ABSTRACT

Ship based multi-axis differential optical absorption spectroscopy (MAX-DOAS) measurements were ~~carried out~~ conducted along the marginal seas of China from 19 April to 16 May 2018~~,~~ to measures the vertical profiles of aerosol, nitrogen dioxide (NO_2), and nitrous acid (HONO). Along the cruise route, we found f~~F~~ive hot spots ~~of~~ with enhanced tropospheric NO_2 VCDs ~~were found~~ in Yangtze River Delta, Taiwan straits, Guangzhou-Hong Kong-Macao Greater Bay areas, Zhanjiang Port, and Qingdao port ~~with averaged NO_2 VCDs of 1.07×10^{16}, 1.30×10^{16}, 7.27×10^{15}, 5.34×10^{15}, and 3.12×10^{15} molec. cm^{-2}, respectively~~. Enhanced HONO concentrations could usually be observed under high-level aerosol and NO_2 conditions, ~~HONO~~ whereas the reverse was not always the case. ~~performs similar spatial distribution characteristics as NO_2 with averaged HONO VCDs in above five hot spot areas of 1.01×10^{15}, 7.91×10^{14}, 6.02×10^{14}, 5.36×10^{14}, and 5.17×10^{14} molec. cm^{-2}, respectively. The averaged near-surface NO_2 concentrations were 8.46 and 11.31 ppb, and the averaged near-surface HONO concentrations were 0.23 and 0.27 ppb under sea-oriented and land-oriented observation azimuths during the whole campaign, respectively.~~ To understand the impacts of relative humidity (RH), temperature, and aerosol on the heterogeneous reaction of NO_2 to form HONO in different scenes, ~~The~~ the Chinese Academy of Meteorological Sciences (CAMS) and Southern University of Science and Technology (SUST) MAX-DOAS stations were selected as the inland and coastal cases, respectively~~to further understand the impacts of relative humidity (RH), temperature, and solar radiation intensity (SRI) on the heterogeneous reaction of NO_2 to form HONO in different scenes~~. ~~The emission ratios of $\Delta HONO/\Delta NO_x$ in sea, CAMS and SUST were $0.46\pm0.31\%$, $0.82\pm0.34\%$, and $0.79\pm0.31\%$, respectively.~~ The RH turning points in CAMS and SUST cases were ~~all~~ both ~65% (60–70%), ~~however,~~ whereas two turning peaks (~60% and ~85%) of RH were found in the sea cases. As temperature increased, t~~T~~he HONO/NO_2 ratio decreased ~~along with the increase of temperature, and~~ with peak values appearing ~~on~~ at ~12.5℃ in CAMS~~,~~. whereas t~~T~~he HONO/NO_2 gradually increased ~~along with increasing temperature,~~ and ~~with~~ reached peak values ~~on~~ at ~31.5℃ in SUST. In the sea case, when the temperature exceeded 18.0℃~~In sea case,~~. the HONO/NO_2 ratio ~~increase~~ rose ~~along~~ with ~~the~~ increas~~e of~~ing temperature ~~with~~ and achieved its peak~~a peak value on~~ at ~25.0℃. ~~under the temperature being larger than 18.0℃.~~ Th~~at~~is ~~means~~ indicated that ~~the~~ high temperature ~~could~~ can contribute to the secondary formation of HONO in the sea atmosphere. In the inland case, the correlation analysis between HONO and aerosol in the near-surface layer showed that the ground surface is more crucial to the formation of HONO via the heterogeneous reaction of NO_2; however, in

the coastal and sea cases, the aerosol surface contributed more. ~~The correlation analysis between HONO and aerosol in near-surface layer illustrated the ground surface plays a more important role than aerosol surface during the HONO formation process from the heterogeneous reaction of NO₂ under inland case, however, aerosol surface plays a more important role during above process under coastal and sea cases.~~ ~~Moreover~~Furthermore, we ~~found~~ discovered that the conversion rate of ~~HONO generation rate from~~ NO₂ to HONO through heterogeneous reaction in the sea case is larger than that in the inland case in higher atmospheric layers (> 600 m) ~~in higher atmospheric layers above 600 m~~. Three typical events were selected to demonstrate three potential contributing factors of HONO production under marine condition (i.e., transport, NO₂ heterogeneous reaction and unknown HONO source). This study elucidates the sea-land and vertical differences in the forming mechanism of HONO via the NO₂ heterogeneous reaction and provides deep insights into tropospheric HONO distribution, transforming process and environmental effects.

1 Introduction

Nitrous acid (HONO) is an important part of the atmospheric nitrogen cycle, and plays a significant role in atmospheric oxidation capacity (Alicke et al., 2003; Kleffmann et al., 2005). Photolysis of HONO in near ultraviolet bands (Eq. 1) is a substantial source of hydroxyl radicals (OH radicals), which are one of the most important oxidants in the tropospheric atmosphere. ~~Previous~~ Earlier studies reported that the contribution of HONO photolysis to OH radicals can reach 40–60%, ~~and even more than~~ while exceeding 80% ~~especially~~ in the early morning (Michoud et al., 2012; Ryan et al., 2018; Xue et al., 2020). ~~OH radicals are one of the most important oxidants in the atmosphere.~~ OH radicals ~~They~~ can oxidize and destroy most atmospheric pollutants, such as CO, NO$_x$ (NO+NO₂), SO₂ and volatile organic compounds (VOCs), thereby further promoting the formation of secondary pollutants (e.g., ozone (O₃), peroxyacetyl nitrate (PAN), and secondary aerosols~~, etc.)~~, and leading to serious haze pollution events (Huang et al., 2014). ~~In addition~~Additionally, as a nitrosating agent, HONO can produce carcinogenic nitrite amines ~~to~~ that pose a threat to human health (Zhang et al., 2015). Therefore, a full understanding of the source and formation mechanism of HONO ~~is~~ has very important ~~scientific~~ally ~~significance~~ significant for the study of tropospheric oxidation and the control of secondary pollution.

