22 **Abstract**

23 Isoprene and monoterpenes emissions to the atmosphere are generally dominated by biogenic  
24 sources. The oxidation of these compounds can lead to the production of secondary organic aerosol,  
25 however the impact of this chemistry in polluted urban settings has been poorly studied. Isoprene  
26 and monoterpenes can form SOA heterogeneously via anthropogenic-biogenic interactions resulting  
27 in the formation of organosulfates (OS) and nitrooxy-organosulfates (NOS). Delhi, India is one of the  
28 most polluted cities in the world, but little is known about the emissions of biogenic VOCs or the  
29 sources of SOA. As part of the DELHI-FLUX project, gas phase mixing ratios of isoprene and speciated  
30 monoterpenes were measured during pre- and post-monsoon measurement campaigns in central  
31 Delhi. Nocturnal mixing ratios of the VOCs were substantially higher during the post-monsoon  
32 (isoprene:  $(0.65 \pm 0.43)$  ppbv, limonene:  $(0.59 \pm 0.11)$  ppbv,  $\alpha$ -pinene:  $(0.13 \pm 0.12)$  ppbv) than the  
33 pre-monsoon (isoprene:  $(0.13 \pm 0.18)$  ppbv, limonene:  $0.011 \pm 0.025$  (ppbv),  $\alpha$ -pinene:  $0.033 \pm$   
34 0.009) period. At night, isoprene and monoterpane concentrations correlated strongly with CO  
35 across during the post-monsoon period. Filter samples of particulate matter less than 2.5 microns in  
36 diameter ( $PM_{2.5}$ ) were collected and the OS and NOS content analysed using ultrahigh-performance  
37 liquid chromatography tandem mass spectrometry (UHPLC-MS<sup>2</sup>). Inorganic sulfate was shown to  
38 facilitate the formation of isoprene OS species across both campaigns. Sulfate contained within OS  
39 and NOS species were shown to contribute significantly to the sulfate signal measured via AMS.  
40 Strong nocturnal enhancements of NOS species were observed across both campaigns. The total

41 concentration of OS/NOS species contributed an average of  $(2.0 \pm 0.9) \%$  and  $(1.8 \pm 1.4) \%$  to the  
42 total oxidised organic aerosol, and up to a maximum of 4.2 % and 6.6 % across the pre- and post-  
43 monsoon periods, respectively. Overall, this study provides the first molecular level measurements  
44 of SOA derived from isoprene and monoterpene in Delhi and demonstrates that both biogenic and  
45 anthropogenic sources of these compounds can be important in urban areas.

46 **1. Introduction**

47 India is undergoing significant urbanization and industrialisation, with a rapidly increasing  
48 population. According to the WHO, India was home to 9 out of the top 10 most polluted cities in the  
49 world in 2020 in terms of annual mean  $PM_{2.5}$  (particulate matter less than 2.5 micrometres in  
50 diameter) concentrations (WHO, 2018). In Delhi, the population-weighted mean  $PM_{2.5}$  was estimated  
51 to be 209 (range:  $120 - 339.5 \mu g m^{-3}$  in 2017, over 40 times the WHO annual mean guidelines of  $5 \mu g m^{-3}$ , and greater than five times India's own standard of  $40 \mu g m^{-3}$  (Balakrishnan et al., 2019). Air  
52 pollution is estimated to cause over 1 million deaths per year in India alone (Landrigan et al., 2018).

53 Numerous studies have investigated  $PM_{2.5}$  concentrations, characteristics and meteorological effects  
54 in Delhi (Anand et al., 2019; Bhandari et al., 2020; Chowdhury et al., 2004; Hama et al., 2020;  
55 Kanawade et al., 2020; Miyazaki et al., 2009; Nagar et al., 2017). The key sources of  $PM_{2.5}$  identified  
56 are secondary aerosol, fossil fuel combustion, municipal waste and biomass burning (Chowdhury et  
57 al., 2004; Sharma and Mandal, 2017; Stewart et al., 2021b, 2021a). Previous studies have also shown  
58 that alongside extremely high emissions of pollutants, regional sources and meteorology in  
59 particular play an important role in high pollution events in Delhi (Bhandari et al., 2020; Sawlani et  
60 al., 2019; Schnell et al., 2018; Sinha et al., 2014).

61 Secondary species have been shown to be significant contributors to  $PM_1$  and  $PM_{2.5}$  mass in Delhi,  
62 with organics contributing 40-70 % of  $PM_1$  mass. (Gani et al., 2019; Shivani et al., 2019; Reyes-  
63 Villegas et al., 2021; Sharma and Mandal, 2017) However, limited molecular level analysis of organic  
64 aerosol (OA) has been undertaken (Chowdhury et al., 2004; Elzein et al., 2020; Miyazaki et al., 2009;  
65 Singh et al., 2021, 2012; Yadav et al., 2021). Kirillova et al., (2014) analysed the sources of water-  
66 soluble organic carbon (WSOC) in Delhi, using radiocarbon measurement constraints. The study  
67 identified that 79 % of WSOC was classified as non-fossil carbon, attributed to biogenic/biomass  
68 burning sources in urban Delhi (Kirillova et al., 2014), similar to other studies from India (Kirillova et  
69 al., 2013; Sheesley et al., 2012). Studies across Asia, Europe and North America have also shown high  
70 contributions from non-fossil sources to ambient PM concentrations in urban environments (Du et  
71 al., 2014; Kirillova et al., 2010; Szidat et al., 2004; Wozniak et al., 2012). The sources of this modern  
72 carbon in urban areas are poorly understood, although biomass burning is a key component (Elser et  
73 al., 2016; Hu et al., 2016; Lanz et al., 2010; Nagar et al., 2017). Recently in Delhi, solid-fuel  
74 combustion sources such as cow dung cake or municipal solid waste have been shown to release  
75 over 1000 different organic components into the aerosol phase at emission (Stewart et al., 2021a).  
76 Alongside biomass burning, one potential source of this non-fossil aerosol is biogenic secondary  
77 organic aerosol (BSOA), which is formed via the oxidation of biogenic volatile organic compounds  
78 (BVOCs) and subsequent gas-particle phase transfer (Hallquist et al., 2009; Hoffmann et al., 1997).

79 Isoprene is the most abundant BVOC, with annual global emissions estimates of between 350 - 800  
80  $Tg yr^{-1}$  (Guenther et al., 2012; Sindelarova et al., 2014). Globally, isoprene is predominately emitted  
81 from biogenic sources, but anthropogenic sources become increasingly important in urban areas  
82 especially at night (Borbon et al., 2001; Hsieh et al., 2017; Khan et al., 2018a; Mishra and Sinha,  
83 2020; Sahu et al., 2017; Sahu and Saxena, 2015). Monoterpene are another important BSOA  
84 precursor, with annual global emissions estimates of between 89 and  $177 Tg yr^{-1}$  (Guenther et al.,  
85

86 2012; Sindelarova et al., 2014). Monoterpenes while mainly biogenic, are also emitted from  
87 anthropogenic sources such as biomass burning, cooking and fragranced consumer products (Cheng  
88 et al., 2018; Gkatzelis et al., 2021; Panopoulou et al., 2020, 2021; Stewart et al., 2021b, 2021c; Zhang  
89 et al., 2020).

90 Numerous studies have identified and quantified molecular level markers from isoprene and  
91 monoterpenes, especially in the Southeastern-US and China (Brüggemann et al., 2019; Bryant et al.,  
92 2020, 2021; Hettiyadura et al., 2019; Huang et al., 2016; Rattanavaraha et al., 2016b; Wang et al.,  
93 2016, 2018a; Yee et al., 2020). The complex sources of isoprene and monoterpenes in highly  
94 polluted urban areas make source identification difficult. As such, the SOA markers in this study will  
95 be referred to as originating from isoprene or monoterpenes, but the emissions are likely from a  
96 mixture of biogenic and anthropogenic sources as discussed previously. (Cash et al., 2021b; Nelson  
97 et al., 2021)

98 Recent studies have started to focus on anthropogenic-biogenic interactions, whereby  
99 anthropogenic pollutants such as  $\text{NO}_x$  and sulfate enhance the formation of biogenically derived SOA  
100 species. Increased NO or  $\text{NO}_2$  concentrations can lead to higher organonitrate (ON) or nitrooxy-  
101 organosulfate (NOS) concentrations through  $\text{RO}_2 + \text{NO}$  or  $\text{VOC} + \text{NO}_3$  pathways. (Morales et al., 2021;  
102 Takeuchi and Ng, 2019) Inorganic sulfate formed from the oxidation of  $\text{SO}_2$  plays a pivotal role in OS  
103 and NOS formation (Bryant et al., 2020; Budisulistiorini et al., 2015; Glasius et al., 2018; Hettiyadura  
104 et al., 2019; Hoyle et al., 2011; Xu et al., 2015). Sulfate allows the acid-catalysed uptake of gas phase  
105 oxidation products into the particle phase. Both chamber and ambient studies have shown the direct  
106 link between sulfate and OS concentrations (Brüggemann et al., 2020a; Bryant et al., 2020;  
107 Budisulistiorini et al., 2015; Gaston et al., 2014; Lin et al., 2012; Riva et al., 2019; Surratt et al.,  
108 2008a; Xu et al., 2015). Yee et al., (2020) highlighted markers from both the high/low-NO isoprene  
109 oxidation pathways correlated linearly with sulfate over a large range of sulfate concentrations (0.01  
110 – 10  $\mu\text{g m}^{-3}$ ) across central Amazonia during the wet and dry seasons and in the SE-US summer. They  
111 conclude that the majority of isoprene oxidation products in pre-industrial settings are still expected  
112 to be in the form of isoprene OS (OSi), suggesting that they cannot be thought of as purely a  
113 biogenic-anthropogenic product (Yee et al., 2020).

114 In this study, offline  $\text{PM}_{2.5}$  filter samples were collected across two campaigns (pre and post-  
115 monsoon) in central Delhi, alongside a comprehensive suite of gas and aerosol atmospheric  
116 pollutant measurements. Filters were analysed using ultra-high performance liquid chromatography  
117 tandem mass spectrometry and isoprene and monoterpane OS/NOS markers identified and  
118 quantified. Isoprene and monoterpane emissions were observed to correlate strongly to  
119 anthropogenic markers, suggesting a mixed anthropogenic/biogenic sources of these VOCs. OSi  
120 species showed strong seasonality and strong correlations to particulate sulfate. NOS species  
121 showed strong nocturnal enhancements, likely due to nitrate radical chemistry. This study is the first  
122 molecular level particle phase analysis of OS and NOS markers from isoprene and monoterpenes in  
123 Delhi and aims to improve our understanding of the sources of isoprene and monoterpane SOA  
124 markers and their formation pathways in extremely polluted urban environments.

