.co.za/dataportal/emissions/ael/matimba-c2/> (accessed on 1 July 2022).

Author contributions. Conceptualisation: D.A.P., R.T., E.J.S.F. and J.D.V.H.; methodology: D.A.P., R.T. and J. D. V. H.; investigation: D.A.P.; formal Analysis: D.A.P.; writing—original draft preparation: D.A.P.; writing—review and editing: D.A.P., E.J.S.F., R.T. and J.D.V.H.; supervision: E.J.S.F., J.D.V.H. and R.T. All authors have read and agreed to the published version of the manuscript.

Competing interests. The authors declare no conflict of interest.