~~At present~~Currently, the known sources of HONO mainly include direct emissions from vehicles, ships, biomass burning and soil, the homogeneous reaction of NO and OH radicals (Eq. 2), the nighttime and daytime heterogeneous reaction of NO₂ (Eq. 3) on aerosols, vegetation, ground and other types of surfaces, and the photolysis of nitrate particles (Eq. 4) ~~(NO$_3^-$)~~ (Alicke et al., 2003; Stemmer et al., 2006; Indarto et al., 2012; Wang et al., 2015; Salgado and Rossi, 2002; Zhou et al., 2011). ~~There are also some obvious unknown~~Sources of HONO exist ~~sources~~ that are poorly understood (Fu et al., 2019). The heterogeneous reaction of NO₂ as a source of HONO has received continuous attention in recent years. It ~~has been~~was found that the heterogeneous reaction of NO₂ is one of the most important sources of HONO in a variety of ~~scenarios~~ scenes such as inland, coastal cities and offshore seas. Liu et al. (2021) reported the contribution of heterogeneous reaction of NO₂ on aerosol surface to HONO is 19.2% in summer, and this contribution ~~of heterogeneous reaction of NO₂~~ on aerosol and ground surfaces to HONO can reach 54.6% in winter in Beijing. Yang et al. (2021) and Zha et al. (2014) found that the generation rate of HONO through the heterogeneous reaction of NO₂ under sea-wind conditions could elevate 3-4 times than that under land-wind conditions in the northern coastal city of Qingdao and the southern coastal city of Hong Kong, respectively. Cui et al. (2019) illustrated that the heterogeneous reaction of NO₂ on aerosol and sea surfaces is an important source of HONO in East China Sea in summer. The process of HONO formed from the heterogeneous reaction of NO₂ is affected by various atmospheric parameters. The relative humidity (RH), temperature, solar radiation intensity (SRI), and aerosol concentration and its relative surface area are the particularly important parameters. ~~Previous~~ Earlier works always used the linear regression relationship between HONO/NO₂ and the above parameters to characterize the influence of these parameters on the formation of HONO through the heterogeneous reaction of NO₂. Although this kind of simple linear regression method may lead to artificial correlations and misleading conclusions, considering the vertical evolution of atmospheric parameters. Wen et al. (2019) found that the increased temperature could promote the heterogeneous reaction of NO₂ to form HONO in sea conditions. The generation rate of HONO could increase rapidly, when the temperature was greater than 20 ℃. Gil et al. (2019) found that the HONO formed from the heterogeneous reaction of NO₂ will increase along with the increase of RH when RH was less than 80% in a case of land park using deep learning forced by measurement results. Fu et al. (2019) reported that RH and SRI were the main parameters driving the heterogeneous reaction of NO₂ to form HONO in Pearl River Delta, and it contributes to 72% of the total source of HONO. Cui et al. (2019) found that the potential of heterogeneous reaction of NO₂ to form HONO will increase with the increase of particle concentration and the specific surface area of single particle in coastal cities.

$$HONO + hv \rightarrow NO + \cdot OH \,(\lambda < 400nm) \tag{1}$$

$$\cdot OH + NO + M \rightarrow HONO + M \tag{2}$$

$$2NO_2 + H_2O \rightarrow HONO + HNO_3 \tag{3}$$

2

$$HNO_3 / NO_3^- + hv \rightarrow HONO / NO_2^- + O \cdot (\lambda \sim 300nm) \tag{4}$$

However, ~~previous~~ earlier researches generally focus~~edes~~ on the near-surface layer of a single scene, and attentions ~~on~~ to the influence mechanism of the heterogeneous reaction of NO_2 to form HONO in vertical direction and in different sea and land scenes are insufficient, which limits the comprehensive assessment to understand the sea-land differences and impact mechanism of HONO formed from the heterogeneous reaction of NO_2. NO_2 could be transported from inland and coastal cities to offshore seas (Tan et al., 2018). This part of NO_2 can promote the HONO formation through heterogeneous reaction on the high-level aerosol and sea surfaces in the atmosphere of sea (Zhang et al., 2020). The formed HONO is ~~completely~~ likely to be ~~transported~~ carried to land cities at night by sea breeze~~under favorable weather conditions.~~, ~~It~~ which will affect the atmospheric oxidation and air quality, and even endanger human health. ~~In a~~Additionally, the vertical distributions and values of atmospheric meteorology and aerosol parameters are significantly different in land and sea scenes, which provide different conditions for the heterogeneous reaction of NO_2 to form HONO in different height layers. ~~Moreover~~Furthermore, aerosols and NO_2 have complex evolution and transmission characteristics in the vertical direction. The vertical upward transport of aerosol and NO_2 can promote the HONO formation through heterogeneous reaction at high altitude, and the vertical downward transport of HONO will impact the atmospheric environment near the ground. The vertical observations in land-sea scenes ~~is~~ are also helpful to distinguish the contribution of the heterogeneous reaction of NO_2 on the aerosol and ground/sea surfaces (Zhang et al., 2020).

~~At present~~Currently, a variety of HONO measurement techniques have been developed, which in principle can be roughly divided into wet chemical ~~methods~~, spectroscopy ~~methods~~, and mass spectrometry methods~~, in principle~~ (Cheng et al., 2013; Bernard et al., 2016; Gil et al., 2019; Guo et al., 2020; Jordan et al., 2020). However, these technical methods can only measure the HONO information near the surface layer. Taking tower and aircraft as platforms, these techniques were performed to measure HONO vertical profiles, and it was found that the peak values of HONO usually appeared under 200 m at urban and suburban areas (Kleffmann et al., 2003; Stemmler et al., 2006; Zhang et al., 2009; Wong et al., 2012; Meng et al., 2020; Zhang et al., 2020). These studies also revealed that the heterogeneous reaction of NO_2 on multiple surfaces (ground and aerosol etc.) was an important source of HONO under planetary boundary layer (PBL), especially in haze days. ~~Moreover~~Furthermore, they also reported that the HONO/NO_2 ratios usually decreased with the increase of height under 200 m at inland and coastal areas. ~~Zhang et al. (2020) measured the vertical distribution of HONO by placing wet chemical HONO samplers at different heights of tower in Being during spring, and found the maximum value of HONO appeared at 120 m sourced from the heterogeneous reaction of NO_2 on aerosol surface under haze conditions. Meng et al. (2020) also used tower by moving the IBBCEAS carried in a box at a constant speed to measure the vertical profiles of HONO in Beijing during winter, and reported that the heterogeneous reaction of NO_2 under the atmospheric boundary layer is an important source of HONO, especially in haze conditions.~~ However, the cost of above techniques used to measure HONO vertical profiles was too high, and the real-time and continuous measurement cannot be realized. Multi-axis differential optical absorption spectroscopy (MAX-DOAS), as a ground-based ultra-hyperspectral remote sensing technology, ~~had been~~was widely used for vertical observation of atmospheric pollutants in the past two decades. ~~Therefore, the measurement of the vertical profiles of HONO under different sea-land scenes based on MAX-DOAS could provide technical supports for learning the sea-land and vertical differences and the influence mechanism of the heterogeneous reaction of NO_2 to form HONO.~~ In the past five years, several researchers ~~have~~ carried out campaigns based on MAX-DOAS to measure the vertical profile of HONO in inland and coastal areas, and revealed their vertical characteristics, sources and the contribution to ~~the sources of HONO and their contribution to~~ atmospheric oxidation at different height layers (Garcia-Nieto et al., 2018; Ryan et al., 2018; Wang et al., 2020; Xing et al., 2021; Xu et al., 2021; He et al., 2023). ~~There were f~~Few studies were conducted on the sources of HONO at different height layers in sea conditions. In this study, ~~it will be the first time to use~~ MAX-DOAS is used for the first time to study the spatiotemporal distribution and the sources of HONO along the Chinese coastline, and to learn the differences of the HONO formed from the heterogeneous reaction of NO_2 in different height layers and land-sea scenes.