## 125 **2.Experimental**

### 126 **2.1 Filter collection and site information**

127  $\text{PM}_{2.5}$  filter samples were collected as part of the Air Pollution and Human Health (APHH)-India  
128 campaign, at the Indira Gandhi Delhi Technical University for Women in New Delhi, India, (28°39'55"  
129 N 77°13'56" E). The site is situated inside the third ring road which caters to huge volumes of traffic,

130 with a major road to the east, between the site and the Yamuna River. Two train stations are located  
131 to the south and southwest of the site, and there are several green spaces locally in all  
132 directions.(Nelson et al., 2021; Stewart et al., 2021c) Filters were collected during two field  
133 campaigns in 2018. The first campaign was during the pre-monsoon period, with 35 filters were  
134 collected between 28/05/2018 and 05/06/2018. The second campaign during the post-monsoon  
135 period, 108 filters were collected between 09/10/2018 and 6/11/2018. Quartz filters (Whatman  
136 QMA, 10" by 8") were pre-baked at 550 °C for 5 hours and wrapped in foil before use. Samples were  
137 collected using an HiVol sampler (Ecotech 3000, Victoria Australia) with selective PM<sub>2.5</sub> inlet at a flow  
138 rate of 1.33 m<sup>3</sup> min<sup>-1</sup>. Once collected, filters were stored in foil at -20 °C before, during and after  
139 transport for UK based analysis.

140 **2.2 Filter extraction**

141 Using a standard square filter cutter, a section of filter was taken with an area of 30.25 cm<sup>2</sup> which  
142 was then cut into roughly 1 cm<sup>2</sup> pieces and placed in a 20 mL glass vial. Next, 8 mL of LC-MS grade  
143 methanol (MeOH, Optima, Fisher Chemical, USA) was added to the sample and sonicated for 45 min.  
144 Ice packs were used to keep the bath temperature below room temperature, with the water  
145 swapped mid-way through. Using a 5 mL plastic syringe, the MeOH extract was then pushed through  
146 a 0.22 µm filter (Millipore) into another sample vial. An additional 2 mL (2 x 1 mL) of MeOH was  
147 added to the filter sample, and then extracted through the filter to give a combined extract ~ 10mL.  
148 This extract was then reduced to dryness using a Genevac solvent evaporator under vacuum. The dry  
149 sample was then reconstituted in 50:50 MeOH:H<sub>2</sub>O (Optima, Fisher Chemical, USA) for analysis  
150 (Bryant et al., 2020; Spolnik et al., 2018). Extraction efficiencies of 2-methyl-glyceric acid (2-MG-OS)  
151 and camphorsulfonic acid were determined using authentic standards spiked onto a pre-baked clean  
152 filter and recoveries were calculated to be 71 % and 99 % respectively.

153 **2.3 Ultra-high performance liquid chromatography tandem mass spectrometry (UHPLC-MS<sup>2</sup>)**

154 The extracted fractions of the filter samples were analysed using an Ultimate 3000 UHPLC (Thermo  
155 Scientific, USA) coupled to a Q-Exactive Orbitrap MS (Thermo Fisher Scientific, USA) using data  
156 dependent tandem mass spectrometry (ddMS<sup>2</sup>) with heated electrospray ionization source (HESI).  
157 The UHPLC method uses a reversed-phase 5 µm, 4.6 mm × 100 mm, polar end capped Accucore  
158 column (Thermo Scientific, UK) held at 40 °C. The mobile phase consisted of water (A, optima grade)  
159 and methanol (B, optima grade) both with 0.1 % (v/v) of formic acid (98 % purity, Acros Organics).  
160 Gradient elution was used, starting at 90 % (A) with a 1-minute post-injection hold, decreasing to 10  
161 % (A) at 26 minutes, returning to the starting mobile phase conditions at 28 minutes, followed by a  
162 2-minute hold allowing the re-equilibration of the column. The flow rate was set to 0.3 mL min<sup>-1</sup>. A  
163 sample injection volume of 4 µL was used. The capillary and auxiliary gas heater temperatures were  
164 set to 320 °C, with a sheath gas flow rate of 45 (arb.) and an auxiliary gas flow rate of 20 (arb.).  
165 Spectra were acquired in the negative ionization mode with a scan range of mass-to-charge (*m/z*) 50  
166 to 750, with a mass resolution of 140,000. Tandem mass spectrometry was performed using higher-  
167 energy collision dissociation with a stepped normalized collision energy of 10,45 and 60. The  
168 isolation window was set to *m/z* 2.0 with a loop count of 10, selecting the 10 most abundant species  
169 for fragmentation in each scan.

170 A mass spectral library was built using the compound database function in Tracefinder 4.1 General  
171 Quan software (Thermo Fisher Scientific, USA). To build the library, compounds from previous  
172 studies (Chan et al., 2010; Nestorowicz et al., 2018; Ng et al., 2008; Riva et al., 2016b; Schindelka et  
173 al., 2013; Surratt et al., 2008a) were searched for in an afternoon and a night-time filter sample  
174 extract analysis using the Xcalibur software. Further details can be found in Bryant et al., 2021 and

175 the SI. Isoprene OS and NOS markers were quantified using authentic standards of 2-MG-OS and 2-  
176 methyl tetrol OS (2-MT-OS) with later eluting monoterpene OS and NOS quantified using  
177 camphorsulfonic acid. Standards were run across a 9-point calibration curve (2 ppm – 7.8ppb,  $R^2 >$   
178 0.99) More details about the method can be found in Bryant et al., 2021. Overall uncertainties  
179 associated with calibrations, proxy standards and matrix effects were estimated. The uncertainties  
180 associated with 2-MG-OS and 2-MT-OS were calculated to be 58.9 % and 37.6 % respectively, mainly  
181 due to the large uncertainties in the matrix correction factors. Isoprene SOA markers quantified by  
182 the average of 2-MT-OS and 2-MG-OS calibrations have an associated uncertainty of 69.9 %. For  
183 monoterpene SOA species which were quantified by camphorsulfonic acid, the associated  
184 uncertainty is estimated to be 24.8 %.

185

## 186 **2.4 Supplementary measurements**

187 A suite of complementary measurements were made alongside the filter collection including  
188 VOCs(Stewart et al., 2021c), oxygenated-VOCs, NO<sub>x</sub>, CO, O<sub>3</sub>, SO<sub>2</sub>, HONO, photolysis rates and  
189 measurements of PM<sub>1</sub> non-refractory aerosol chemical components with a high resolution Aerosol  
190 Mass Spectrometer (HR-AMS). Detailed instrument descriptions can be found in Nelson et al.,  
191 (2021). Briefly, VOCs and oxygenated-VOCs were measured via two gas-chromatography (GC)  
192 instruments (DC-GS-FID and GC-GC-FID). NO<sub>x</sub> was measured via a dual channel chemiluminescence  
193 analyser with fitted with a blue light converter for NO<sub>2</sub> (Air Quality Designs Inc., Colorado) alongside  
194 CO which was measured with a resonance fluorescent instrument (Model AI5002, Aerolaser GmbH,  
195 Germany). O<sub>3</sub> was measured as outlined by Squires et al., (2020) using an ozone analyser (49i,  
196 Thermo Scientific). SO<sub>2</sub> was measured using a 43i SO<sub>2</sub> analyser (Thermo scientific). High-resolution  
197 aerosol mass spectrometry measurements were conducted as outlined in Cash et al., (2021). Ion  
198 chromatography measurements were undertaken by the experimental approach outlined by Xu et  
199 al., (2020) as part of an intercomparison study. Briefly, filter cuttings were taken from the filter and  
200 extracted ultrasonically for 30 mins in 10 mL of ultrapure water and then filtered before analysis (Xu  
201 et al., 2020).

202 Meteorology data was downloaded from the NOAA Integrated Surface Database via the Worldmet R  
203 package for the Indira Gandhi International Airport (code: 421810-99999) (Carslaw, D ., accessed:  
204 2021). The planetary boundary layer height (PBLH) was obtained from the ERA5 (ECMWF ReAnalysis  
205 5) data product at 0.25° resolution in 1-hour time steps at the position Lat 28.625°, Lon. 77.25°. The  
206 data for both campaigns was then selected between the start time of the first filter of that  
207 campaign, and the end time of the last filter of the same campaign.

## 208 **3. Results**

### 209 **3.1 Meteorology**

210 The time series for temperature, RH, planetary boundary layer height (PBLH) and ventilation  
211 coefficient (VC) across the pre- and post-monsoon campaigns are shown in Figure S1. For the pre-  
212 monsoon campaign, the average air temperature was  $(35.8 \pm 4.5) ^\circ\text{C}$  compared to  $(24.7 \pm 4.6) ^\circ\text{C}$  in  
213 the post-monsoon campaign (Table S2). The pre-monsoon campaign also showed higher average  
214 wind speeds, with an average of  $(3.8 \pm 1.4) \text{ ms}^{-1}$ , compared to  $(1.7 \pm 1.3) \text{ ms}^{-1}$  in the post-monsoon  
215 campaign. The average RH of the pre- and post-monsoon were  $(39.4 \pm 13.6) \%$  and  $(57.3 \pm 16.6) \%$   
216 respectively, both showing similar diurnals with a minimum around mid-morning and nocturnal  
217 maximum (Figure S2). The PBLH shows a similar diurnal between the two campaigns, with the  
218 nocturnal boundary layer breaking down around 06:00-07:00 with a midday peak, before re-

219 establishing the nocturnal boundary layer around 19:00. The pre-monsoon PBLH has an average  
220 maximum of  $\sim$ 2400 m compared to post-monsoon  $\sim$ 1700 m and a minimum of 270 m compared to  
221 52 m (Figure S2). The ventilation coefficient (VC = wind speed x PBLH) has been used previously to  
222 identify periods of adverse meteorological conditions and gives an idea of how stagnant atmospheric  
223 conditions are and the general role of the atmosphere in the dilution of species. (Gani et al., 2019)  
224 As shown in Figure S1, the conditions during the post-monsoon campaign were much more stagnant  
225 than the pre-monsoon campaign. The VC was on average 4.5 times higher during the pre-monsoon  
226 campaign compared to the post-monsoon campaign (Table S2) in line with previous studies (Gani et  
227 al., 2019; Saha et al., 2019). The more stagnant conditions during the post-monsoon campaign likely  
228 traps nocturnal emissions and their reaction products close to the surface, allowing for a significant  
229 build-up of concentrations.

