21 **Abstract.** Recently, volatile chemical products (VCPs) have been increasingly recognized as important precursors for
22 secondary organic aerosol (SOA) and ozone in urban areas. However, their atmospheric chemistry, physical
23 transformation, and their impact on climate, environment, and human health remain poorly understood. Here, the yields
24 and chemical composition at the molecular level of gas and particle phase products originating from the photooxidation
25 of one of these VCPs, benzyl alcohol (BnOH), are reported. The SOA was generated in the presence of seed aerosol from
26 nebulized ammonium sulfate solution in a 14.5 m³ smog chamber operated in flow mode. More than 50 organic
27 compounds containing nitrogen and/or up to seven oxygen atoms were identified by mass spectrometry. While a detailed
28 non-targeted analysis has been made, our primary focus has been to examine highly oxygenated and nitro-aromatic
29 compounds. The major components include ring-opening products with high oxygen to carbon ratio (e.g., malic acid,
30 tartaric acids, arabic acid, trihydroxy-oxo-pentanoic acids, and pentaric acid), and ring-retaining products (e.g.,
31 benzaldehyde, benzoic acid, catechol, 3-nitrobenzyl alcohol, 4-nitrocatechol, 2-hydroxy-5-nitrobenzyl alcohol, 2-
32 nitrophenol, 3,4-dihydroxy-5-nitrobenzyl alcohol). The presence of some of these products in the gas and particle
33 phases simultaneously provides evidence of their gas/particle partitioning. These oxygenated oxidation products made
34 dominant contributions to the SOA particle composition in both low and high NO_x systems. Yields, organic mass to
35 organic carbon ratio, and proposed reaction schemes for selected compounds are provided. The aerosol yield was 5.2%
36 for BnOH/H₂O₂ at SOA concentration of 52.9 μg m⁻³ and ranged between 1.7-8.1 % for BnOH/NO_x at SOA concentration
37 of 40.0-119.5 μg m⁻³.

compounds, SOA

49 **1 Introduction**

50 Modeling atmospheric organic aerosol (OA) using chemical transport models (CTMs) is complex, challenging, and
51 often can lead to model-measurement discrepancies (Zhao et al., 2016). Applying CTMs to urban areas reveals that
52 traditional VOCs including combustion-related processes cannot account for the observed OA mass, leaving a substantial
53 fraction unresolved (Hayes et al., 2015). Recent studies suggest that this discrepancy is due in part to unaccounted, rapidly
54 reacting SOA and ozone precursors from unknown sources (Hodzic et al., 2009; Hayes et al., 2015; McDonald et al., 2018;
55 Akherati et al. 2019; Lu et al., 2020). Volatile chemical products (VCPs), such as personal care products, cleaning agents,
56 coatings, adhesives, and pesticides have emerged as possible sources in urban areas (McDonald et al., 2018). Their
57 emissions can be larger than those from usual sources, such as motor vehicles (Coggon et al., 2021). Laboratory, modeling,
58 and field studies for VCPs have been conducted to assess their potential to affect ambient OA and ozone formation in
59 urban and suburban locations (McDonald et al., 2018; Khare et al., 2018; Stockwell et al., 2021; Seltzer et al., 2021;
60 Gkatzelis et al., 2021; Milani et al., 2021; Pennington et al., 2021; Coggon et al., 2021). The contribution of VCPs to
61 ambient OA is not fully understood and only limited modeling studies have been reported (Mohr et al., 2015; Vlachou et
62 al., 2018; Pennington et al., 2021; Qin et al., 2021; Seltzer et al., 2021). Additionally, few experimental and chamber
63 studies of VCPs have been conducted with limited characterization of aerosol products (Wu and Johnston, 2016, 2017;
64 Harrison and Well, 2012; Charan et al., 2020, 2021; Humes et al., 2022). For example, the analysis of SOA from the
65 oxidation of cyclic methyl siloxanes (Wu and Johnston, 2016, 2017; Fu et al. 2020; Alton and Browne, 2020; Charan et
66 al., 2021) and cyclic siloxanes (Janecek et al., 2019) has been conducted. Kinetic studies with limited products
67 characterization have been reported for the oxidation of benzyl alcohol (BnOH) by hydroxyl radicals (Bernard et al.,
68 2013; Wang, 2015; Harrison and Well, 2009, 2012). Recently, Humes et al. (2022) highlight the importance of oxygenated
69 aromatic VCPs emission to generate urban SOA and oxygenated products in both gas and aerosol phases. Therefore,
70 understanding the atmospheric chemistry of VCPs is important to assess their role in air quality and climate and to improve
71 SOA chemistry in CTMs thereby allowing for better estimates in health studies and source apportionment.

72 The challenges associated with evaluating VCP impacts on urban OA can be addressed by identifying atmospheric
73 VCP concentrations and SOA markers linking those VCP to ambient particulate matter (PM). Benzyl alcohol (C_7H_8O) is
74 an important ring containing VCP used as an organic intermediate and a solvent in a wide range of applications (Antonelli
75 et al. 2002). BnOH is emitted also from flowers and flowering trees (Do et al., 1969; Horvat et al., 1990; Larsen and Poll,
76 1990; Humpf and Scheier, 1991; Boatright et al., 2004; Vallat and Dorn, 2005; Orlova et al.; 2006) and found in indoor

77 air (Weschler, 2011). Gas kinetic studies of loss rates and product distributions have been conducted using flow tubes and
78 environmental chambers. Bernard et al. (2013) examined the rate and mechanisms of the OH + BnOH reaction. Similarly,
79 Harrison and Wells (2009, 2012) investigated the rate constants for the BnOH reaction with ozone, OH and NO₃ radicals.
80 Carter et al. (2005) conducted chamber experiments to assess ozone and PM formation from BnOH and related
81 compounds. Product studies from BnOH oxidation have focused mainly on gas phase (GP) products. Several carbonyl
82 products (benzaldehyde (BnAld), formaldehyde, glyoxal, butenedial, 4-oxopentanal, 3-hydroxy-2-propanaldehyde), and
83 benzyl nitrate, o-hydroxybenzyl alcohol, o-dihydroxy benzene were reported from the above studies. With respect to the
84 particle phase (PP), Charan et al. (2020) reported aerosol yields from BnOH oxidation together with a limited number of
85 SOA products. Finally, Wang (2015) conducted a theoretical study to elucidate the reaction mechanism of the oxidation
86 of BnOH with OH radicals.