2 Methods and methodologies

2.1 ~~The m~~Measurement cruise

The ship-based atmospheric observation campaign along the marginal seas of China was ~~carried out~~conducted from 19 April to 16 May 2018. The latitude and longitude ranges of the entire campaign covered 21.12ºN–35.89ºN and 110.67ºE–122.16ºE. The detailed voyage records of the observation ship are shown in Table 1. An integrated and fully automated MAX-DOAS instrument was installed aboard the stern deck of the ship (Figure S1(a)). ~~In order t~~To ensure that the instrument is always kept in a horizontal position, a photoelectric gyro was used. The angle between the observation ~~direction~~ and ~~the~~ heading direction~~s~~ of the ship was always maintained at 135º during the whole campaign. The telescope unit of the instrument pointed towards sea during cruise NO.3 and NO.6. The telescope unit pointed towards inland during cruise NO.1, NO.4 and NO.5. During cruise NO.2, the observation telescope always pointed to Chongming island. The measurement ship only sailed in daytime from 19 April to 02 May, and

3

continuously sailed in all the daytime and nighttime from 3 May to 16 May 2018. The ship docked in Daishan port on 9–10 May and no observations were ~~carried out~~conducted during these two days.

The aim of this campaign was to learn the vertical differences of NO$_2$ heterogeneous reaction to produce HONO in marginal seas of China and compare the influence mechanism of that in inland cities. ~~In order t~~To fully understand the differences of the impacts of RH, temperature and aerosol on the HONO secondary formation in land and sea conditions, the Chinese Academy of Meteorological Sciences (CAMS) and Southern University of Science and Technology (SUST) MAX-DOAS stations were selected as inland and coastal areas for analysis, respectively. CAMS ~~was~~is located in the urban of Beijing (116.32ºE, 39.94ºN), and SUST ~~was~~is located in Shenzhen (114.00ºE, 22.60ºN) (Figure S2). This study will provide scientific guidance for understanding regional oxidation capacity and controlling the secondary air pollution.

2.2 MAX-DOAS measurements

2.2.1 Instrument setup

The compact instrument consists of an ultraviolet spectrometer (AvaSpec-ULS2048L-USB2, 300-460 nm spectral range, 0.6 nm spectral resolution) at a 20℃ fixed temperature with a deviation of < 0.01℃, a one-dimensional CCD detector (Sony ILX511, 2048 individual pixels) and a telescope unit driven by a stepper motor to collect scattered sunlight from different elevation angles. The accuracy of elevation angle is < 0.1 ℃ and the telescope field of view (open angle) is < 0.3º. A full scanning sequence consists of 11 elevation angles (1º, 2º, 3º, 4º, 5º, 6º, 8º, 10º, 15º, 30º and 90º). The integration time of one individual spectrum was set to 30 s, and each scanning sequence took about 5.5 min. Besides, the controlling electronic devices and connecting fiber are mounted inside. The instrument is equipped with a high-precision Global Position System (GPS) to record the real-time coordinated positions of the ~~ship~~ cruise ship. The detailed description of the setup of MAX-DOAS in CAMS and SUST can be found in Liu et al. (2021).

2.2.2 Data processing and filtering

The MAX-DOAS measurements could be influenced by the exhaust from the measurement ship. Therefore, the data contaminated by the exhaust were filtered out. As shown in Figure S1(b), the direction and speed of the plume exhausted from the ship depends on the ship ~~direction/speed~~ and the true wind speed~~s~~/direction~~s~~. Individual measurements taken under unfavorable plume directions (plume directions between 45 and 135◦ with respect to the heading of the ship) were discarded. ~~In order t~~To avoid the strong influence of the stratospheric absorption, the spectra measured with solar zenith angle (SZA) lager than 75 ° were filtered out. Under these two filtering criteria, 4.9 and 8.3% of all data were rejected before DOAS analysis (Xing et al., 2017, 2019, 2020).

2.2.3 DOAS analysis

The MAX-DOAS measured spectra were analyzed using the software QDOAS which is developed by BIRA-IASB (http://uv-vis aeronomie.be/software/QDOAS/). The DOAS fit results are the differential slant column densities (DSCDs), i.e. the difference of the slant column density (SCD) between the off-zenith ~~spectrum~~ and the corresponding zenith reference ~~spectrum~~spectra. Details of the DOAS fit settings are listed in Table1. A typical DOAS retrieval example for the oxygen dimer (O$_4$), nitrogen dioxide (NO$_2$) and nitrous acid (HONO) are shown in Figure 1. The stratospheric contribution was approximately eliminated by taking the zenith spectra of each scan as reference in the DOAS analysis. Before profile retrieval, DOAS fit results of O$_4$, NO$_2$ and HONO with root mean square (RMS) of residuals larger than 3×10^{-3} were filtered. ~~Moreover~~Furthermore, the SCD data under the color index (CI) being < 10% of the thresholds obtained through fitting a fifth-order polynomial to CI data which is a function of time was filtered out, ~~in order~~ to ensure a high signal-to-noise ratio (SNR) of the spectra. This filtering criteria remove 2.1, 3.9. and 5.3% for O$_4$, NO$_2$ and HONO, respectively.

2.3 Vertical profile retrieval

Aerosol and trace gases (i.e., NO$_2$ and HONO) vertical profiles are retrieved from MAX-DOAS measurements using the algorithm reported by Liu et al. (2021). The inversion algorithm is developed based on the Optical Estimation Method (OEM) (Rodgers, 2000), which employs the radiative transfer model VLIDORT as the forward model. The detailed retrieval procedure is displayed in Appendix I and Figure S3.

In this study, an exponential decreasing a priori with a scale height of 1.0 km was used as the initial profile for both the aerosol and trace gases retrieval (Figure S4). The surface concentrations of aerosol ~~and trace gases~~, NO$_2$, and HONO were set to 0.~~3–2~~ km^{-1} , 3.0 ppb, and ~~5~~1.0 ppb, respectively. We assume a fix set of aerosol optical properties with asymmetry parameter of 0.69, a single scattering albedo of 0.90 and ground albedo of 0.05. ~~Moreover~~Furthermore, the uncertainty of the aerosol and trace gases a priori profile was set to 100% and the correlation length was set to 0.5 km. The averaging kernels indicated that the sensitivity of the profile retrieval tended to decrease with increasing altitude, and was especially sensitive to the layers within 0–1.5 km (Figure S5). The sum of the diagonal elements in the averaging kernel matrix is the degrees of freedom (DOF), which denotes the number of independent pieces of information contained in the measurements.

2.4 Error analysis

For profile retrieval, the error sources can be divided into four different types: smoothing error, measurement noise error, forward model error, and model parameter error (Rodgers, 2004). However, in terms of this classification, some errors are difficult to be calculated or estimated. For example, forward model error, which is caused by an imperfect representation of the physics of the system, is hard to be quantified due to the difficulty of acquiring an improved forward model. Given calculation convenience and contributing ratios of different errors in total error budget, we mainly took into account error sources based on the following classification, which were smoothing and noise error, algorithm error, cross section error and uncertainty related to the aerosol retrieval (only for trace gas). Here, we estimated the contribution of different error sources to the trace gas vertical column densities (VCDs) and AOD, and near-surface (0–200 m) trace gas concentrations and aerosol extinction coefficients (AECs), respectively. The detailed demonstrations and estimation methods are displayed below, and the final results are summarized in Table 3.