### 230 **3.2 Gas phase observations**

231 Time series of the observed mixing ratios (ppbv) of NO, NO<sub>2</sub> and O<sub>3</sub> are shown in Figure 1, for the  
232 pre- and post-monsoon campaigns. The campaign averaged diurnal profiles are shown in Figure S3  
233 and the mean, median and maximum mixing ratios are given in Table S2. It should be noted that only  
234 one week of data was available for the pre-monsoon period. During the post-monsoon campaign,  
235 extremely high mixing ratios of NO were observed with a campaign maximum mixing ratio of  $\sim$ 870  
236 ppbv during the early morning of the 1<sup>st</sup> of November. During the early part of the pre-monsoon  
237 campaign, a large enhancement in NO was observed with mixing ratios around 400 ppbv (Figure S4),  
238 followed by significantly lower concentrations throughout the rest of the campaign. The campaign-  
239 average NO diurnal profile shows very high NO mixing ratios at night (pre-:  $\sim$  50 ppbv, post-:  $\sim$ 300  
240 ppbv), with low afternoon mixing ratios  $< 2$  ppbv due to ozone titration. These high NO  
241 concentrations at night likely reduce any night-time chemistry through reactions with NO<sub>3</sub> radicals  
242 and ozone. NO<sub>2</sub> during the pre-monsoon was observed to increase as the boundary layer reduced in  
243 the late afternoon, with a mid-afternoon minimum. During the post-monsoon, a double peak in  
244 concentrations was observed, in line with increasing ozone in the morning, and increasing NO in the  
245 afternoon. Ozone showed a strong diurnal variation across both campaigns, with average afternoon  
246 mixing ratios  $\sim$  75 ppbv with pre- and post-monsoon maximums of 182 ppbv and 134 ppbv  
247 respectively. Night-time O<sub>3</sub> concentrations were significantly higher during the pre-monsoon  
248 campaign, likely due to the significantly lower NO concentrations.

### 249 **3.3 Particle phase observations**

250 The sampling site was heavily polluted in terms of particulate matter. The mean  $\pm \sigma$  PM<sub>2.5</sub>  
251 concentration (Table S2) during the pre-monsoon campaign was  $(141 \pm 31) \mu\text{g m}^{-3}$  with a spike in  
252 concentrations of  $672 \mu\text{g m}^{-3}$  on the 01/6/2018 at 21:00 (Figure 1). The diurnal (Figure S5) shows  
253 concentrations generally flat throughout the day. During the post-monsoon campaign, the average  
254 PM<sub>2.5</sub> concentration was higher at  $(182 \pm 94) \mu\text{g m}^{-3}$ , with a spike in concentrations of  $695 \mu\text{g m}^{-3}$  at  
255 the end of the campaign (Figure 1). The diurnal shows a mid-afternoon minimum with high morning  
256 and night concentrations. HR-AMS was used to measure the PM<sub>1</sub> sulfate and total organics.  
257 Campaign averaged total organics concentrations were approximately double in the post-monsoon  
258  $(48.7 \pm 35.4) \mu\text{g m}^{-3}$  compared to the pre-monsoon  $(19.8 \pm 13.7) \mu\text{g m}^{-3}$ . During the pre-monsoon  
259 campaign, concentrations are generally flat throughout the day, with an increase in the late  
260 afternoon, likely as the boundary layer decreases (Figure S5). During the post-monsoon, a much  
261 more prominent diurnal is observed, with a mid-day minimum and high night-time concentrations.  
262 This diurnal is likely driven by boundary layer conditions. Sulfate averaged  $(7.5 \pm 1.8) \mu\text{g m}^{-3}$  during  
263 the pre-monsoon campaign, with slightly lower average concentrations observed in the post-

264 monsoon:  $(5.6 \pm 2.7) \mu\text{g m}^{-3}$  as shown in Figure S5. The sulfate diurnal variations are similar to those  
265 of the organic aerosol.

300 **3.4 Isoprene and monoterpane measurements**

301 Isoprene was measured hourly using gas-chromatography with flame-ionisation-detection (GC-FID)  
302 across the two campaigns (Nelson et al., 2021), with the time series shown in Figure 2. The time  
303 series highlights similar diurnal variability each day, driven by biogenic emissions. Figure 3 shows the  
304 average diurnal profiles of isoprene during pre-monsoon (a) and post-monsoon (b). The mean  
305 isoprene mixing ratios were  $(1.22 \pm 1.28)$  ppbv and  $(0.93 \pm 0.65)$  ppbv, with maximum isoprene  
306 mixing ratios of 4.6 ppbv and 6.6 ppbv across the pre- and post-monsoon, respectively. This is in the  
307 same range as measured in Beijing (winter mean:  $(1.21 \pm 1.03)$  ppbv, summer mean:  $(0.56 \pm 0.55)$   
308 ppbv, Acton et al., (2020)), Guangzhou (year round  $(1.14)$  ppbv) (Zou et al., 2019) and Taipei  
309 (summer daytime:  $(1.26)$  ppbv, autumn daytime:  $(0.38)$  ppbv) (Wang et al., 2013). The diurnal  
310 variability observed in the pre-monsoon period corresponds to a typical biogenic emission driven  
311 profile, with a rapid increase of isoprene around 05:00, reaching a peak around or after midday,  
312 before a nocturnal minimum. Figure 3 indicates that average daytime peak isoprene mixing ratios  
313 during the pre-monsoon campaign were roughly double that of the post-monsoon campaign. In  
314 contrast, average nocturnal mixing ratios of isoprene were 5 times higher in the post-monsoon  
315 compared to the pre-monsoon ( $(0.65 \pm 0.43)$  ppbv versus  $(0.13 \pm 0.18)$  ppbv). In the post-monsoon  
316 campaign, isoprene mixing ratios show a strong biogenic emission driven diurnal profile at the start  
317 of the campaign. However, towards the end of the post monsoon measurement period, the isoprene  
318 mixing ratios become less variable with a high mixing ratio maintained overnight (Figure 2). This is  
319 potentially due to more stagnant conditions as observed by the VC in Figure S1.

338

Figure 2. Time series across the pre- (left) and post-monsoon (right) campaigns of Isoprene (a,b),  $\alpha$ -pinene (c,d), limonene (d,e). The vertical dotted lines represent midnight for each day.

339 A recent study in Delhi averaged across post-monsoon, summer and winter campaigns found that at  
340 vegetative sites biogenic isoprene contributed on average 92 - 96 % to the total isoprene, while at  
341 traffic dominated sites only 30 – 39 % of isoprene was from biogenic sources (Kashyap et al., 2019).  
342 This is similar to the contributions of biogenic isoprene (40 %) to total isoprene mixing ratios at the  
343 traffic dominated Marylebone Road London site.(Khan et al., 2018a) To gain some understanding of

344 the sources of isoprene at our site in Delhi, the observed concentrations of isoprene were correlated  
 345 to CO, which is an anthropogenic combustion tracer (Figure 5) similar to previous studies.(Khan et  
 346 al., 2018a; Wagner and Kuttler, 2014) The isoprene concentrations were split between night and day  
 347 (pre-monsoon; night: 19:00 – 05:00 h, day 05:00 – 19:00 h, post-monsoon; night: 17:00-06:00 h, day:  
 348 06:00-17:00 h), based on the observed isoprene diurnals as shown in Figure 3. Isoprene correlated  
 349 strongly with CO during the night across both campaigns (pre-monsoon:  $R^2= 0.69$ , post-monsoon:  
 350  $R^2= 0.81$ ), but no correlation was observed during the day ( $R^2 < 0.1$ ). This suggests that daytime  
 351 isoprene is predominantly from biogenic sources, although a small amount will be from  
 352 anthropogenic sources, and that nocturnal isoprene is emitted from anthropogenic sources, as seen  
 353 in other locations. (Khan et al., 2018b; Panopoulou et al., 2020; Wang et al., 2013) The night-time  
 354 isoprene mixing ratios (pre-monsoon:  $(0.13 \pm 0.18)$  ppbv, post-monsoon:  $(0.65 \pm 0.43)$  ppbv) were  
 355 substantially higher than measured previously in Beijing and London ( $<50$  pptv, (Bryant et al., 2020;  
 356 Khan et al., 2018b)), but pre-monsoon concentrations were similar to those observed at night in  
 357 Taipei ( $0.19$  ppbv)(Wang et al., 2013). The high night-time concentrations during the post-monsoon  
 358 period, towards the end of October are also likely influenced by the formation of a very low  
 359 boundary layer, trapping pollutants near the surface, affecting all species similarly. An increase in  
 360 biomass burning may also be a factor. Therefore, during the post-monsoon campaign a significant  
 361 amount of isoprene oxidation products will be of anthropogenic origin.