87 In this study, we report a detailed non-targeted chemical analysis of GP and SOA products originated from the
88 photooxidation of BnOH in the presence and absence of oxides of nitrogen (NO_x), with the aim to better understand the
89 chemical composition at the molecular level. Gas chromatography-mass spectrometry (GC-MS) and high-performance
90 liquid chromatography were used for the identification of a range of organic compounds including oxygenated
91 nitroaromatics and related compounds bearing up to seven oxygen atoms. Nitroaromatics are pollutants of concern due to
92 their toxicity, light-absorption properties, and relatively long residence times in the environment. Highly oxygenated
93 compounds can partition into pre-existing particles or be involved in new particle formation. Also, in the present study,
94 SOA and secondary organic carbon (SOC) yields were measured with the results compared to published data. A chemical
95 mechanism is then proposed to represent and account for selected gas- and aerosol-phase products observed in this study.

96

97 **2 Experimental methods**

98 All chemicals including N, O-*bis*(trimethylsilyl) trifluoroacetamide (BSTFA) derivatization reagent with 1%
99 trimethylchlorosilane (TMCS) as catalyst and benzyl alcohol (99%), 2-methyl-4-nitrophenol, L-(+)-tartaric acid, D-(-)-
100 tartaric acid, and meso-tartaric acid were purchased from Aldrich Chemical Co. (Milwaukee, WI) at the highest purity
101 (99.8%) available and were used without further purification. In addition to standards reported in our previous studies
102 (Jaoui et al., 2004; 2018), 3-nitrobenzyl alcohol, benzoic acid, and 4-nitrocatechol were purchased from Tokyo Chemical
103 Industry (OR, USA); while pentaric acid, 2,3-dihydroxy-4-methoxy-4-oxobutanoic acid, and arabic acid were obtained
104 from Aurum Pharmatech, LLC (NJ, USA).

105 **2.1 Chamber description and operation**

106 All experiments were conducted in a 14.5 m³ fixed-volume chamber having TFE Teflon coated walls and maintained
107 at a positive pressure of 0.1 Torr. The chamber operation, procedures, and instrumentation have been described previously
108 (Kleindienst et al. 2006; 2009), and here just experiment-specific details are primarily included. A combination of
109 fluorescent bulbs having radiation from 300-400 nm was used to photolyze NO₂. In the absence of NO_x, the radiation
110 system was altered to include UV-313 sunlamps to adequately photolyze H₂O₂. The chamber was operated in steady-state
111 (SS or flow) mode to provide continuously stable effluent concentrations. Under these conditions, reactants and products
112 equilibrate with the chamber surfaces to minimize irreversible losses of gases and particles. The SS operation allows for
113 extended sampling periods to improve the accuracy and precision of the measurements (Shilling et al., 2008).
114 Temperature, relative humidity, and UV light intensity were measured continuously with an uncertainty of 5%. Pre-
115 experiment and post-experiment procedures (see section 2.5 below) were routinely carried out before and after each
116 experiment to minimize contamination in the chamber. The reactant generation system provided constant sources of zero
117 air, reactants, water vapor, and ammonium sulfate (AS) seed aerosol. The reactant flow of gases (e.g., NO_x) into the
118 chamber was regulated using mass flow controllers. BnOH was injected using a syringe pump, vaporized in a heated glass
119 bulb, and injected with zero air. For experiments in the absence of NO_x, a 50% aqueous solution of H₂O₂ was vaporized
120 and injected using a second syringe pump, and photolyzed to produce OH radicals. Typical chamber AS concentrations
121 were approximately 1 µg m⁻³. Each SS experiment went through an initial transient period of 18-24 h until the reactant
122 and product concentrations reached steady state.

123

124 **2.2 Gas-phase measurements**

125 A wide variety of instruments were used to measure the reactants and products. Nitric oxide (NO) and NO_x were
126 measured with a TECO (Franklin, MA) oxides of nitrogen analyzer with an upstream nylon filter to remove nitric acid
127 produced from OH + NO₂. The NO_x analyzer was calibrated with a NIST-traceable NO standard. Initial H₂O₂
128 concentrations were estimated by UV absorption using the ratio of the H₂O₂ to O₃ absorbances at 254 nm, as described
129 by Kleindienst et al. (2009). Experiments in the absence of NO_x were conducted dry to avoid aqueous loss of H₂O₂. BnOH
130 concentrations in the inlet and within the chamber were measured semi-continuously using an SRI Model 8610C compact
131 gas chromatograph with flame ionization detector (GC-FID; SRI Instruments, Torrance CA). The purity of the BnOH
132 was verified with GC-MS analysis.