a. Smoothing errors arise from the limited vertical resolution of profile retrieval. Measurement noise errors denote the noise in the spectra (i.e., the fitting error of DOAS fits). They can be quantified by averaging the error of retrieved profiles, as the error of the retrieved state vector equals the sum of these two independent errors. We calculated the sum of smoothing and noise errors on near-surface concentrations and column densities, which were 14 and 5 % for aerosols, 16 and 17 % for NO_2, and 20 and 22 % for HONO, respectively in the sea scene. The corresponding values were 13 and 5 % for aerosols, 14 and 16 % for NO_2, and 18 and 20 % for HONO, respectively at SUST and 13 and 5 % for aerosols, 15 and 17 % for NO_2, and 19 and 21 % for HONO at CAMS.

b. Algorithm error is the discrepancy between the measured $\mathbf{y}$ and modelled DSCDs. $\mathbf{F(x,b)}$ This error contains forward model error from an imperfect approximation of forward function (e.g., spatial inhomogeneities of absorbers and aerosols), forward model parameter error from selection of parameters $\mathbf{b}$, and error not related to the forward function parameters, such as detector noise (Rodgers, 2004). Algorithm error is a function of the viewing angle, and it is difficult to assign this error to each altitude of profile. Usually, the algorithm errors on the near-surface values and column densities are estimated by calculating the average relative differences between the measured and modeled DSCDs at the minimum and maximum elevation angle (except 90 °), respectively (Wagner et al., 2004). Considering its trivial role in the total error budget, we estimated these errors on the near-surface values and the column densities at 4 and 8 % for aerosols, 3 and 11 % for NO_2, and 20 and 20 % for HONO, according to Wang et al. (2017) and Wang et al. (2020).

c. Cross section error is the error arising from an uncertainty in the cross section. According to Thalman and Volkamer, (2013), Vandaele et al. (1998), and Stutz et al. (2000), we adopted 4, 3, and 5 % for O_4 (aerosols), NO_2, and HONO, respectively.

d. The trace gas profile retrieval error represents the one, which is sourced from aerosol extinction profile retrieval and propagated to retrieved trace gas profile. This error could be roughly estimated based on a linear propagation of the total error budgets of the aerosol retrievals. The errors of trace gases were roughly estimated at 15% for VCDs and 10% for near-surface concentrations for the two trace gases in the sea scene. The corresponding values were 14 and 10 % for near-surface concentrations and VCDs, respectively at SUST, and 14 and 10 % at CAMS.

The total uncertainty was calculated by adding all the error terms in the Gaussian error propagation, and the final results were listed in the bottom row of Table 3. We found that the sum of smoothing and noise errors played a dominant role in the total uncertainty.

2.5 Ancillary data

Meteorological data (including temperature, pressure, relative humidity, visibility, solar radiation intensity, wind speed and wind direction) with a temporal resolution of 1 min was measured in the weather station installed on the ship. NO was measured using NO analyzer (Thermo Scientific model 42i) with a 1 min resolution. The speed of the ship was calculated referred to the GPS data.

The temperature and relative humidity of two ground-based stations (i.e., CAMS and SUST) were collected from Weather Underground website, temporal resolution of which is around 3 hours.

The backward trajectory was calculated using HYSPLIT (Hybrid Single-Particle Lagrangian Integrated Trajectory) developed by the National Oceanic and Atmospheric Administration Air Resource Laboratory (NOAA-ARL). The meteorological data with a 1°×1° spatial resolution and 24 layers were collected from the Global Data Assimilation System (GDAS).

3 Results and Discussion

3.1 Overview of the MAX-DOAS observation over marginal seas of China

A radiative transfer model SCIATRAN was used to convert SCDs of NO_2 and HONO to their tropospheric vertical column densities (VCDs). The vertical profiles of aerosol, NO_2 and HONO retrieved from MAX-DOAS, the temperature and pressure vertical profiles simulated using a dynamical-chemical model (WRF-Chem), and the geo-position data collected by GPS were introduced as inputs in SCIATRAN for the NO_2 and HONO air mass factor (AMF) calculation. Missing data are due to power and instrument system failure, interference of ship plume, unfavorable weather condition (i. e., heavy rain), and night sailing. During the cruise of Chongming to Zhanjiang, NO_2 VCDs varied from 1.05×10^{14} to 4.02×10^{16} molec.cm^{-2} with an averaged value of 3.90×10^{15} molec. cm^{-2}. From

Zhanjiang to Qingdao, NO$_2$ VCDs varied from 1.08×10^{14} to 2.60×10^{16} molec.cm^{-2} with an averaged value of $4.27\times$ 10^{15} molec. cm^{-2} ~~from Zhanjiang to Qingdao~~. From Chongming to Zhanjiang, HONO VCDs varied from 1.00×10^{14} to 2.58×10^{15} molec. cm^{-2} with a mean value of 2.39×10^{14}molec. cm^{-2}. From Zhanjiang to Qingdao, HONO VCDs varied from 1.01×10^{14} to 2.61×10^{15}molec. cm^{-2} with a mean value of 2.74×10^{14} molec. cm^{-2}.

Figure 2 showed the spatial distribution of NO$_2$ and HONO VCDs over the marginal seas of China. ~~It should be noted that f~~Five ~~elevated~~ enhanced tropospheric NO$_2$ VCDs hot spots were observed during the whole campaign, i.e., the coastal areas of Yangtze River Delta, Taiwan straits, Guangzhou-Hong Kong-Macao Greater Bay areas, Zhanjiang Port, and Qingdao port. In the coastal areas of Yangtze River Delta, the hot spots were mainly distributed in the Yangtze River estuary, Hangzhou Bay, Ningbo port, Taizhou port, and Wenzhou port. These areas are mostly important shipping channels or shipping ports, and are great NO$_2$ emission sources. The averaged NO$_2$ VCDs in above five areas reached 1.07×10^{16}, 1.30×10^{16}, 7.27×10^{15}, 5.34×10^{15}, and 3.12×10^{15} molec. cm^{-2}, respectively (Figure S6(a)). HONO exhibited similar spatial distribution characteristics as NO$_2$, and the averaged HONO VCDs in above five hot-spot areas reached 1.01×10^{15}, 7.91×10^{14}, 6.02×10^{14}, 5.36×10^{14}, and 5.17×10^{14} molec. cm^{-2}, respectively (Figure S6(b)). It indicates that NO$_2$ is an important precursor of HONO. ~~Previous~~ Earlier studies ~~have~~ reported that HONO can ~~be produced~~ generated from NO$_2$ through heterogeneous reaction on the surface of aerosol and sea (Yang et al., 2021). However, there are obvious differences in the concentration distribution of HONO and NO$_2$ in the southeast coastal area of Jiangsu (from Qidong to Dongtai). In this area, NO$_2$ showed a higher concentration (1.66×10^{16} molec. cm^{-2}, which is 4 times higher than the mean NO$_2$ VCD), while HONO showed a lower concentration (2.06×10^{14} molec. cm^{-2}, which is ~80% of the mean HONO VCD). It ~~migh~~maybt be the fresh ship emission plume on the route enhancing the NO$_2$ concentration and HONO has not been fully formed from NO$_2$ heterogeneous reaction in time, ~~due to~~since the observations from ship-based MAX-DOAS are instantaneous. ~~On the other hand, the solar radiation intensity in this day (12 May, 2018) was significantly lower than other days (Fig. S2), and this weather condition was not conductive to the HONO formation through the heterogeneous reaction of NO$_2$.~~