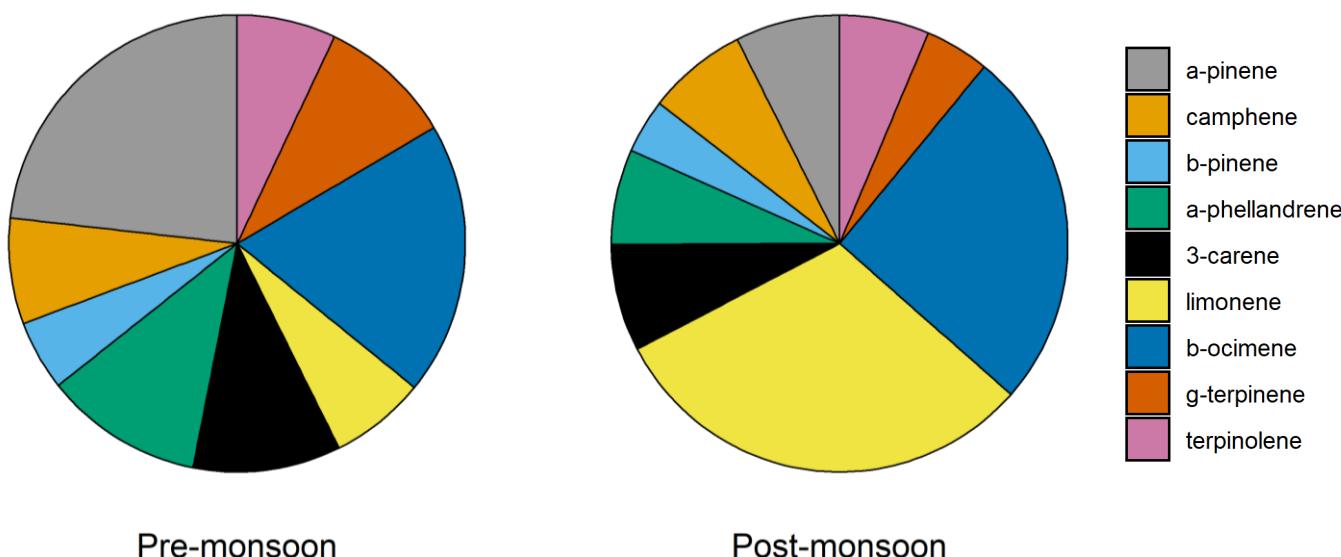

379 Figure 3. Diurnal variations across the pre (left) and post-monsoon (right)  
 380 campaigns of Isoprene (a,b), limonene (c,d) and  $\alpha$ -pinene (e,f). The grey  
 shaded area represents the 95 % confidence interval. The green shaded area  
 represents the times driven by biogenic emissions, as defined by the isoprene  
 diurnals.

381  
382  
383

384 Several monoterpenes were measured using GCxGC-MS. The time series of two monoterpenes,  
385 limonene and  $\alpha$ -pinene, are shown in Figure 2. The  $\alpha$ -pinene mixing ratio averaged  $(0.034 \pm 0.011)$   
386 ppbv during the pre-monsoon and  $(0.10 \pm 0.11)$  ppbv during the post monsoon periods. This is in  
387 comparison to limonene, which averaged  $(0.01 \pm 0.02)$  ppbv and  $(0.42 \pm 0.51)$  ppbv across the pre-  
388 and post-monsoon campaigns, respectively. A strong diurnal variation was observed for both  
389 monoterpenes during the post-monsoon, peaking during the night (Figure 3), with a midday  
390 minimum. Nocturnal mixing ratios of the two monoterpenes were substantially higher during the  
391 post-monsoon (Limonene:  $(0.59 \pm 0.11)$  ppbv,  $\alpha$ -pinene:  $(0.13 \pm 0.12)$  ppbv) than the pre-monsoon  
392 (Limonene:  $(0.011 \pm 0.025)$  ppbv,  $\alpha$ -pinene:  $(0.033 \pm 0.009)$  ppbv) period. The diurnal variations across  
393 both campaigns are likely driven by both emissions as well as boundary layer effects. The boundary layer effect  
394 however is much stronger during the post-monsoon, with a shallower nocturnal boundary layer, as such the  
395 post-monsoon period has a more pronounced diurnal. Limonene was dominated by 3 short lived spikes in  
396 concentrations towards the start of the campaign (Figure 2).  $\alpha$ -pinene concentrations generally  
397 increased during the morning, before decreasing during the afternoon. Multiple monoterpenes  
398 were measured concurrently using GCxGC-MS (Nelson et al., 2021; Stewart et al., 2021c). For all MT  
399 species, the post monsoon period had higher mean mixing ratios, with large nocturnal  
400 enhancements in mixing ratios. There are likely multiple factors leading the higher concentrations  
401 during the post-monsoon, including accumulation due to boundary layer effects, a lack of nocturnal  
402 radical chemistry and an increase in biomass burning (Jain et al., 2014). The average isomeric  
403 speciation of the measured monoterpenes showed low variability between day and night-time  
404 samples during each campaign, but significant differences were observed between the campaigns  
405 (Figure 4). Higher contributions from limonene and  $\beta$ -ocimene were observed during the post-  
406 monsoon compared to the pre-monsoon. The reason for the difference in composition is likely due  
407 to differences in sources and/or sinks between the two periods.

408

413     periods.

414

415

416

417

418

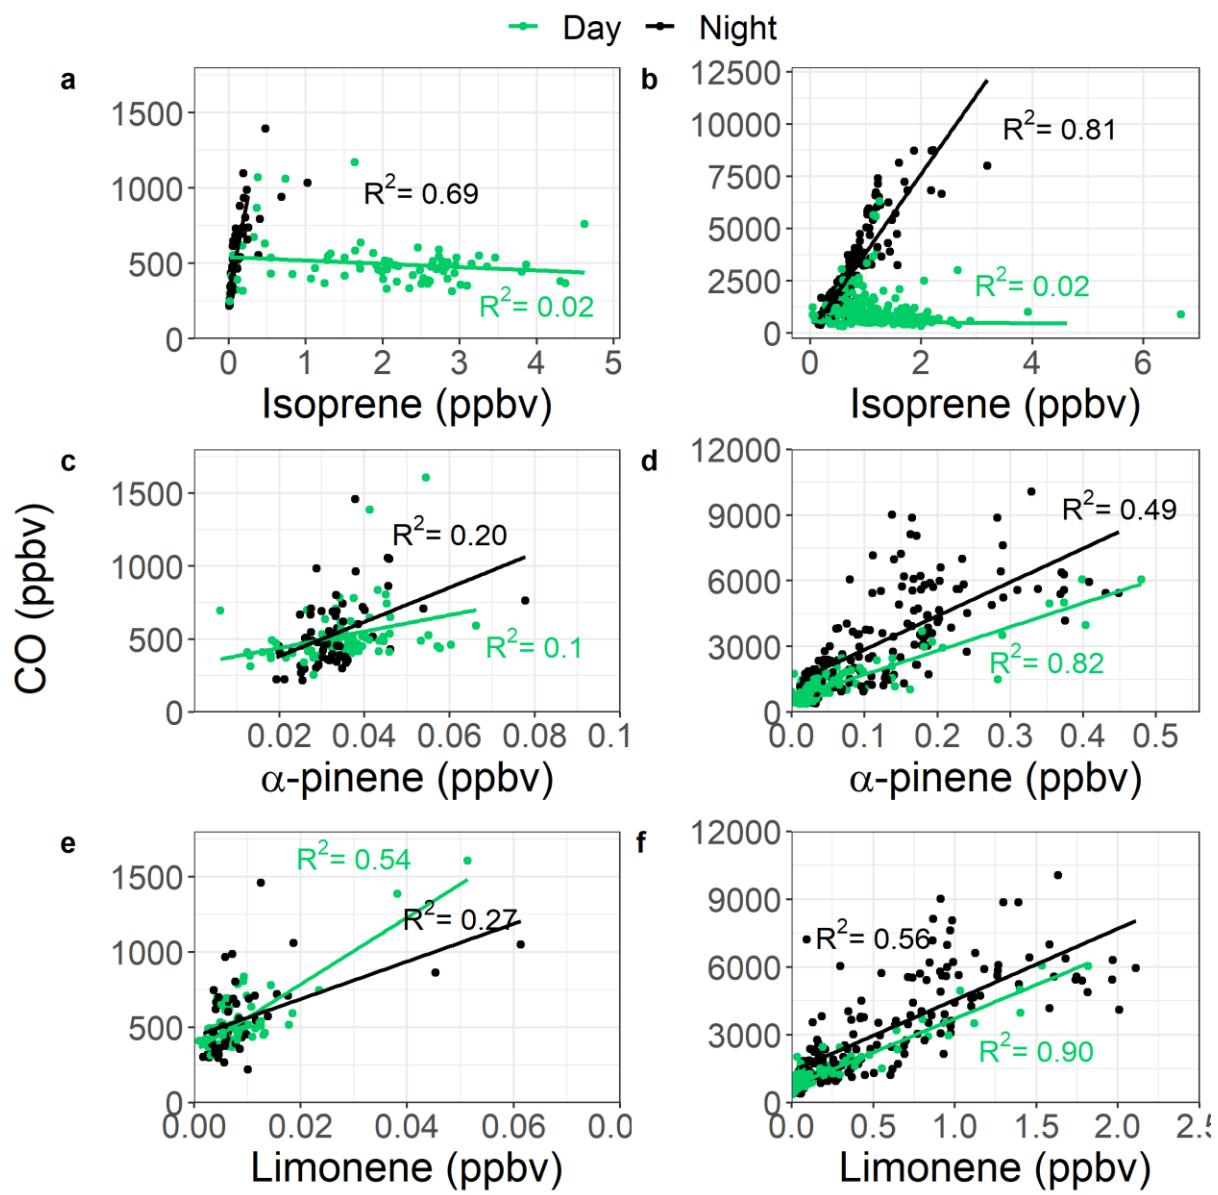

419

420

421

422     During the post-monsoon,  $\alpha$ -pinene and limonene correlated strongly with CO during the day ( $\alpha$ -  
423     pinene;  $R^2 = 0.82$ , limonene;  $R^2 = 0.90$ ) and moderately at night ( $\alpha$ -pinene;  $R^2 = 0.49$ , limonene;  $R^2 =$   
424     0.56) as shown in Figure 5, suggesting anthropogenic sources. Other potentially important  
425     anthropogenic monoterpene sources include biomass burning, cooking and the use of personal  
426     care/volatile chemical products (Coggon et al., 2021; Gkatzelis et al., 2021; Hatch et al., 2019; Klein  
427     et al., 2016). The shallow nocturnal boundary layers across both campaigns leads to relatively high  
428     concentrations of total monoterpenes, with a maximum mixing ratio of 6 ppbv observed during the  
429     post-monsoon (Stewart et al., 2021c). After sunrise, the expanding boundary layer dilutes the high  
430     concentrations alongside increasing OH concentrations from photolytic sources such as the  
431     photolysis of HONO and carbonyls which likely causes a rapid decrease in the monoterpene mixing  
432     ratios. (Lelieveld et al., 2016)