133 Low molecular weight carbonyls and dicarbonyls were quantified by derivatization using 2,4-dinitrophenylhydrazine
134 (Smith et al., 1989). Samples were collected at 0.5 L min⁻¹ for 25 min and derivatized in a 4 mL solution of acidified
135 DNPH and then heated for 40 min at 70°C. Air samples were drawn for 20 min at a rate of 0.50 L min⁻¹ through an
136 impinger containing 5 mL of a DNPH solution in acetonitrile. The resulting solutions were analyzed by high-performance
137 liquid chromatography with a ultraviolet detector (HPLC/UV) (Smith et al., 1989). A 15-component hydrazone standard
138 (comprising formaldehyde-, acetaldehyde-, acrolein, acetone-, propionaldehyde-, crotonaldehyde-, methacrolein-,
139 butyraldehyde-, 2-butanone-, BnAld-, glyoxal-, valeraldehyde-, m-tolualdehyde-, methylglyoxal-, and hexaldehyde;
140 AccuStandard, Inc.) at a free carbonyl concentration of 30 µg mL⁻¹ for each component was used for calibration. Separate
141 dihydrazone standards of glyoxal-DNPH and methylglyoxal-DNPH were also formulated. Carbonyls were separated
142 using a Hewlett-Packard (HP) 1100 HPLC system having an Agilent Zorbax ODS 4.6 x 250 mm, 5-µm column maintained
143 at 30°C eluted with binary acetonitrile-water gradient. A 10 µL injection volume was used for all standards and samples.
144 Carbonyls were quantified by UV absorption with a diode array detector set to 360 nm. Control and sample processing
145 were managed with HP ChemStation software. More highly oxidized gas-phase organic species were also collected with
146 a 60-cm, 4-channel XAD4-coated annular denuder for off-line analysis (Jaoui and Kamens, 2001). Once collected, the
147 denuders were extracted and analyzed according to the methodology described in section 2.4 below.

148

149 **2.3 Aerosol-phase: bulk parameter measurements**

150 Organic carbon (OC) was measured using a semi-continuous elemental carbon-organic carbon (EC-OC) instrument
151 (Sunset Laboratories, Tigard, OR) (Offenberg et al., 2007). The pumping system draws chamber effluent through a quartz
152 filter at a rate of 8 L min⁻¹ with carbon-strip denuder to remove gas-phase organics that might interfere with the
153 measurement. With a sample collection time of 0.5 h and an analysis time of 0.25 h, the duty cycle for the measurement
154 of OC was 0.75 h (Lewandowski et al., 2015). The aerosol volume, size distribution, and total number density were
155 measured using a scanning mobility particle sizer (SMPS), (Model 3071A, TSI, Inc., Shoreview, MN) and a condensation
156 particle counter (CPC) (Model 3010, TSI, Inc., Shoreview, MN). The SMPS operating conditions were as follows: sample
157 flow 0.2 L min⁻¹; sheath flow 2 L min⁻¹; size scan from 19 to 982 nm.

158

159 **2.4 Molecular characterization of GP and PP oxygenated organic products**

160 A non-targeted chemical analysis was conducted focusing mainly on species bearing hydroxy and carboxylic groups
161 (Jaoui et al., 2004, 2013, 2018). For each experiment, six 47-mm glass fiber (GF) filters were taken for 24 h at a flow rate
162 of 16.7 L min⁻¹. A second set of samples used an in-line 60-cm XAD-4 coated annular denuder (followed by a GF filter)
163 and analyzed for gas-phase organic products (Jaoui and Kamens, 2001). After collection, GF filters were extracted by
164 sonication with 5 mL methanol for 1 h, and denuders were extracted with 30 mL 1:1 dichloromethane/methanol mixture
165 (Jaoui and Kamens, 2001). Prior to extraction, denuders and GF filters were spiked with *cis*-ketopinic acid (KPA), trans-
166 p-menth-6-ene-2,8-diol (PMD), and d₅₀-tetracosane (TCS) as internal/recovery standards (IS/RS). Denuder extraction
167 solvents were rotary evaporated to ~1 mL and filtered using 0.45- μ m PTFE syringe filters. A 2 μ L portion of this extract
168 was analyzed by GC-MS (Jaoui and Kamens, 2001). The remaining denuder and filter extracts were evaporated to dryness
169 under a gentle stream of N₂ at room temperature using an N-Evap evaporation bath (Organomation Associates, Inc.,
170 Berlin, MA), then derivatized with BSTFA (Jaoui et al., 2004). This technique provides a sensitive method for measuring
171 low levels of highly oxidized organic compounds, including semi- and intermediate-volatile compounds in the GP and
172 PP.

173 The GC-MS analysis was conducted on an Agilent GC (7890B) coupled with a quadrupole mass spectrometer
174 (5977B). The injector, heated to 270 °C, was operated in splitless mode. Compounds were separated on a 60-m-long, 0.25-
175 mm-i.d. RTx-5MS column (Restek, Inc., Bellefonte, PA) with a 0.25- μ m film thickness. The GC oven temperature was
176 initiated at 84 °C, held for 1 min, then increased at 8 °C min⁻¹ to 200 °C, followed by a 2-min hold, then an increase at 10
177 °C min⁻¹ to 300 °C and a 15-min hold. The ion source, ion trap, and interface temperatures were 200, 200, and 300 °C,
178 respectively. Mass spectra were collected in both the methane-chemical (CI) and electron ionization (EI) modes.