The surface concentration of NO$_2$ and HONO were extracted from their corresponding vertical profiles. As shown in Figure 3, the total averaged near-surface NO$_2$ concentrations under sea-oriented and land-oriented measurements were 8.46 and 11.31 ppb, respectively. The total averaged near-surface HONO concentrations were 0.23 and 0.27 ppb under sea-oriented and land-oriented measurements. The total averaged near-surface HONO/NO$_2$ ratios in sea-oriented and land-oriented measurements were 0.027 and 0.024, respectively. ~~Previous~~ Earlier studies reported that vehicle and ship emissions were the main primary HONO sources on land and sea, respectively, and NO$_2$ heterogeneous reaction on the surfaces of ground, sea, vegetation and aerosol were the ~~HONO~~ important secondary HONO sources (Liu et al., 2021). Additionally, t~~Th~~ey also found that the surface HONO concentration under the sea case was lower than that under the land case, especially in the morning and evening (Yang et al., 2021). Figure 4 showed the time series of AOD, the surface concentrations of NO$_2$ and HONO, and the surface HONO/NO$_2$ during the whole campaign. We ~~could find~~found that the time series of AOD and NO$_2$ were similar. The high AOD and NO$_2$ usually appeared in busy shipping channels and ports, and the obvious high-value areas were the coast of the Yangtze River Delta, the Taiwan Strait, Xiamen port, Zhanjiang port and Qingdao port (with mean AOD and NO$_2$ of 1.28 and ~~mean NO$_2$ of~~18.90 ppb, respectively). HONO always appeared under high AOD and NO$_2$ conditions, however, high AOD and NO$_2$ were not necessarily accompanied with high ~~production rate of~~ HONO concentration. This was because the heterogeneous formation of HONO requires suitable meteorological conditions (i.e., RH and temperature) in addition to its precursor (NO$_2$) and the reaction surface (aerosol) (Liu et al., 2019). The high HONO/NO$_2$ values were found on 02, 13 and 14 May with an average value of 0.45 ~~during the whole campaign~~. ~~Moreover~~Furthermore, we found the high values of HONO/NO$_2$ always appeared from 11:00 to 14:00 during a whole day. ~~That is due to the high production rate of HONO and the high photolysis rate of NO$_2$ during noontime.~~

3.2 ~~The r~~Relationship between HONO/NO$_2$ with RH, Temperature, and aerosol in land and sea

~~In order to fully understand the differences of the impacts of RH, temperature and aerosol on the HONO secondary formation in land and sea conditions, the Chinese Academy of Meteorological Sciences (CAMS) and Southern University of Science and Technology (SUST) MAX-DOAS stations were selected as inland and coastal areas for analysis, respectively.~~ Sun et al. (2020) reported that HONO concentrations could increase up to 40–100% over the shipping routes and international ports~~navigation areas~~, and Huang et al. (2017) reported vehicle exhaust could contribute to ~12–49% of the atmospheric HONO budget. Since the direct emissions of the measurement ship ~~have been~~were removed before data analysis, the primary source of HONO during the whole campaign was mainly from the direct emissions of cargo ships. By subtracting the average marine background of NO$_x$ and HONO from the ship plume emission values, the impact of background values is reduced and the emission ratio of $\Delta HONO/\Delta NO_x$ can be obtained, and this emission ratio can be used for quantifying the primary HONO (Sun et al., 2020; Xu et al., 2015). In this study, w~~W~~e used an averaged $0.46\pm0.31\%$ emission ratio of $\Delta HONO/\Delta NO_x$ ~~in this study~~referring to Sun et al. (2020) to understand the primary source of HONO on the sea surface during the campaign. The NO was measured using in situ instrument, and sea-surface NO$_2$ was extracted from the retrieved NO$_2$ vertical profiles (NO$_x$ = NO + NO$_2$). ~~In a~~Additionally, the calculation method of emission ratios of $\Delta HONO/\Delta NO_x$ in CAMS and SUST was

referred ~~to~~ from Xu et al. (2015), Liu et al. (2018), and Xing et al. (2021) (Appendix II). The averaged emission ratios in CAMS and SUST were 0.82±0.34% and 0.79±0.31%, respectively. The direct emissions ~~have been~~were deduced in the following study of the secondary formation of HONO. The ratios of HONO/NO$_2$ in CAMS, SUST and the ship-based campaign could be found in Figure ~~S3~~S7. ~~Moreover~~Furthermore, the main secondary formation pathway of HONO ~~are is believed mainly from~~considered as the heterogeneous reaction of NO$_2$ on the surface. The linear regression between HONO and NO$_2$ in land and static sea scenarios is shown in Figure 5. We found the fitting slopes in static sea scenes was ~8–10 times larger than that in land scenes, especially on sea-oriented measurements under static weather condition (slope ≈ 0.06). The correlation coefficients (R) in inland and static sea ~~scenes~~scenarios were all > 0.62, except in SUST (R = 0.58)~~. That,~~ which indicates the formation rate of secondary HONO from NO$_2$ heterogeneous reaction in static sea ~~scenes~~scenarios ~~might~~may be faster than that in land ~~scenes~~scenarios. The corresponding temperature and RH conditions of each spot are displayed in Figure S8, which roughly reveals the impact of RH and temperature on the process of NO$_2$ forming HONO through heterogeneous reactions.

3.2.1 RH dependence on HONO formation

The scatter plots of HONO/NO$_2$ against RH in different land and sea conditions are illustrated in Figure 6. The highest values can represent varying range of data in each interval and reveal concentration levels of data distribution. ~~In order t~~To eliminate the influence of other factors, the average of the six highest HONO/NO$_2$ in each 10% RH interval is calculated to reflect the distribution range of data in each interval (Liu et al., 2019). The dependence of the averaged top-6 HONO/NO$_2$ on RH reveal an overall variation tendency of HONO/NO$_2$ against RH. ~~We found the RH turning points i~~In the inland (CAMS) and coastal (SUST) cases, the RH turning points are ~~all~~both ~65% (60–70%), where increasing trend switches to decreasing tendency. The HONO/NO$_2$ increases along with RH when RH is less than 65%, and the HONO/NO$_2$ will decrease when RH is larger than 65%~~.~~. ~~That means~~which implies that it contributes to the HONO formation from the heterogeneous reaction of NO$_2$ on wet surfaces with the gradual increase of RH until 65%. The decrease of HONO/NO$_2$ with RH larger than 65% is presumably due to the efficient uptake of HONO on wet surfaces and the wet surfaces being less accessible or less reactive to NO$_2$ when RH being larger than 65% (Liu et al., 2019). However, two turning peaks of RH were found in the sea cases. The first RH turning peak occurred in ~60%, which is the similar ~~with~~to that under the inland and coastal cases~~.~~. ~~While~~and another RH turning peak appeared in ~85% (80–90%). ~~That~~This ~~mean~~implies that~~s~~ high RH also could increase the HONO formation in sea cases~~.~~. ~~A~~In ~~a~~additionally, the HONO/NO$_2$ decreased sharply when RH was larger than 95%, because the reaction surface will asymptotically approach a water droplet state to limit the formation of HONO with RH larger than 95%.