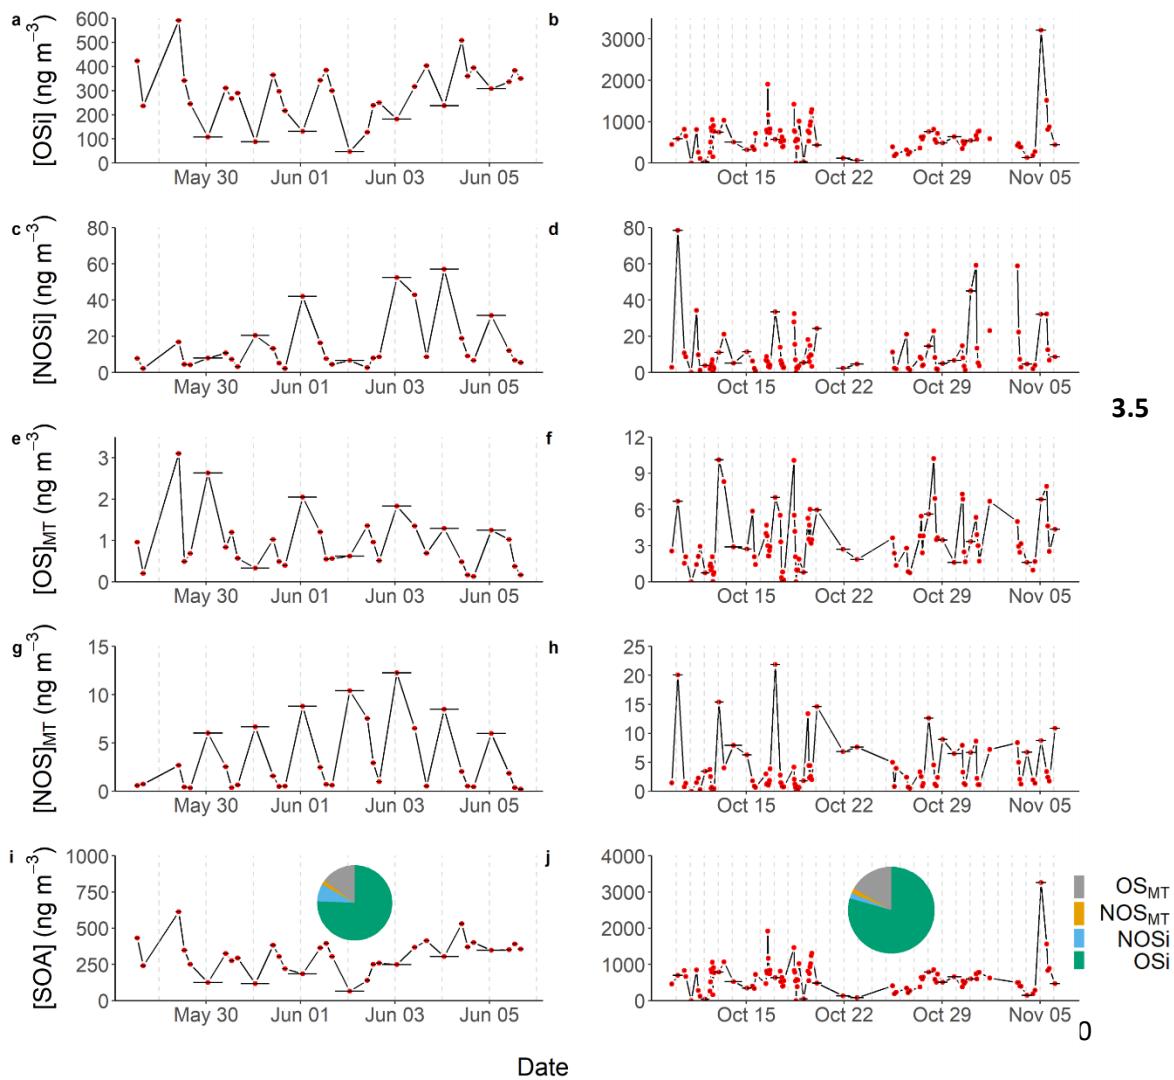

Figure 6. Time series across the pre- (left) and post-monsoon (right) campaigns of the quantified SOA tracers: OSi (a,b), NOSi (c,d), OS<sub>MT</sub> (e,f), NOS<sub>MT</sub> (g,h) and the sum of all SOA tracers (i,j) with the average campaign contributions. The vertical dotted lines represent midnight for each day. Only species identified in more than 40 % of the samples for each campaign were included.

At the measured concentrations, monoterpenes and isoprene are an important source of ozone and OH reactivity at this site (Nelson et al., 2021). The resultant oxidised products will also be a key source of SOA production. The UHPLC-MS<sup>2</sup> analysis identified and quantified 75 potential markers across four classes of SOA, isoprene OS (OSi) and NOS (NOSi) derived species and monoterpene OS (OS<sub>MT</sub>) and NOS (NOS<sub>MT</sub>) species. Figure 6 shows the contribution to the total quantified SOA (qSOA),

473 which consists of the time averaged sum of the four SOA classes (OSi, NOSi, OS<sub>MT</sub>, NOS<sub>MT</sub>), across the  
474 pre- and post-monsoon campaigns. OSi species were the dominant SOA class quantified in this  
475 study, contributing 75.6 % and 79.4 % of the qSOA across the pre- and post-monsoon campaigns  
476 respectively. NOSi species contributed significantly more to the qSOA during the pre-monsoon (7.6  
477 %) compared to the post-monsoon (2.1 %) period. Similar contributions from the monoterpane  
478 derived SOA species were observed across both campaigns.

479 **3.5.1 Isoprene OS and NOS markers**

480 OSi species are predominantly formed by photo-oxidation of isoprene by OH radicals with the  
481 subsequent products formed dependent on ambient NO concentrations (Wennberg et al., 2018).  
482 The pathways are split into high-NO and low-NO, although the NO concentrations that constitute  
483 high and low are a sliding scale depending on the amount of reactivity (defined as  $([\text{OH}] \times k_{\text{OH}})$ )  
484 (Newland et al., 2021). Under low-NO conditions, isoprene epoxydiol isomers (IEPOX) (Paulot et al.,  
485 2009) are formed which can then undergo reactive uptake to the particle phase by acid-catalysed  
486 multiphase chemistry involving inorganic sulfate, to form 2-MT-OS (Lin et al., 2012; Riva et al., 2019;  
487 Surratt et al., 2010). Under high-NO conditions, 2-methyl glyceric acid is the dominant gas-phase  
488 marker produced, which can undergo reactive uptake to the particle phase to form 2-MG-OS (Lin et  
489 al., 2013a; Nguyen et al., 2015; Surratt et al., 2006, 2010).

490 A total of 21 potential OSi C<sub>2-5</sub> markers previously identified in chamber studies (Nguyen et al., 2010;  
491 Riva et al., 2016a; Surratt et al., 2007, 2008b) and other ambient studies (Bryant et al., 2020;  
492 Budisulistiorini et al., 2015; Hettiyadura et al., 2019; Kourtchev et al., 2016; Rattanavaraha et al.,  
493 2016a; Wang et al., 2018b, 2021b) were quantified in the collected ambient samples. It should be  
494 noted that several of the smaller (C<sub>2-3</sub>) OSi tracers likely form from glyoxal, methylglyoxal and  
495 hydroxyacetone as well as isoprene, and as such present a potential non-isoprene source of OSi  
496 (Galloway et al., 2009; Liao et al., 2015).

497 Figure 6 shows the time series of total OSi concentrations observed across pre- (left, 5a) and post-  
498 (right, 5b) monsoon campaigns. Total OSi time averaged concentrations (Table 1) were c.a. 2.3 times  
499 higher during the post-monsoon ( $\sim 556.6 \pm 422.5 \text{ ng m}^{-3}$ ) campaign than the pre-monsoon campaign  
500 ( $\sim 237.8 \pm 118.4 \text{ ng m}^{-3}$ ). These concentrations are similar to those observed in Beijing during summer  
501 2017 ( $237.1 \text{ ng m}^{-3}$ , (Bryant et al., 2020)), but higher than those observed in Shanghai in 2018 (40.4  
502  $\text{ng m}^{-3}$ ) and 2019 (34.3  $\text{ng m}^{-3}$ ) (Wang et al., 2021b). As previously discussed, OSi species have been  
503 shown to form via the gas-phase photo-oxidation of isoprene, with the reactive uptake of the  
504 oxidised species into the particulate phase via sulfate (Lin et al., 2013a; Surratt et al., 2010).  
505 Recently, a heterogeneous photo-oxidation pathway from 2-MT-OS ( $\text{C}_5\text{H}_{12}\text{O}_7\text{S}$ ) to several OSi species  
506 was proposed, including  $\text{C}_5\text{H}_{10}\text{O}_5\text{S}$ ,  $\text{C}_5\text{H}_8\text{O}_5\text{S}$ ,  $\text{C}_5\text{H}_{12}\text{O}_8\text{S}$ ,  $\text{C}_5\text{H}_{10}\text{O}_8\text{S}$  and  $\text{C}_4\text{H}_8\text{O}_5\text{S}$  (Chen et al., 2020). 2-  
507 MT-OS showed moderate correlations (pre-monsoon :  $R^2 = 0.52-0.72$ , post-monsoon:  $R^2 = 0.14-0.35$ )  
508 with these OSi tracers that were lower than observed in Beijing summer ( $R^2 = 0.83-0.92$ ) (Bryant et  
509 al., 2020). These correlations could suggest that this is a more common formation route in pre-  
510 monsoon Delhi, than in post-monsoon. However, the correlations could also be driven by the  
511 common pathways between the OSi species, with the reactive uptake of gas phase intermediates via  
512 sulfate reactions. The lower correlations during the post-monsoon could be due to increased  
513 influences of anthropogenic sources coupled to the stagnant conditions.