179

180 **2.5 Experimental and quality control procedures**

181 Before each experiment started, the chamber was flushed with zero air (hydrocarbon-free) for 24 h from an Aadco
182 clean generator (Cleves, OH, USA). Experiments were conducted in either the absence or presence of NO_x. For
183 experiments with NO_x, BnOH and NO were added to the chamber through flow controllers to the target concentration.
184 For experiments in the absence of NO_x, the photolysis of H₂O₂ was the source of OH. H₂O₂ as a 50 % aqueous solution
185 was injected through a syringe pump into a heated glass bulb where it vaporized and then was mixed rapidly by the main
186 dilution air flow. For these experiments, BnOH was added as described above. Ammonium sulfate seed aerosol was also
187 introduced into the chamber for all experiments to serve as a condensing medium for semivolatile organic products that

188 might form. After the reactants reached steady state concentrations (24 hours), the background was characterized using
189 all instruments to check for artifacts including background GP and PP species. Background chamber air was also
190 characterized using off-line analysis of denuder and/or filters as described above. Previous studies show that BnAld and
191 to a lesser extent benzoic acid, benzyl benzoate and dibenzyl ether present either as impurity, or as decomposition products
192 upon BnOH exposure to air at room temperature or sonication (Urakami et al., 2000; Ferri et al., 2006; Abend et al., 2004).
193 Here we investigated the effect of chamber air, sonication, and BSTFA derivatization on BnOH artifacts as described in
194 the supplementary information (SI) in section 1. A small amount of BnAld impurity was detected using the direct injection
195 (DI) method and estimated to be <0.1% in the purchased solution. When BnOH was exposed to clean air in the chamber
196 in the absence of light, sonication, and/or BSTFA derivatization, our results show additional low level of BnOH
197 conversion to BnAld and benzoic acid using DI and BSTFA methods, which is similar to the findings of Abend et al.
198 (2004), Urakami et al. (2000), and Ferri et al. (2006). Additional results and descriptions are provided in section S1 (SI).

199 Experiments were initiated by turning on the lights and allowing the irradiated chamber effluent to reach SS
200 conditions over a 24-h period which permits active sampling by the on-line instruments and the collection of denuder and
201 filter samples for subsequent off-line analysis. For organic intermediates wall losses are typically not an issue due to
202 reactions being conducted within a Teflon chamber. This potential issue is mitigated further from operating the chamber
203 in a SS mode where compound loss and re-evaporation quickly comes to steady state. Short lifetimes of radical
204 intermediates with other gas-phase constituents also render a negligible wall-loss. The stability of BnOH in the chamber
205 was investigated and BnOH was found to be highly stable with results given in the SI (section S1). Denuders and GF filter
206 samples were also analyzed to probe reproducibility of the analytical technique. The analysis showed consistent results.

207 Gas and particle samples from BnOH photooxidation are dominated by oxygenated species, several not having
208 authentic standards, and thus a portion of each sample was derivatized. Initially, we eliminated peaks detected in blank
209 and background samples. For compounds having standards, comparisons were made between the retention times and mass
210 spectra (CI and/or EI mode) of the chamber-derived peaks and those of the standards. For compounds not having
211 standards, individual peak identifications were associated with a product peak only if its retention time and mass spectrum
212 was consistent with the fragmentation pattern of the BSTFA-derivatized compound. All recorded spectra in this study
213 were compared with those derived from reference standards, the literature, the NIST library, and an archive of mass
214 spectra from product compounds determined in our laboratory over the past twenty years.

215

216 **3 Results and discussion**

217 The initial conditions of the experiments conducted in this study are summarized in Table 1. Three NO_x experiments
218 were carried-out with initial BnOH ranging from 0.36 – 0.72 ppm and NO from 0.096 – 0.19 ppm. One experiment without
219 NO_x was conducted with initial H₂O₂ and BnOH levels of 3.0 and 0.32 ppm, respectively. NO_x experiments were
220 conducted at ~30% RH, and the H₂O₂ experiment at < 4% RH to minimize H₂O₂ uptake onto chamber surfaces. Chamber
221 temperatures were set to 25 °C. Each experiment was conducted for up to five days for samples requiring substantial
222 masses or extended collection times and frequencies.

223 Steady state concentrations of NO, BnOH, O₃, and NO_y for the four experiments are given in Table 2. The reacted
224 BnOH and NO were calculated from the difference between the initial and steady-state concentrations. For NO_x
225 experiments, the range of reacted BnOH concentrations was 0.22 – 0.34 ppm having a reproducibility of 20–30%. Under
226 these conditions, steady state concentrations of NO_y, and O₃ were in the range of 0.08 – 0.16 and 0.011 – 0.15 ppm,
227 respectively. With NO present at steady-state, peroxy-peroxy (RO₂–RO₂) reactions were minimized. A constant aerosol
228 source was maintained for initial conditions given in Table 1. The major aerosol parameters measured (SOA, SOC, and
229 OM/OC) are given in Table 3. SOC uncertainties were taken from the reproducibility of the semi-continuous measurement
230 and typically better than 10% for a single run. For the organic mass (OM), the uncertainties are determined from the
231 reproducibility of side-by-side filter measurements which are typically better than 5%. An estimate of the systematic
232 errors due to minor changes in reactant concentrations, minor variations in chamber temperature, and similar factors bring
233 the total uncertainty to between 15-25% for these parameters (Kleindienst et al., 2009). SOA/SOC values were then
234 determined from the corrected data and given in Table 3. For experiments in the presence of NO_x, SOA/SOC values
235 ranged from 1.7-2.0. Similarly, in the absence of NO_x, the measured SOA/SOC value was 2.1.

236

237 **3.1 Secondary organic aerosol and secondary organic carbon yields**

238 Secondary organic aerosol yield (Y_{SOA}) and secondary organic carbon yield (Y_{SOC}) were calculated from the
239 following respective relationships $Y_{\text{SOA}} = \text{SOA}/\Delta\text{HC}$ (1); $Y_{\text{SOC}} = \text{SOC}/\Delta\text{HC}_\text{C}$ (2) where SOA is the corrected organic
240 aerosol mass concentration originated from filter measurements (6 filters) and ΔHC is the reacted BnOH concentration.
241 SOC is the organic carbon concentration found in Table 3 and ΔHC_C is the reacted BnOH carbon concentration. SOA and
242 SOC were corrected for wall loss to the chamber which had previously been determined for organic aerosol to be 0.067
243 h⁻¹ (Kleindienst et al. 2012). Uncertainties in the yield come from the experimental uncertainties in SOA and SOC