3.2.2 Temperature dependence on HONO formation

The scatter plots of HONO/NO$_2$ against temperature in different land and sea conditions are shown in Figure 7. Similar to the scatter plots of HONO/NO$_2$ against RH, we also adopted ~~To eliminate the influence of other factors,~~ the average~~d of the six highest~~top-6 HONO/NO$_2$ values in each 5℃ ~~temperature~~interval ~~is calculated~~to represent a general variation tendency of HONO/NO$_2$ against temperature. In the inland condition (CAMS), the HONO/NO$_2$ decreased along with the increase of temperature, and the highest values of HONO/NO$_2$ ~~peak values~~appeared ~~on~~at ~~the temperature being~~ ~12.5℃. However, we found ~~the~~that HONO/NO$_2$ increased along with the increase in temperature, and the highest values of HONO/NO$_2$ appeared ~~with~~at ~31.5℃ ~~temperature~~in coastal condition (SUST)~~.~~. ~~That~~which indicates that the HONO formation from NO$_2$ heterogeneous reaction will be accelerated under lower and higher temperature in the inland and coastal conditions, respectively. In the sea condition, the HONO/NO$_2$ increased along with the increase ~~of~~in temperature with a high value under ~25.0℃ ~~temperature~~when the atmospheric temperature was larger than 18.0℃, and simultaneously, a ~1.9 averaged HONO/NO$_2$ high value was found under ~15.0℃ (14.0–17.0℃)~~temperature~~. ~~Moreover~~Furthermore, we found that the appearance of HONO/NO$_2$ high values under lower temperature (14.0–17.0℃) was usually accompanied by ~~landing wind~~land breeze. Wen et al. (2019) also reported that relatively high temperature could contribute to the formation of HONO in the sea condition.

3.2.3 Impact of aerosol on HONO formation

~~In order t~~To further understand the HONO formation from NO$_2$ heterogeneous reaction on aerosol surface, several correlation analyses were ~~carried out~~conducted. As shown in Figure 8, the linear regression plot~~s~~ between HONO and aerosol~~, and between HONO/NO$_2$ and aerosol~~ in land and sea conditions ~~were~~was performed. It was found that the correlation coefficient (R) between HONO and aerosol varied in the order of coastal (0.55) > sea (0.51) > inland (0.14). ~~In a~~Additionally, the fitting slopes under coastal and sea conditions (0.07) are about 2.3 times larger than that under inland condition (0.03)~~.~~. ~~That means~~which implies that the ground surface maybe more important than aerosol surface during the process of HONO formed from NO$_2$ heterogeneous reaction in the ground surface layer of the inland. In the coastal and sea conditions, the aerosol and sea are ~~all~~both important ~~to~~in provid~~ing~~e heterogeneous reaction surface for NO$_2$ to form HONO (Cui et al., 2019; Wen et al., 2019; Yang et al., 2021). ~~In a~~Additionally, we found the averaged values of HONO/NO$_2$ were 0.011±0.004, 0.014±0.006, 0.008±0.003 and 0.007±0.003~~are 0.011, 0.014 and 0.008~~ when aerosol extinctions are 0–0.3, 0.3–0.6, ~~and~~0.6–0.9 and > 0.9 km^{-1} in the inland case,

respectively (Figure 8(b)). As shown in Figure 8, t~~T~~he high values of HONO/NO$_2$ ~~are~~ were mainly under aerosol extinction being less than 1.0 km^{-1} with averaged values of 0.012±0.006 and 0.090±0.004~~0.16 and 0.32~~ in the coastal and sea cases, respectively. It indicates that aerosol surface plays a more important role ~~to~~ in form~~ing~~ HONO through NO$_2$ heterogeneous reaction in the sea condition than that in the land condition.

3.3 Vertical distributions of HONO/NO$_2$ under different aerosol condition in land and sea

~~In order t~~To further investigate the height dependence of HONO/NO$_2$ under land and sea conditions, two cases in Pearl River Delta (PRD) were selected from the whole campaign. As shown in Figure 9, "A" and "B" were under similar aerosol level (the extinction coefficients in surface layer being 0.45-0.60 km^{-1}) and vertical distribution structure, and were all observed from 10:00 to 11:00. The instrument viewed sea accompanied with sea wind in "A" named sea scene, and the instrument viewed land accompanied with land wind in "B" named land scene. The NO$_2$ in the sea and land scenes have a similar vertical structure, and the NO$_2$ concentration in land scene are larger than that in sea scene except on the surface layer. The HONO have the same vertical distribution structure in the above two scenes, and the HONO concentration in the land scene always larger than that in the sea scene. In Figure 9(e), we found that HONO/NO$_2$ under 0–400 m in the land scene is higher than that in the sea scene, however, the HONO/NO$_2$ values are obviously lower in the land scene than that in the sea scene above 400 m. ~~Moreover~~Furthermore, the growth rate of HONO/NO$_2$ with the increase of height in the sea scene is significantly faster than that in the land scene above 400 m. ~~It~~This indicates the generation rates of HONO sourced from NO$_2$ heterogeneous reaction on aerosol surface in the sea scene is larger than that in the land scene above 400 m. Under 400 m, the HONO generation rates in land scene is larger than that in the sea scene.

~~In a~~Additionally, we selected inland cases (CAMS) to learn the difference of height dependence of HONO/NO$_2$ compared with sea scenes under different aerosol loads. As shown in Figure 10, the sea and inland scenes had ~~the~~ similar aerosol levels (low aerosol level: < 0.2 km^{-1}) and vertical structure. ~~Moreover~~Furthermore, the NO$_2$ and HONO in the sea and inland scenes have ~~the~~ similar vertical structure, ~~but~~ although their concentrations in the sea scene are all larger than that in the inland scene. In Figure 10(d), we ~~could find~~found that the HONO/NO$_2$ in the sea scene was obviously larger than that in the inland scene above 400 m. The HONO/NO$_2$ in the sea scene was about 4.5 times larger than that in the inland scene especially above 600 m. As shown in Figure 11, the aerosols under the sea and inland scenes ~~were also with the~~exhibited similar extinction levels (relatively high level: ~0.8 km^{-1}) and vertical structure. The NO$_2$ concentration in the sea scene was higher than that in the inland scene but with a similar vertical structure. The HONO concentration in the sea scene was lower than that in the inland scene under 400 m, while ~~it~~ the concentration in the sea scene ~~is~~ was larger than that in the inland scene above 400 m. In Figure 11 (d), we found the HONO/NO$_2$ in the inland scene was larger than that in the sea scene under 600 m, while the HONO/NO$_2$ in the sea scene was about 2 times larger than that in the inland scene above 600 m. ~~Above a~~All the above cases indicated that the HONO generation rate from NO$_2$ heterogeneous reaction in the sea scene was larger than that in the inland scene in higher atmospheric layers above 400–600 m. The high-altitude (> 400–600 m) atmospheric parameters in the sea scene were more conductive to promote the HONO formation through the heterogeneous reaction of NO$_2$. As shown in Figure ~~S4~~S9, the ratio of HONO/NO$_2$ also generally increased with the increase ~~of~~ in height above 0.2 km during the whole ship-based campaign. The greatest sensitivity under 1.5 km and the high degree of freedom (DOF) for aerosol, NO$_2$ and HONO gave confidence in the retrieval results (Figure ~~S5~~S10).