514 Figure 7 shows the binned OSi concentrations for each filter collection time across the pre- and post-  
515 monsoon campaigns to create a partial diurnal profile. During the pre-monsoon, the daily variation  
516 in OSi concentrations was much clearer, with day-time maxima and nocturnal minima, which are in  
517 line with daily peak isoprene (Figure 3) and OH radical concentrations. The highest observed OSi

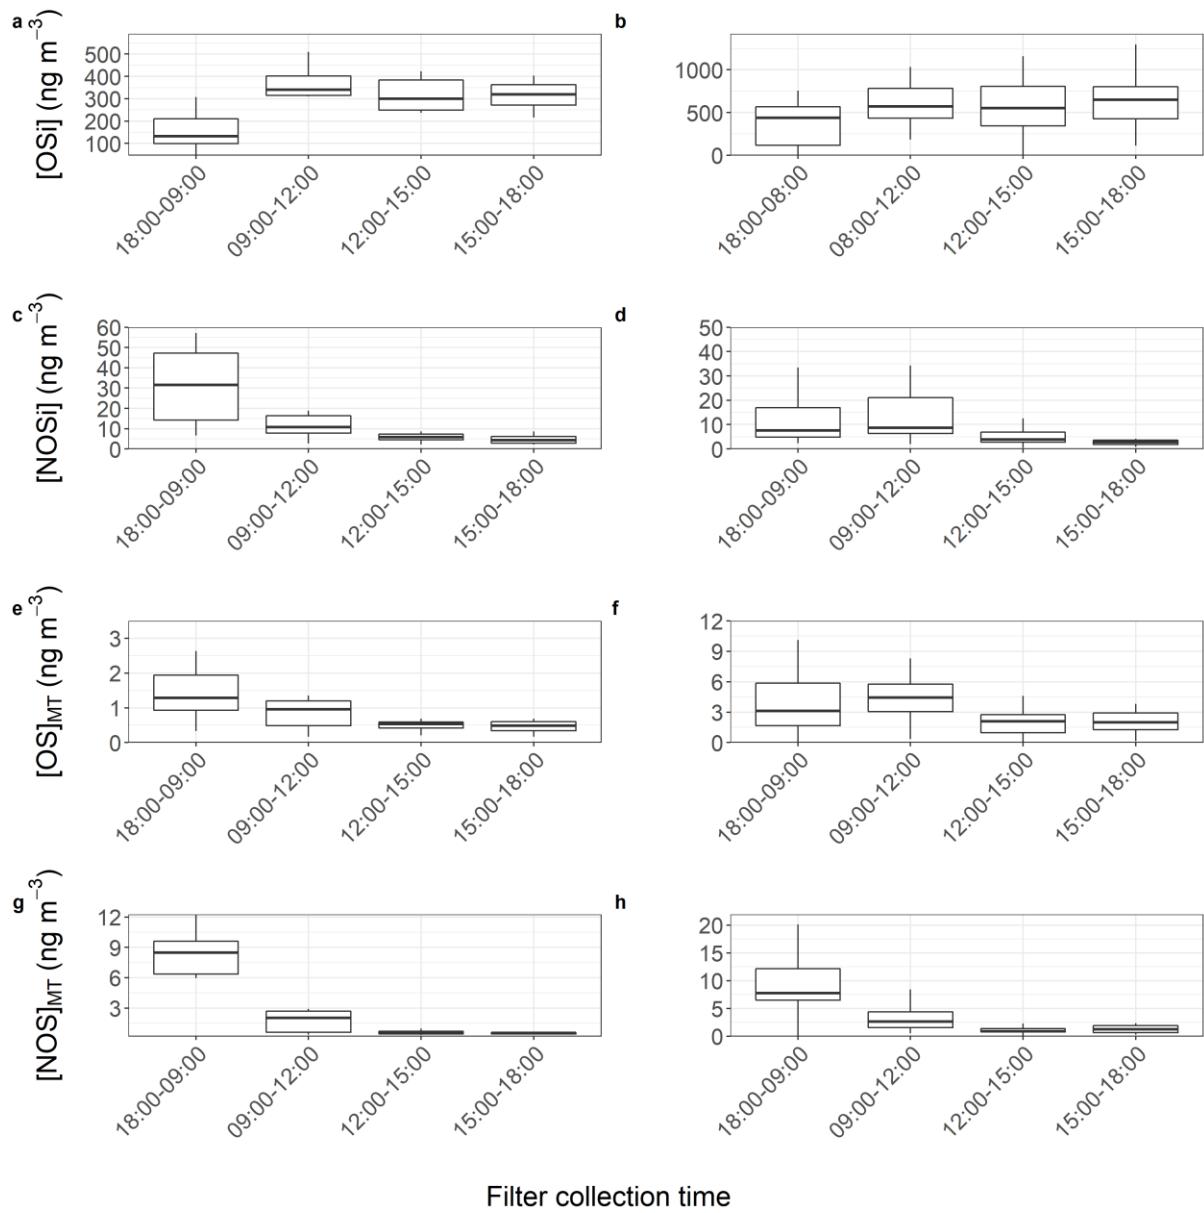

518 concentrations during the pre-monsoon were  $\sim 600 \text{ ng m}^{-3}$ , which occurred at the start of the  
519 campaign. High isoprene concentrations may have been the cause, but unfortunately isoprene  
520 measurements were not available during this period to confirm. However, high OSi concentrations  
521 also occurred when particulate inorganic sulfate concentrations were at their highest (Figure S6),  
522 while sulfate measured via the HR-AMS was also high during this period (Figure 1). During the post-  
523 monsoon, although a similar diurnal pattern was observed, the variation was less pronounced, with  
524 higher OSi concentrations observed at the start and end of the campaign (Figure 6). Due to the  
525 secondary nature of sulfate, the sulfate concentrations are less likely to be influenced by the  
526 boundary layer effects, compared to directly emitted VOCs. The low OSi concentrations during the  
527 middle of the campaign, coincide with lower isoprene and inorganic sulfate concentrations, but also  
528 low VC values, suggesting more stagnant conditions.

529 The sum of OSi species across all filters sampled showed a variable correlation with particulate  
530 sulfate across both campaigns. The pre-monsoon correlation was similar to those observed in  
531 Beijing, Guangzhou and the SE-US ( $R^2: 0.55$ ) (Bryant et al., 2020, 2021; Budisulistiorini et al., 2015;  
532 Rattanavaraha et al., 2016a) while the post-monsoon was significantly weaker ( $R^2: 0.28$ ). However, a  
533 clear relationship between OSi tracers and inorganic sulfate can be seen in Figure 8 across both  
534 campaigns, where the highest OSi concentrations occurred under the highest particulate sulfate  
535 concentrations. During the post-monsoon campaign, OSi concentrations levelled off at high sulfate  
536 concentrations. In the pre-monsoon this levelling off is not observed, potentially due to the lower  
537 number of samples. The high concentrations of organics measured by the HR-AMS (Table S2) during  
538 the post-monsoon ( $48.7 \pm 35.4 \text{ } \mu\text{g m}^{-3}$ ) compared to the pre-monsoon ( $19.8 \pm 13.7 \text{ } \mu\text{g m}^{-3}$ ), suggests  
539 the reactive uptake of the gaseous OSi intermediates to the aerosol phase may be limited due to  
540 extensive organic coatings on the sulfate aerosol. Multiple studies have now shown that organic  
541 coatings on sulfate aerosol can limit the reactive uptake of IEPOX, suggesting the pre-monsoon is  
542 volume limited but the post-monsoon is diffusion limited. (Gaston et al., 2014; Lin et al., 2014; Riva  
543 et al., 2016c)

544 Isoprene NOS (NOSi) have been shown to be produced by photo-oxidation in the presence of NO  
545 and from  $\text{NO}_3$  oxidation chemistry (Hamilton et al., 2021; Ng et al., 2017; Surratt et al., 2008b). Ten  
546 different NOSi tracers were screened for across the two campaigns, with eight identified in the pre-  
547 monsoon and ten in the post-monsoon. These tracers included: mono-nitrated ( $\text{C}_5\text{H}_9\text{O}_{10}\text{NS}$ ,  
548  $\text{C}_5\text{H}_{11}\text{O}_9\text{NS}$ ,  $\text{C}_5\text{H}_{11}\text{O}_8\text{NS}$ ), di-nitrated ( $\text{C}_5\text{H}_{10}\text{O}_{11}\text{N}_2\text{S}$ ), and tri-nitrated ( $\text{C}_5\text{H}_9\text{O}_{13}\text{N}_3\text{S}$ ) species. These tracers  
549 have been identified previously in China (Bryant et al., 2020, 2021; Hamilton et al., 2021; Wang et  
550 al., 2018b, 2021b). Unlike the OSi tracers, total NOSi concentrations were on average higher during  
551 the pre-monsoon ( $32.6 \pm 19.9 \text{ } \text{ng m}^{-3}$ ) compared to the post-monsoon ( $20.2 \pm 13.3 \text{ } \text{ng m}^{-3}$ ). This is  
552 likely due to extremely high night-time NO concentrations during the post-monsoon quenching  $\text{NO}_3$   
553 radicals, limiting the isoprene +  $\text{NO}_3$  pathway. The NOSi time series and diurnal shown in Figures 5  
554 and 6 respectively highlight the strong nocturnal enhancements in concentrations during the pre-  
555 monsoon, suggesting isoprene +  $\text{NO}_3$  formation pathway is dominant. Due to the long sampling time,  
556 it is likely that these species are forming in the early evening as  $\text{NO}_3$  oxidation becomes more  
557 competitive with OH, while isoprene concentrations are still relatively high. During the post-  
558 monsoon, NOSi concentrations were highest at night and the early morning. The high morning  
559 concentrations could be due to non-local sources mixing down as the shallow night-time boundary  
560 layer breaks down. Ideally, future work in Delhi or India should focus on the measurements of  
561 radicals and OH reactivity ( $k_{\text{OH}}$ ), in order to improve our understanding of the chemistry occurring in  
562 extremely polluted environments. A large spike in NOSi concentrations is observed at the start of the  
563 post-monsoon campaign, which was not observed for the OSi tracers, this coincides with lower NO  
564 concentrations than the rest of the post-monsoon campaign, reducing the  $\text{NO}_3$  quenching by NO,