244 production and the reacted BnOH concentrations. The uncertainty in the reacted BnOH results from the reproducibility
245 of the initial and steady-state values and is estimated to range from 20 - 30% given the low volatility of BnOH and
246 challenges for introducing oxygenated species into the chamber in a consistent manner. Such challenges are also present
247 in a batch mode experiment given the difficulty to determine BnOH time profiles given its volatility and high reactivity
248 toward oxidants (Shilling et al., 2008; Kroll et al., 2007). Similar findings have been reported for sesquiterpenes oxidation
249 (Jaoui et al., 2013). As a result, aerosol yields of higher accuracy are often reported to be associated with steady state as
250 opposed to batch mode experiments (Shilling et al., 2008). Moreover, in this work we explored the possibility of BnOH
251 being taken up by ammonium sulfate (AS) seed aerosol prior to start of the irradiation or by SOA after it is initiated. This
252 test was conducted using GC-MS analysis of derivatized (BSTFA) and underivatized denuder and GF filter extracts
253 collected before and after the reaction starts (SI; Section S1). Under the experimental conditions used in this study, BnOH
254 was undetected in AS and SOA, thus limiting any participation in particle chemistry that may occur.

255 The production of aerosol, and thus the yield, were found to be highly sensitive to the precise initial conditions
256 (Tables 1, 3). Yields for the four experiments are shown in Table 3. Y_{SOA} values were determined for SOA concentrations
257 from 39.6 - 119.5 $\mu\text{g m}^{-3}$ and ranged between 3.6 and 8.1%. Similarly, Y_{SOC} was measured for SOC concentrations from
258 23.2 - 58.9 $\mu\text{gC m}^{-3}$ and found to range between 2.7 and 5.1%. In the absence of NO_x , SOA and SOC yields were 5.2
259 and 3.1 % measured for SOA and SOC concentrations of 52.9 $\mu\text{g m}^{-3}$ and 24.8 $\mu\text{gC m}^{-3}$, respectively. For the two systems
260 at similar SOA concentrations ER890 and ER892, the SOA yield was higher for the experiment with NO_x . This may
261 result from the reaction of BnOH with NO_x which tends to produce high levels of BnAld (Table 4), which may undergo
262 secondary reactions leading to additional SOA formation (see section 3.3). As expected, the data in Table 3 indicate that
263 Y_{SOA} and Y_{SOC} are lower at the lower SOA and SOC concentrations, respectively.

264 These SOA and SOC yields can be compared with other studies. Recently, Charan et al. (2020) reported SOA yields
265 for the photooxidation of BnOH in the presence of NO_x with the initial OH coming from the photolysis of H_2O_2 . Their
266 chamber was operated in a batch mode and SOA yields approaching unity were reported. By contrast, three additional
267 studies reported much lower SOA yields of 9%, 30%, and 41% from McDonald et al. (2018), Carter et al. (2005), and Li
268 et al. (2018), respectively. The yield reported by McDonald et al. (2018) was based on a multi-generation oxidation model;
269 that of Carter et al. (2005) was estimated as described in the original report, and that of Li et al. (2018) was based on
270 measurements in the presence of NO_x and a surrogate urban hydrocarbon. The results of our study are much closer in
271 value to McDonald et al. (2018). The study by Charan et al. (2020) suggests that conditions can be found where BnOH

272 SOA yields are substantially greater than that found in this study and those previously reported. The major differences
273 between the Charan et al. study and the present work were the chamber-mode operation, the seed aerosol type and levels,
274 and the mix of oxidants used. While it can be difficult to compare the yields from the two studies some comments can be
275 made. (1) As noted, the Charan et al. yields result from conventional batch mode irradiations of BnOH, H₂O₂ and NO_x.
276 (2) SOA levels were measured using an SMPS which measures aerosol volume which is then converted to aerosol mass
277 using a density of 1.4 μg nL⁻¹. (3) Perhaps the biggest difference between the two studies is the use of an extremely high
278 initial seed aerosol mass, approximately two orders of magnitude higher than in this study. Thus, it is possible that an
279 adsorption mechanism played a part in contributing to the measured yields. (4) Finally, the use of high initial H₂O₂
280 concentrations relative to BnOH make it possible that H₂O₂ effectively competed with BnOH for OH via the reaction of
281 OH + H₂O₂ --> HO₂ + H₂O thus generating a system rich in HO₂. Thus, aging process may be more prominent than in our
282 study. The uncertainties associated with SOA and reacted BnOH measurements and wall loss correction are unlikely to
283 account for the differences in the two studies. However, SOA yields have been reported to increase considerably as a
284 function of initial seed aerosol (Zhang et al. 2014), as well as to increase with the OH radical exposure (Wang et al.,
285 2018). Qualitatively these two factors might bring the present SOA yields into reasonable agreement with Charan et al.
286 (2020), when data were extrapolated to similar seed aerosol and OH exposures. And as previously noted, in the low initial
287 seed aerosol used in our study no benzyl alcohol was detected in the seed aerosol or deposited on SOA. As further
288 plausibility for the results from the present study, Humes et al. (2022) recently reported yields from 12% - 18% for two
289 oxygenated aromatic species (1-phenoxy-2-propanol, and phenoxy-ethanol), compounds having similar structures to
290 BnOH.