3.4 Case study

The important factors and precursors to drive the formation of HONO through heterogeneous reaction had complex evolution and transport characteristics. To further clarify the role of these parameters in the heterogeneous process of NO$_2$ to form HONO, three typical processes were selected to reveal the favorable conditions for HONO formation at the sea scene.

3.4.1 20 April: A typical transport event

As shown in Figure 12, the aerosol mainly distributed in 0-200 m with a mean extinction coefficient larger than 0.74 km^{-1}. NO$_2$ was mainly distributed near the ground surface with a mean concentration of 28.54 ppb before 13:20. The NO$_2$ during this period ~~might~~ may come from local ship emissions, ~~due to~~as this area is a main shipping channel~~s~~. From 14:25 to 17:10, a high-concentration NO$_2$ air mass (averaged 13.29 ppb) was found at ~2.0 km. ~~In order t~~To understand the~~ir~~ source of this high-altitude NO$_2$ air mass, we further investigated the possible influence of transport by using the backward trajectories. We calculated 24 h backward trajectories of air masses at 500, 1000, and 2000 m using HYSPLIT (Figure S11) ~~(Hybrid Single-Particle Lagrangian Integrated Trajectory) developed by the National Oceanic and Atmospheric Administration Air Resource Laboratory (NOAA-ARL). The meteorological data with a 1° × 1° spatial resolution and 24 layers were collected from the Global Data Assimilation System (GDAS)~~. In Figure ~~13~~S11, we found that the dominant wind direction during this period was southeast at all heights, i.e., 500, 1000 and 2000 m. The transport of air masses carried NO$_2$ emitted by ships in Ningbo and Zhoushan ports, to main cargo ports of China and ~~, to~~ Shanghai. ~~Moreover~~Furthermore, the concentration of NO$_2$ was low (averaged 2.32 ppb) near the ground surface from 14:25 to 17:10. As shown in Figure 12 (e) and (g), a low pressure (< 1020 hPa), north dominant

wind direction with the wind speed > 12 m/s appeared at the ground surface during this period, which implies that the clean air from north reduced the local surface NO_2. The HONO was mainly distributed near the surface with a mean concentration of 0.07 ppb, and the two peaks were found in the early morning (averaged 0.15 ppb) and at 12:15 (averaged 0.11 ppb), respectively (Figure S12). The relatively high concentration of HONO appearing in the early morning was possibly attributed to the accumulation with the stabilization of boundary layer and attenuation of solar radiation after the sunset the day before (Xing et al., 2021). The HONO peak appearing at 12:15 may be sourced from the heterogeneous reaction of NO_2 on the aerosol surface under a ~80% RH, 18.5℃ temperature, and 1×10^3 W/m² SRI conditions.

3.4.2 28 April: A typical event of HONO produced from NO_2 heterogeneous reaction

From a typical port observation case, the measurement ship moored at Xiamen port on 28 April. As shown in Figure 13, we found two peaks for aerosol and NO_2 from 09:00–11:00 and 14:00–16:00 (averaged aerosol extinction coefficient > 0.8 km⁻¹, averaged NO_2 concentration > 12.0 ppb), respectively. NO_2 was mainly distributed near the sea surface layer 0–200 m, and a high-concentration NO_2 air mass was found in 1.0–2.0 km during 13:00–14:00 due to the short distance transport of NO_2 emitted from ships in Xiamen port (Figure S13). However, aerosol appeared in the range of 0.0–2.0 km during 09:00–11:00 and 14:00–16:00. In Figure 13 (g), we found that the wind speeds in the above two peak periods were obviously higher than that in other periods. From 09:00–11:00, the wind speed was ~5.0 m/s with a northwest dominant direction (urban), and the wind speed was ~6.0 m/s with a southeast dominant direction (port gateway) during 14:00–16:00, which indicates that the short-distance high-altitude transport caused the appearance of high-extinction aerosol mass during the above two periods.

Furthermore, we found the high-concentration HONO only appeared at 14:00–16:00 with a 0.57 ppb averaged concentration under 0.9 km, while it was only about 0.14 ppb during 09:00–11:00 period. The slightly increase of RH and temperature (Tem) at 14:00–16:00 (RH: ~75.0%, Tem: 23.7℃) may contribute to HONO formation through heterogeneous reaction of NO_2 on the aerosol surface than that at 09:00-11:00 (Figure 13 (d)-(e), Section 3.2). Contrarily, the solar radiation intensity (SRI) (~600 W/m²) at 09:00–11:00 was obviously larger than that (~250 W/m²) at 14:00–16:00 (Figure 13 (f)). The higher SRI accelerated the photolysis of HONO during 09:00–11:00 period (Kraus et al., 1998). Therefore, the lower formation rate and higher photolysis rate lead to a significantly lower HONO concentration at 09:00–11:00 than that at 14:00–16:00.

3.4.3 03 May: A typical event with unknown HONO source

The measurement ship conducted observation in the sea area near Zhanjiang on 03 May, 2018. As shown in Figure 14, we found that there was an obvious sinking process for aerosol from ~1.0 km during 09:00–16:00, and eventually accumulated near the sea surface with a high extinction coefficient > 0.92 km⁻¹. The NO_2 was mainly concentrated near the sea surface layer (0–400 m) with an averaged concentration of 8.93 ppb from 08:00 to 09:00. Thereafter, with the rise the planetary boundary layer (PBL) height after sunrise, NO_2 was gradually mixed and spread throughout the PBL from 09:00 to 13:00. During this period, it was accompanied by the increase of the NO_2 concentration (averaged 11.2 ppb) under PBL (Figure S14). It is due to the contribution of ship emissions near the sea surface. Contrarily, the regional transport of NO_2 from land also increased the NO_2 concentration in this area of the sea, with wind speed increasing from 2.5 to 7.8 m/s with a north wind direction from 10:00 to 16:00 (Figure 14 (g)).

Several HONO peaks (> 0.2 ppb) at 0.5-1.0 km were found from 09:45 to 13:00, and the aerosol and NO_2 high values were also observed at this height layer, simultaneously, which implies that the heterogeneous reaction of NO_2 on aerosol surface is more important than that on the sea surface for HONO source under sea atmosphere. Additionally, HONO concentration obviously elevated after 14:00, especially during 14:00–16:00 (> 0.4 ppb). It may be sourced from heterogeneous reaction of NO_2 on the aerosol surface, under RH being ~92.5% (Figure 14 (d)). The photolysis of HONO also decreased with SRI < 150 W/m² (Figure 14 (f)) during this period. Furthermore, a HONO peak (> 0.32 ppb) was observed during 16:40–17:10. However, the NO_2 concentration always kept low (< 1.5 ppb) after 16:00, and the temperature was lower than 17 ℃ (Figure 14 (e)), which indicates the heterogeneous reaction of NO_2 not being the source of the observed HONO peak. The wind was north dominant with an average speed at 7.8 m/s after 15:00, which implies that the regional transport may not be the source of the observed high-concentration of HONO. Furthermore, the SRI was lower than 87.5 W/m², and it shows the photolysis of nitrate aerosol also not being the source of the elevated HONO. The unknown HONO source in this area of the sea need to be further explored.