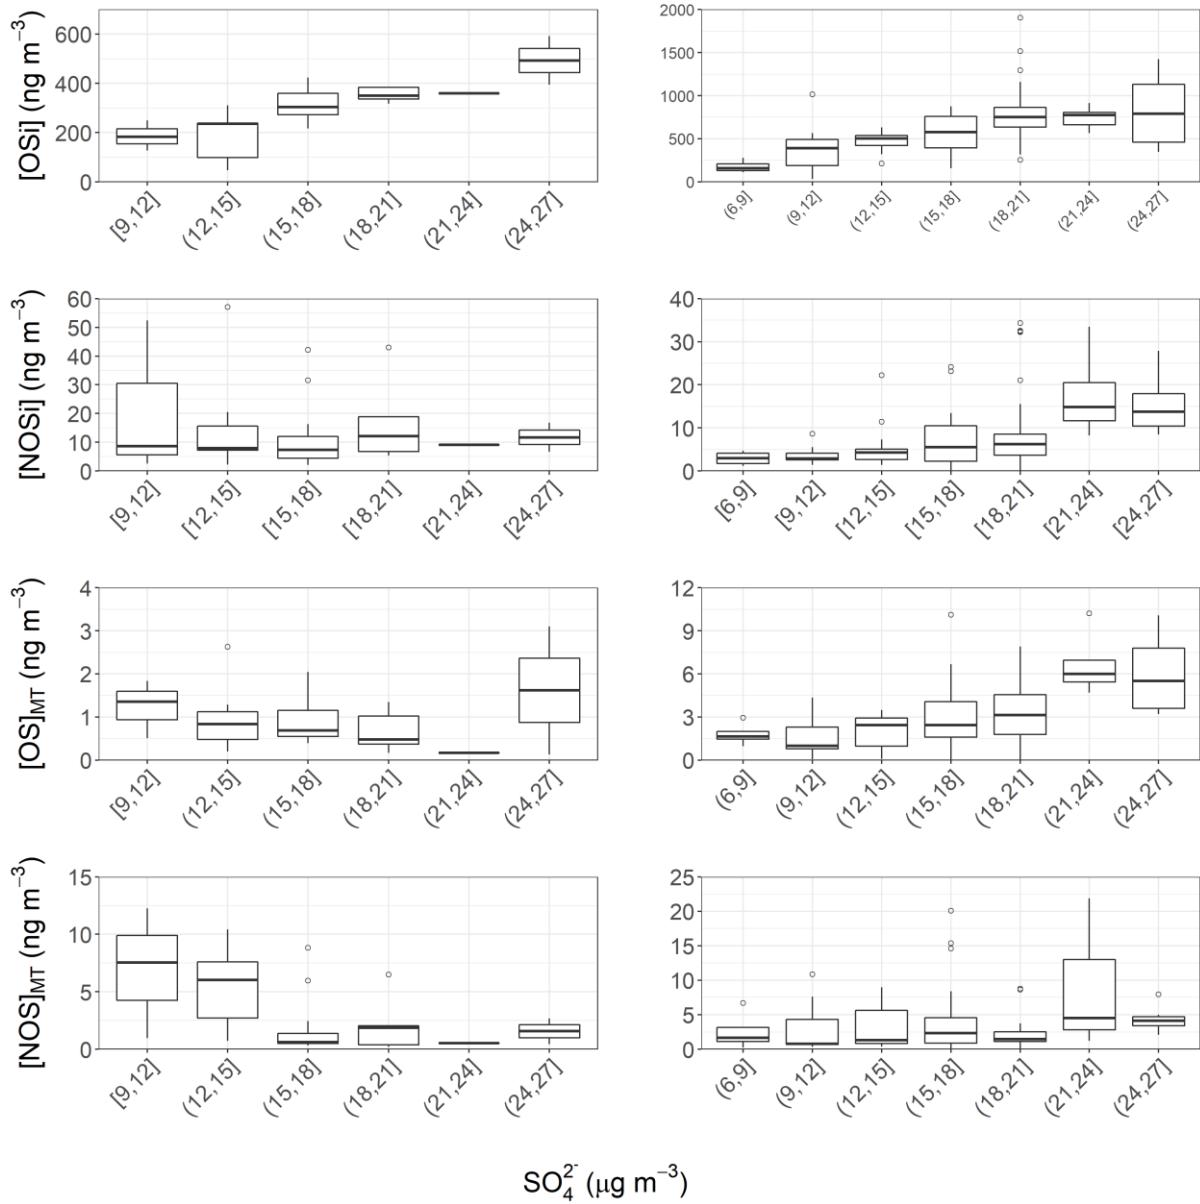

565 allowing for more isoprene +  $\text{NO}_3$  oxidation. The NOSi species did not correlate towards particulate  
 566 sulfate ( $R^2 < 0.2$ ) across either campaign, suggesting that uptake onto sulfate is not the limiting step  
 567 in NOSi formation (unlike for the OSi species).

Figure 8. Quantified SOA (OS<sub>i</sub>, NOS<sub>i</sub>, OS<sub>MT</sub>, NOS<sub>MT</sub>) vs inorganic sulfate concentrations across the pre- (left) and post-monsoon (right) campaigns. The lower and upper part of the box representing the 25<sup>th</sup> and 75<sup>th</sup> percentiles, with the upper and lower lines extending no further than 1.5 times the interquartile range of the highest and lowest values within the hinge respectively. Only species identified in more than 40 % of the samples for each campaign were included.

585

586 **3.5.2 Monoterpene OS and NOS markers**

587 Monoterpene derived OS ( $OS_{MT}$ ) and NOS ( $NOS_{MT}$ ) markers have also been identified from the  
588 oxidation by OH,  $NO_3$  and  $O_3$  in the presence of  $SO_2$  or sulfate seed in simulation studies  
589 (Brüggemann et al., 2020b; Iinuma et al., 2007; Kleindienst et al., 2006; Surratt et al., 2008a; Zhao et  
590 al., 2018). Compared to isoprene, the ozonolysis of monoterpenes is a key degradation pathway,  
591 with higher SOA yields from ozonolysis observed when compared to isoprene (Åsa M. Jonsson et al.,  
592 2005; Atkinson and Arey, 2003; Eddingsaas et al., 2012a, 2012b; Kristensen et al., 2013; Mutzel et  
593 al., 2016; Simon et al., 2020; Zhao et al., 2015). A recent study in the SE-US suggests that the  
594 degradation of 80 % of monoterpenes at night is due to ozonolysis at that location (Zhang et al.,  
595 2018). Monoterpene derived OS and NOS species have been extensively observed, with ON  
596 contributing considerably to OA (Lee et al., 2016; Xu et al., 2015; Zhang et al., 2018). Recently NOS  
597 hydrolysis has also been shown to be a potential formation route of OS particle phase species (Darer  
598 et al., 2011; Passananti et al., 2016).

599 Twenty-three monoterpene-derived organosulfate ( $OS_{MT}$ ) species, which have been seen previously  
600 in chamber (Surratt et al., 2008b) and ambient studies (Brüggemann et al., 2019; Wang et al., 2018b,  
601 2021b), were identified across the pre- and post-monsoon campaigns. It should be noted that  
602 recently  $OS_{MT}$  artefacts has been shown to form when filters have been sampled without a denuder.  
603 (Brüggemann et al., 2020b). However, the strong diurnal variations of the  $OS_{MT}$  species, and lack of  
604 correlation with  $SO_2$  suggest this process is unlikely to have contributed significantly to the  $OS_{MT}$   
605 measured in this study. Post-monsoon concentrations were similar ( $3.96 \pm 1.6$ )  $ng\ m^{-3}$  to the pre-  
606 monsoon ( $3.05 \pm 1.3$ )  $ng\ m^{-3}$ , with  $C_9H_{16}O_6S$  the dominant species across both campaigns,  
607 contributing on average  $\sim 29$  % of the  $OS_{MT}$  mass.  $C_9H_{16}O_6S$  has been observed in chamber studies  
608 (Surratt et al., 2008a) as well as in ambient samples in Denmark, Shanghai and Guangzhou  
609 previously(Bryant et al., 2021; Nguyen et al., 2014; Wang et al., 2017). It should be noted that the  
610 majority of the  $OS_{MT}$  were not identified in every sample, and as such only tracers which were  
611 identified in at least 40 % of the samples were examined further.

612 Total  $OS_{MT}$  showed a strong diurnal profile across both campaigns, peaking at night, with an  
613 afternoon minimum (Figures 5 & 6). During the pre-monsoon campaign, the highest  $OS_{MT}$   
614 concentrations were observed during a day-time sample, coinciding with peak sulfate and NO  
615 concentrations. Both limonene and  $\alpha$ -pinene also show peaks during this filter sampling period of  $\sim$   
616 0.05 ppbv. Spikes in limonene and  $\alpha$ -pinene concentrations were also observed on the 31<sup>st</sup> of May,  
617 but  $OS_{MT}$  concentrations were much lower, likely due to the lower sulfate concentrations. During the  
618 post-monsoon campaign, nocturnal enhancements are observed (Figure 7), suggesting  $MT + NO_3$   
619 chemistry is important. Like the  $NOS_i$  markers, higher  $OS_{MT}$  concentrations were observed during the  
620 early morning sample, likely due to a lower PBLH concentrating the markers coupled to  $MT+OH/O_3$   
621 occurring after sunrise in the post-monsoon. The night-time formation of the  $OS_{MT}$  species is in line  
622 with previous studies (Bryant et al., 2021), and with the diurnal variations of  $\alpha$ -pinene and limonene,  
623 which peak at night. Previous chamber studies investigating reactions of monoterpenes with  $NO_3$   
624 radicals have also shown formation of  $OS_{MT}$  with the same molecular formulae as measured here  
625 (Surratt et al., 2008a).

626  $OS_{MT}$  concentrations observed in Delhi are much lower than those of the  $OS_i$ , similar to other studies  
627 (Hettiyadura et al., 2019; Wang et al., 2018b, 2021b). Considering the high concentrations of  
628 extremely reactive  $\alpha$ -pinene and limonene observed during the post-monsoon period, higher  $OS_{MT}$   
629 concentrations might be expected. One possible reason for the low  $OS_{MT}$  is the inability of  $OS_{MT}$

630 precursor species to undergo reactive uptake into the aerosol phase under atmospherically relevant  
631 acidic conditions, with chamber studies suggesting extremely acidic conditions are needed for  
632 uptake to occur (Drozd et al., 2013). Delhi is characterised by large concentrations of free ammonia  
633 and alkaline dust, and previous studies have highlighted that it has less acidic aerosol (pH 5.7 – 6.7,  
634 Kumar et al., 2018) across the year than Beijing (pH 3.8 – 4.5, Ding et al., 2019) and the SE-US (pH 1.6  
635 – 1.9, Rattanavaraha et al., 2016a).