291

292 **3.2 Reaction products identification**

293 Three methods were used in this study to identify oxygenated reaction products at the molecular level: (1) DNPH as
294 derivatizing agent for small carbonyls (Smith et al. 1989); (2) BSTFA as derivatizing agent for hydroxyl and carboxylic
295 compounds for GP and PP (Jaoui et al., 2004); and (3) direct injection (DI) method providing the capability for analysing
296 slightly polar to non-polar compounds without the use of derivatization (Jaoui and Kamens, 2001). For the BSTFA and
297 DI methods, the analysis of laboratory generated GP and PP products from BnOH oxidation shows a series of organic
298 compounds containing nitro, ketone, carboxylic acid, and/or alcoholic functional groups. Many of these compounds do
299 not have authentic standards and their identifications were based on the interpretation of the mass spectra of the derivatized

300 and/or underivatized compound (Jaoui and Kamens 2001; Jaoui et al., 2004, 2005). The identification should be regarded
301 as tentative except for compounds that have authentic standards. For the BSTFA method, the recognition of characteristic
302 ions was used to guide the analysis of mass spectra of the derivatives obtained in both electron ionization (EI) and chemical
303 ionization (CI) using methane as reagent gas. BSTFA reacts with -COOH and -OH groups to form BSTFA derivatives.
304 Characteristic ions are m/z 73, 75, 147, and 149. Adduct ions in CI from the derivatives include m/z $M^+ + 73$, $M^+ + 41$,
305 $M^+ + 29$, and $M^+ + 1$; fragment ions include m/z $M^+ - 15$, $M^+ - 73$, $M^+ - 89$, $M^+ - 117$, $M^+ - 105$, $M^+ - 133$, and/or
306 $M^+ - 207$. The approach used for the identification is as follows: peaks detected in blank and background chamber samples
307 were eliminated first. A peak was associated with a reaction product only if its corresponding mass spectrum was
308 consistent with the fragmentation pattern of the BSTFA derivatization reagent. All recorded spectra were compared with
309 spectra derived from various reference compounds, authentic standard, NIST library, the PubChem website
310 (pubchem.ncbi.nlm.nih.gov), and/or by MS assignment. While the off-line technique is an integrated technique that
311 requires long sampling times, it does provide a sensitive method for products identification at the molecular level as well
312 as measuring low concentrations of highly oxidized organic compounds, and semivolatile compounds in the GP. Thus,
313 products found by this collection technique could be informative for possible precursors for the types of compounds that
314 may form in the PP. In the following discussion, data are first presented to support tentative identifications of oxidation
315 products in the GP and PP.

316 **Gas phase products.** GP measurements were made of major carbonyl products formed during the photooxidation of
317 BnOH including formaldehyde, acetaldehyde, acetone, methacrolein, 2-butanone, BnAld, glyoxal, and methylglyoxal.
318 Steady-state concentrations are given in Table 4. Under the conditions shown in Tables 1 and 2, high concentrations were
319 observed for BnAld and glyoxal, and to a lesser extent formaldehyde in experiments with NO_x, and high concentrations
320 of formaldehyde, acetaldehyde, and to a lesser extent BnAld and glyoxal in the experiment without NO_x. BnAld level
321 was a factor of ~5 higher in NO_x experiments compared to H₂O₂ experiments, and formaldehyde a factor of ~36 lower.
322 Glyoxal and methylglyoxal concentrations largely were similar in both NO_x and H₂O₂ experiments. The formation of
323 BnAld, glyoxal, and formaldehyde as major products (Table 4) have already been reported from the oxidation of BnOH
324 with yields of 25 (± 5), 20 (± 2), and 3.0% (± 0.2), respectively (Bernard et al., 2013; Harrison and Wells, 2012).

325 GP samples were also collected on five-channel annular denuders. Each denuder sample was extracted and analyzed
326 directly with GC-MS without derivatization. The remaining extract was silylated, and GC-MS analyzed qualitatively.

327 Typical total ion chromatograms (TIC) of GP products detected and identified in this study are shown in Figure 1. Figure
328 1 shows portions of three TIC in +EI of GP samples taken from experiments ER889 at steady state (underivatized: Figure
329 1a), ER892 (underivatized: Figure 1b), and ER889 (silylated derivatives: Figure 1c). Peaks assigned in Figure 1 were
330 identified either by comparison with an authentic standard or by MS assignment. For clarity, only the main products are
331 shown, although several peaks could not be structurally identified. SOA generated from BnOH photooxidation is
332 dominated by oxygenated ring-opening products (see below). However, ring-retaining products were among the main
333 products observed in the GP including semivolatile organic compounds (SVOCs) (Figure 1c). Chromatograms associated
334 with the underivatized samples (Figure 1a, b) were used mainly to identify BnOH and BnAld in the system, although
335 several additional peaks absent in the background chromatogram were observed. At steady state, BnOH was not reacted
336 completely as it was detected in both systems only in the GP using both DI and BSTFA methods (Figure 1). BnAld was
337 detected in both systems in the gas and particle phases, although it was not present with BSTFA method because of the
338 absence of OH or COOH groups. Figure S3 shows EI mass spectra of BnAld identified using authentic standard, and
339 those associated with three peaks eluting at 11.3, 12.0, and 12.8 min. Although no structural information could be
340 associated with these three peaks, molecular weights of 152, 152, 138 Da (all derivatized and underivatized masses are
341 Dalton (Da) but are not designated as such hereafter), were tentatively obtained.