4 Summary and Conclusions

Currently, many uncertainties in the study of the HONO forming mechanism through the heterogeneous reaction of NO$_2$ exist. Earlier studies mostly focused on the near-surface layer, and the assessment of the contribution of NO$_2$ heterogeneous reaction to HONO formation in the vertical direction of the boundary layer is insufficient. Therefore, we aim to learn the sea-land and vertical differences of the HONO forming mechanism from NO$_2$ heterogeneous reaction and provide deep insights into the distribution characteristics, transforming process and environmental effects of tropospheric HONO. Ship based MAX-DOAS observations along the marginal seas of China were performed from 19 April to 16 May 2018. ~~, simultaneously~~Simultaneously, two ground-based MAX-DOAS observations were ~~carried out~~conducted in the inland station CAMS and the coastal station SUST ~~during the same time~~ to measure the aerosol, NO$_2$, and HONO vertical profiles. ~~, to learn the sea-land and vertical differences of NO$_2$ heterogeneous reaction to produce HONO.~~

Along the cruise route, ~~The latitude and longitude ranges of the entire ship based campaign covered 21.12°N-35.89°N and 110.67°E-122.16°E, respectively.~~ ~~w~~We found five hot spots of enhanced tropospheric NO$_2$ ~~and HONO~~ VCDs in Yangtze River Delta, Taiwan straits, Guangzhou-Hong Kong-Macao Greater Bay areas, Zhanjiang Port, and Qingdao port. ~~The averaged values of NO$_2$ in above five areas were 1.07×10^{16}, 1.30×10^{16}, 7.27×10^{15}, 5.34×10^{15}, and 3.12×10^{15} molec. cm^{-2}~~Under high-level NO$_2$ conditions in the above five hot spots, we also observed, enhanced HONO levels~~and the averaged HONO concentrations in above five areas were 1.01×10^{15}, 7.91×10^{14}, 6.02×10^{14}, 5.36×10^{14}, and 5.17×10^{14} molec. cm^{-2}, respectively~~. ~~However~~Contrastingly, the low-concentration HONO accompanied high-level NO$_2$ ~~we found NO$_2$ showed a higher concentration (1.66×10^{16} molec. cm^{-2}), while HONO showed a lower concentration (2.06×10^{14} molec. cm^{-2})~~ in the southeast coastline of Jiangsu province. ~~Moreover, the averaged near-surface NO$_2$ concentrations were 8.46 and 11.31 ppb, and the averaged near-surface HONO concentrations were 0.23 and 0.27 ppb under sea-oriented and land-oriented observation azimuths during the whole campaign, respectively.~~ When peak AOD and NO$_2$ conditions were observed, enhanced HONO were observed, although the reverse was not always the case.~~HONO always appeared under high AOD and NO$_2$ conditions.~~

~~In order t~~To ~~further~~ understand the impacts of RH, temperature, and ~~SRI~~ aerosol on the heterogeneous reaction of NO$_2$ to produce HONO, the emission ratios of $\Delta HONO / \Delta NO_x$ ~~in sea, inland and coastal areas~~ were calculated ~~with values of 0.46±0.31%, 0.82±0.34%, and 0.79±0.31%~~ to ~~remove~~ quantify the contribution of the primary HONO source to the total production of HONO. We found that the RH turning points in CAMS and SUST cases were both ~65% (60–70%), whereas two turning peaks (~60% and ~85%) of RH were found in the sea cases. This implied that high RH could contribute to the secondary formation of HONO in sea atmosphere. With increase in temperature, the HONO/NO$_2$ decreased with peak values appearing at ~12.5℃ in CAMS, whereas the HONO/NO$_2$ gradually increased and reached peak values at ~31.5℃ in SUST. In the sea case, when the temperature exceeded 18.0℃, the HONO/NO$_2$ increased with the increasing temperature and achieved peak at ~25.0℃. This indicated that high temperature could promote the secondary formation of HONO in the sea and coastal atmosphere. Additionally, the correlation analysis under different sea-land conditions indicated that the ground surface is more crucial to the formation of HONO from NO$_2$ heterogeneous reaction in the inland case, whereas the aerosol surface contributed more in the coastal and sea cases.

~~We found the RH turning points in CAMS and SUST are all ~65% (60-70%). The HONO/NO$_2$ increased with increase of RH under 65%, and the HONO/NO$_2$ decreased when RH is larger than 65%. However, two turning peaks (~60% and ~85%) of RH were found in sea case. That means high RH could contribute to the secondary formation of HONO in sea atmosphere. Moreover, the HONO/NO$_2$ decreased with the increase of temperature, and with peak values on ~12.5℃ in CAMS, however, it increase with increasing temperature, and peaked at ~31.5℃ in SUST. In sea case, the HONO/NO$_2$ increased with the increase of temperature with a peak value on ~25.0℃ under the temperature > 18.0℃, simultaneously, a ~1.9 averaged HONO/NO$_2$ high value was found under ~15.0℃. It illustrated the high temperature could promote the formation of HONO from NO$_2$ heterogeneous reaction in sea and coastal atmosphere. In addition, the correlation analysis under different sea-land conditions told us the ground surface plays a more important role than aerosol surface during the HONO formation from the heterogeneous reaction of NO$_2$ under inland case, while the aerosol surface plays a more important role during above process under coastal and sea cases.~~ Furthermore, we found that the HONO/NO$_2$ in the sea case ~~is~~ was about 4.5 times larger than that in the inland case above 600 m ~~under aerosol extinction coefficient~~ when AEC was ~0.2 km^{-1}, and the HONO/NO$_2$ ratio in the sea case ~~is~~ was about 2 times larger than that in the inland case above 600 m ~~under~~ when ~~aerosol extinction coefficient~~AEC was ~0.8 km^{-1}.~~,~~ which implied ~~That~~that mean~~t~~s the generation rate of HONO from NO$_2$ heterogeneous reaction in the sea case is larger than that in the inland ~~CASE~~ case in higher atmospheric layers ~~(~~above~~≥~~ 600 m~~)~~. To have a deep understanding of three potential contributing factors of HONO production under marine condition, we selected three typical events, which represented the impacts of transport, NO$_2$ heterogeneous reaction and unknown HONO source, respectively.

725

726 **Table 3.** Error budget estimation (in %) of the retrieved near-surface (0-200 m) trace gas concentrations and AECs,
727 and trace gas VCDs and AOD.

			Error source				Total
			Smoothing and noise errors	Algorithm error	Cross section error	Related to the aerosol retrieval (only for trace gases)	
Cruise route	Near-surface	aerosol	14	4	4	-	15
		NO$_2$	16	3	3	15	22
		HONO	20	20	5	15	32
	VCD or AOD	AOD	5	8	4	-	10
		NO$_2$	17	11	3	10	23
		HONO	22	20	5	10	32
SUST	Near-surface	aerosol	13	4	4	-	14
		NO$_2$	14	3	3	14	20
		HONO	18	20	5	14	31
	VCD or AOD	AOD	5	8	4	-	10
		NO$_2$	16	11	3	10	22
		HONO	20	20	5	10	30
CAMS	Near-surface	aerosol	13	4	4	-	14
		NO$_2$	15	3	3	14	21
		HONO	19	20	5	14	31
	VCD or AOD	AOD	5	8	4	-	10
		NO$_2$	17	11	3	10	23
		HONO	21	20	5	10	31