636 Unlike the OS<sub>MT</sub> species, the NOS<sub>MT</sub> species (C<sub>10</sub>H<sub>17</sub>NO<sub>7</sub>S, C<sub>9</sub>H<sub>15</sub>NO<sub>8</sub>S, C<sub>10</sub>H<sub>17</sub>NO<sub>9</sub>S, C<sub>9</sub>H<sub>15</sub>NO<sub>9</sub>S,  
637 C<sub>10</sub>H<sub>17</sub>NO<sub>8</sub>S) showed strong seasonality, with pre- and post-monsoon concentrations of (7.6 ± 3.8) ng  
638 m<sup>-3</sup> and (17.6 ± 6.1) ng m<sup>-3</sup> respectively. This is opposite to the quantified NOSi species, which  
639 showed higher pre-monsoon concentrations. This is likely due to much higher post-monsoon  
640 concentrations of monoterpenes. Of the NOS<sub>MT</sub> species observed, C<sub>10</sub>H<sub>17</sub>NO<sub>7</sub>S was the most  
641 abundant, contributing on average 79 % and 76 % of the NOS<sub>MT</sub> concentrations across the pre- and  
642 post-monsoon respectively. Previous studies have also highlighted C<sub>10</sub>H<sub>17</sub>NO<sub>7</sub>S to be the dominant  
643 monoterpane derived sulfate containing tracer (Wang et al., 2018b). In the post-monsoon nine  
644 C<sub>10</sub>H<sub>17</sub>NO<sub>7</sub>S isomers were observed, and seven in the pre-monsoon. The summed C<sub>10</sub>H<sub>17</sub>NO<sub>7</sub>S  
645 concentrations during the pre- (5.96 ± 3.33) ng m<sup>-3</sup> and post-monsoon (13.36 ± 4.98) ng m<sup>-3</sup>, are of a  
646 similar magnitude to those observed in other locations as shown in Table 2. These concentrations  
647 are also similar to those quantified by authentic standards across four Chinese megacities (Wang et  
648 al., 2021a). Like the OS<sub>MT</sub> species, some NOS<sub>MT</sub> species were not identified in many of the filter  
649 samples, and as such tracers which were observed in more than 40 % of the samples were summed  
650 for further analysis. The NOS<sub>MT</sub> pre-monsoon time series (Figure 6) shows a similar temporal profile  
651 to the NOSi species, with lower concentrations during the enhancement in NO concentrations  
652 (Figure S4) at the start of the campaign. NOS<sub>MT</sub> showed strong diurnal variations across both  
653 campaigns (Figure 7), peaking at night with lower concentrations during the afternoon, as seen  
654 previously (Bryant et al., 2021; Wang et al., 2018b). Therefore, the formation of NOS<sub>MT</sub> is likely  
655 dominated by NO<sub>3</sub> radical chemistry. Both NOS<sub>MT</sub> and OS<sub>MT</sub> species showed limited correlation  
656 towards SO<sub>2</sub> and particulate sulfate ( $R^2 < 0.1$ ), indicating that although sulfate is essential to their  
657 formation, sulfate availability does not control NOS<sub>MT</sub> concentrations.

658

### 659 **3.5.3 Contributions of total Isoprene and monterpene OS and NOS (qSOA) to particulate mass**

660 Particulate concentrations in Delhi are among the highest across the world (WHO, 2018), with  
661 concentrations over 600  $\mu\text{g m}^{-3}$  being observed during this study. qSOA, defined here as the sum of  
662 all OSi, NOSi, OS<sub>MT</sub>, and NOS<sub>MT</sub> tracers quantified (including those not identified in more than 40 % of  
663 the samples), was calculated to determine the total contribution these species make to particulate  
664 mass in Delhi. Total oxidised organic aerosol (OOA), a proxy for SOA in PM<sub>1</sub>, was derived from the  
665 HR-AMS measurements during the pre- and post-monsoon campaigns, with averages of (19.8 ± 13.7)  
666  $\mu\text{g m}^{-3}$  and (48.7 ± 35.4)  $\mu\text{g m}^{-3}$  respectively. qSOA contributed on average (2.0 ± 0.9) % and (1.8 ±  
667 1.4) % to the total OOA. Isoprene and monterpene derived species contributed on average 83.2 %  
668 and 16.8 % of qSOA across the pre-monsoon respectively compared to 81.5 % and 18.5 % during the  
669 post-monsoon respectively. During certain periods qSOA contributed a maximum of 4.2 % and 6.6 %  
670 to OOA during the pre- and post-monsoon, respectively. This is under the assumption that when the  
671 OS and NOS species fragment in the AMS ion source they lose their sulfate and nitrate groups. This is  
672 similar to the contributions made by OSi markers in Beijing to total OOA (2.2 %) (Bryant et al., 2020).  
673 Previous studies in the SE-US have reported much higher contributions of isoprene species to total  
674 OA. As quantified by an aerosol chemical speciation monitor, summed iSOA tracers on average  
675 accounted for 9.4 % of measured OA at Look Rock, downwind of Maryville and Knoxville, but up to a

676 maximum of 28.1 % (Budisulistiorini et al., 2015). This is lower than that measured at a rural site at  
677 Yorkville, Georgia with just low-NO isoprene SOA tracers accounting for between 12-19 % of total OA  
678 (Lin et al., 2013b).

679 Sulfate was also measured in the  $PM_1$  size range by HR-AMS, with pre- and post-monsoon mean  
680 concentrations of  $(7.5 \pm 1.8) \mu\text{g m}^{-3}$  and  $(5.5 \pm 2.7) \mu\text{g m}^{-3}$ . The sulfate containing OS and NOS species  
681 quantified in this study may fragment in the AMS to produce a sulfate signal which is not related to  
682 inorganic sulfate. To estimate the contribution that sulfate contained within qSOA species could  
683 make to total AMS sulfate, the quantified mass of sulfate contained within each marker was  
684 calculated based on the fraction of sulfate to each marker molecular mass. For example, 2-MT-OS  
685 has an accurate mass of *m/z* 216.21, meaning the percentage of 2-MT-OS mass associated with  
686 sulfate is ~44 %. During the pre-monsoon campaign the qSOA sulfate accounted for on average 2.2  
687 % to the total  $PM_1$  sulfate, but up to 4.8 % on certain days. qSOA contributed considerably more to  
688 the sulfate in the post-monsoon campaign, with an average of  $(6.1 \pm 4.5) \%$  with a maximum of 18.7  
689 %. This finding indicates the need to consider the sources of particulate sulfate measured by the  
690 AMS when calculating aerosol pH. The sulfate contribution from the fragmentation of common small  
691 OS compounds (hydroxymethylsulfonate, methylsulfonic acid) can be distinguished in the AMS using  
692 the relative ratio of sulfur containing peaks.(Chen et al., 2019; Javed et al., 2021) However, more  
693 work is needed to determine how larger OS and NOS fragment in the AMS such as those quantified  
694 in this study. Overall, this highlights that isoprene and MT oxidation can make significant  
695 contributions to organic and sulfate-containing aerosol, even in extremely polluted environments  
696 such as Delhi. It should be noted that this is just a subset of potentially many more SOA from  
697 isoprene and monoterpene markers and only focusses on sulfate containing species.

698

## 699 Conclusion

700 Isoprene- and monoterpene-derived organosulfate (OS) and nitrooxy organosulfate (NOS) species  
701 were quantified during pre- and post-monsoon measurement periods in the Indian megacity of  
702 Delhi. An extensive dataset of supplementary measurements was obtained alongside filter samples,  
703 including isoprene and speciated monoterpenes. Isoprene and monoterpene emissions were found  
704 to be highly influenced by anthropogenic sources, with strong correlations to anthropogenic tracers  
705 at night across both campaigns. High nocturnal concentrations of pollutants were observed due to a  
706 low boundary layer height and stagnant conditions, especially during the post-monsoon period.

707 Isoprene OS markers (OS<sub>i</sub>) were observed in higher concentrations during the post-monsoon  $(557 \pm$   
708  $423) \text{ ng m}^{-3}$  compared to the pre-monsoon campaign  $(238 \pm 118) \text{ ng m}^{-3}$ . OS<sub>i</sub> showed a moderate  
709 correlation with inorganic sulfate across both campaigns. However, concentrations levelled off at  
710 high sulfate concentrations during the post-monsoon which is consistent with organic coatings  
711 limiting uptake of isoprene epoxides. Isoprene NOS species (NOS<sub>i</sub>) showed nocturnal enhancements  
712 across both campaigns, while the highest average concentrations were observed in the morning  
713 samples of the post-monsoon campaign. The high morning concentrations are likely due to the  
714 oxidation of VOCs by OH radicals from photolytic processes throughout the morning. Monoterpene  
715 derived OS (OS<sub>MT</sub>) and NOS (NOS<sub>MT</sub>) markers were observed to have nocturnal enhancements in  
716 concentrations, in-line with their precursors. NOS<sub>MT</sub> markers were observed in similar concentrations  
717 to those of other megacities. Total quantified SOA contributed on average  $(2.0 \pm 0.9) \%$  and  $(1.8 \pm$   
718  $1.4) \%$  to the total OOA. Considering high OOA concentrations were observed across the two  
719 campaigns, the total markers contributed up to a maximum of 4.2 % and 6.6 % across the pre- and  
720 post-monsoon respectively. Overall, this work highlights that even small numbers of isoprene and

721 monoterpene derived SOA markers can make significant contributions to OA mass, even in highly  
 722 polluted megacities.

723

724 Table 1. Molecular formulae, retention times and time weighted means (ng m<sup>-3</sup>) of  
 725 organosulfates (OS) and nitrooxy organosulfates (NOS) from isoprene (i) and monoterpenes  
 726 (MT) observed across pre- and post-monsoon campaigns in Delhi.

### 735 Data availability

736 Data used in this study can be accessed from the CEDA  
737 archive: <https://catalogue.ceda.ac.uk/uuid/ba27c1c6a03b450e9269f668566658ec> (Nemitz et al.,  
738 2020).

### 739 Author contributions

740 DJB prepared the manuscript with contributions from all authors. DJB, BSN, SJS, SHB, WSD, ARV,  
741 JMC, WJFA, BL, EN and JRH provided measurements and data processing of pollutants used in this

742 study. MJN and ARR contributed to scientific discussion. S, RG, BRG, TH and EN assisted with  
743 logistics. CNH, JDL, ARR, JFH provided overall guidance to the experimental setup and design.