342 Select GP products containing OH groups identified in the present study are summarized in Table 5. Table 5 contains
343 proposed structures, molecular weights of the silylated derivatives (MW_{BSTFA}) and underivatized compounds (MW),
344 formula, and the 5 most intense ions associated with BSTFA derivatives in EI mode. Table 5 shows if GP products are
345 detected also in the PP. Figure S4 shows EI mass spectra associated with selected peaks observed in Figure 1c, including
346 BnOH-1TMS, benzoic acid-1TMS, catechol-2TMS, and 2-hydroxybenzyl alcohol-2TMS. 2-Hydroxybenzyl alcohol-
347 2TMS (2OHBnOH) peak eluted at 21.4 min was one of the largest peaks detected in the chromatogram in Figure 3c. The
348 2OHBnOH-2TMS EI mass spectrum (Figure S4, bottom) shows strong characteristic fragments ions at m/z 73, 179 (M^+
349 - 89), 253 (M^+ - 15), 268 (M^+), and its corresponding CI mass spectrum shows ions at m/z 253 (M^+ - 15), 179 (M^+ - 89)
350 and weak adducts at $M^+ + 1$, $M^+ + 29$, and $M^+ + 41$ that are consistent with the presence of two (-OH) groups, indicating
351 a BSTFA derivatized molecular weight of 268 Da. Bernard et al (2013) have identified 2OHBnOH and catechol in the
352 GP of the reaction of BnOH and OH radicals. In our study, catechol was observed only in the H_2O_2 system in the PP.
353 Additional peaks were observed, which their mass spectra are consistent with products bearing OH and/or COOH groups,
354 however, their structural identification could not be obtained due to lack of authentic standards and the complexity of the

355 interpretation of their mass spectra. BnAld was reported to undergo secondary reactions (Sankar et al., 2014) and may
356 play an important role as precursor for some oxygenated species observed in this study.

357 **Particle phase products.** One of the advantages of conducting experiments in SS mode is collecting sufficient gas and
358 aerosol masses on denuders and filters for qualitative and quantitative offline analysis. In this study, aerosol collected on
359 GF filters were solvent extracted, with the resulting extracts subjected to BSTFA derivatization followed by GC-MS
360 analysis. SOA generated from both NO_x and H₂O₂ systems was dominated by oxygenated organic compounds, for which
361 mass spectra for more than 50 species have been recorded. These species may have undergone several generations of
362 atmospheric oxidation. Several individual large peaks have been detected in addition to a significant number of small
363 peaks as shown in Figure 2. Figure 2 shows portions between 9 and 28 min of the TIC chromatograms of the silylated
364 derivatives of the aerosol extracts associated with BnOH/NO_x (top) and BnOH/H₂O₂ (bottom). The portion after 28 min
365 is discussed in the next section. The chromatograms in Figure 2 can be directly compared because the chamber air sampled
366 and the amount of extract analyzed for each system were the same. This evaluation revealed that more than 70% of peaks
367 eluted from each system are identical, suggesting similar chemistry is involved in BnOH reaction products formed in the
368 presence and absence of NO_x. In addition, a series of peaks dominated by fragments with odd *m/z* were observed only in
369 BnOH/NO_x and their mass spectra were associated with nitrogen containing compounds as discussed in the NACs section
370 below. This suggests that the composition of a portion of SOA produced in the presence of NO_x is different than that
371 formed in the absence of NO_x, which can be clearly illustrated by the filters and extracts color shown in Figure 2 (bottom).
372 Consistent with the presence of nitroaromatics, filter F2 and methanol extract (E2) has lost most of the color seen in F1
373 and E1. The presence of NO_x in the system produced material (filter F1) of a deep brown color. Most species structurally
374 identified in this study have not been reported in the literature, and mass spectra associated with several peaks are provided
375 either in the main manuscript or in the SI. Additional reaction products (e.g., oligomers, organonitrates) might have been
376 present in the SOA but could not be detected based on the analytical techniques used in this study. Note that formulae, in
377 particular chemical structure, could not be obtained for several peaks recorded in this study due to challenges interpreting
378 their mass spectra. A set of compounds identified and detected before 28 min in the present study are summarized in
379 Table 5.

380 Ring retaining products (e.g., 2-hydroxy benzyl alcohol, benzoic acid, 4-hydroxy benzoic acid, and catechol) were
381 detected in the PP in both systems. As noted above, some ring-retaining products were detected also in the GP as shown

382 in Table 5. Salicylaldehyde and 3-hydroxybenzaldehyde were present only in the GP. These two hydroxy-aldehydes may
383 undergo additional secondary reactions leading to some ring-opening products observed in this study. Representative EI
384 mass spectra of the TMS-derivatives associated with four compounds are shown in figure 3 including benzoic acid,
385 benzene-1,2-diol (catechol), 4-hydroxybenzoic acid, and 2-hydroxybenzyl alcohol. Additional EI and CI mass spectra are
386 shown in figures S4 and S5 in the SI. The EI mass spectrum of the BSTFA derivative of 2-hydroxybenzyl alcohol
387 displayed in figure 3 shows abundant fragment ions at m/z 73, 147, 267 (M^+), 253 ($M^+ - 15$), and 179 ($M^+ - 89$), and
388 weak ions at m/z 91, 223 and 163. The corresponding CI mass spectrum displayed in figure S4d shows abundant fragment
389 ions at m/z 268 (M^+), 253 ($M^+ - 15$), and 179 ($M^+ - 89$) and adduct ions at m/z 293 ($M^+ + 29$) and 309 ($M^+ + 41$). This
390 fragmentation pattern is consistent with the presence of a compound with two hydroxyl groups and a benzene ring (m/z
391 91) having molecular weight 268 for the BSTFA derivative, and MW 124 for its underivatized form. Similarly, the BSTFA
392 EI mass spectrum of 4-hydroxybenzoic acid (Figure 3c) shows characteristic fragment ions at m/z 73, 193 ($M^+ - 89$), 223
393 ($M^+ - 60$), 267 ($M^+ - 15$) and 282 (M^+), and its CI mass spectrum fragment ions at m/z 73, 193, 67 and adducts at 283,
394 and 311. Again, these fragments and adducts are consistent with the presence of two (-OH) groups and a molecular weight
395 of the derivatized compound of 282 and 138 for the underivatized compound. The presence of a peak at m/z 153 ($M^+ -$
396 117) is consistent with a compound bearing an organic acid group. The EI mass spectra recorded in this study for 2-
397 hydroxybenzyl alcohol and 4-hydroxybenzoic acid are identical to the reference NIST spectrum (webook.nist.gov). Figure
398 S5 shows EI mass spectra associated with four peaks eluted at 12.86, 15.58, 16.24, and 19.78 min consistent with the
399 fragmentation pattern of BSTFA derivatives, although their structures could not be obtained.

400 **Highly oxygenated compounds (HOCs).** Recent studies show that highly oxygenated compounds (e.g., HOMs) play an
401 important role in understanding SOA formation (Berndt et al. 2016, Jaoui et al., 2019; 2021 and references therein, Piletic
402 and Kleindienst, 2022). These compounds may result from several generations of atmospheric oxidation. In this study,
403 several ring-opening products eluted late in the chromatograms ($RT > 25$ min), with a relatively high O:C ratio of > 1.3
404 likely contributes to their condensation in the PP, were detected. Three groups of these oxidation products were detected
405 in the PP in both systems. Figure 4 shows the portion between 25 and 34 min of selected GC-MS extracted-ion
406 chromatograms where these groups (color coded) elute and uses the selected ions m/z 423, 437, and 525 (merged in one
407 chromatogram) to best illustrate them: (a) BnOH/NO_x; (b) BnOH/H₂O₂; (c) chamber background. Groups 1, 2, and 3
408 consist of three (green), eight (blue) and four (red) peaks, respectively, and are completely absent from the background
409 chromatogram (figure 4c). Results from a comprehensive interpretation of EI and CI mass spectra associated with peaks

410 shown in figure 4 enabled the identification of several isomers associated with each group. Figure 5 displays three EI
411 mass spectra associated with each group main peak, along with proposed structure and chemical formulae. Table 6 gives
412 the major highly oxygenated compounds identified in this research, including the main peaks from each of these groups,
413 in the order of their underivatized molecular weight. Table 6 gives the chemical formulas, O:C mass ratio, the five most
414 abundant ions associated with each TMS derivative in methane-CI and EI modes, the molecular weights of the
415 underivatized (MW) and TMS-derivatized compounds (MW_{BSTFA}), and the proposed chemical structures of the
416 compounds.

417 Group 1 consists of *meso*-tartaric acid (*mTA*) (Rt 26.04 min), and *L/D*-tartaric acids (*lTA/dTA*) (Rt 27.66 min)
418 identified based on authentic standards. The mass spectra of BSTFA derivatives of *lTA* and *dTA* standards (Figure S6,
419 SI) are very similar (eluting at the same time) and are only slightly different from the *mTA* (Figure S6: SI); however,
420 *lTA/dTA* and *mTA* elute at two different retention times (Figure 4, S6). The peak associated with *mTA*, and *lTA/dTA* are
421 among the largest peak observed in this portion of the chromatograms. Note, *lTA* isomer is the most abundant tartaric
422 acid present in nature (DeBolt et al., 2006). The fragments and adducts observed for the peak eluting at 25.19 min are
423 similar to those of *mTA* and *d-lTA* and are consistent with the presence of four OH groups, a MW of 452 for the
424 derivatized compound and 164 for the underivatized compound, and a $C_4H_6O_6$ chemical formula. Tartaric acid has been
425 reported in ambient aerosol (Rohrl and Lammel, 2002; Gowda et al., 2016) and in chamber 1,3-butadiene SOA (Jaoui et
426 al., 2014). Recent studies suggest that tartaric acid and other hydroxy carboxylic acids undergo heterogeneous OH reaction
427 in aqueous solution, with the presence and position of OH group(s) playing an important role in fragmentation and
428 functionalization of organic aerosol (Cheng et al., 2016).

429 Group 2 consists of eight peaks (figure 4: blue) eluting between 28.5 and 31.5 min. The EI and CI mass spectra
430 associated with each peak display similar fragment and adduct ions across the range of 50 to 600 Da. The interpretation
431 of these mass spectra allows us to infer the molecular weight (MW) of the underivatized compounds as 164 and MW_{BSTFA}
432 of 452 for the TMS derivatives. The BSTFA CI mass spectrum of the peak eluted at 29.48 (largest peak) shows
433 characteristic fragment ions at m/z 73, 437 [$M^+ - 15$], 363 [$M^+ - 89$], and 305 [$M^+ - 105$], and an adduct at 453 [$M^+ + 1$],
434 481 [$M^+ + 29$], and 493 [$M^+ + 41$]. These fragments and adducts are consistent with the presence of four OH groups and
435 an MW of 452 for the derivatized compound and 164 for the underivatized compound. The presence of peaks at m/z 347
436 [$M^+ - 105$], and 335 ($M^+ - 117$) are consistent with a compound bearing alcoholic and carboxylic OH groups
437 simultaneously. This mass spectrum is similar to the one from methyltartaric acid reported previously from isoprene

438 oxidation by our group (Jaoui et al., 2019). The silylated methyltartaric acid mass spectrum (Jaoui et al., 2019) and mass
439 spectra associated with group 2 are only slightly different, however, they elute at different retention times. The peaks have
440 been tentatively identified as isomers of trihydroxy-oxo-pentanoic acid, with the structure of 4-oxo-D-arabonic acid
441 isomer shown in Table 6.

442 Group 3 consists of four peaks eluting between 32.5 and 34 min (figure 4: red). The EI and CI mass spectra associated
443 with each peak display similar fragment and adduct ions across the range of 50 to 600 Da. As a descriptive example, an
444 EI mass spectrum is shown in Figure 5 for peak eluted at 33.1 min. A comprehensive interpretation of EI and CI mass
445 spectra associated with group 3 peaks (Figures 4, 5), allows us to infer the molecular weight (MW) of the underivatized
446 compounds as 180, and MW_{BSTFA} of 540 for the TMS derivatives, with a chemical formulae $C_5H_8O_7$. The compounds
447 corresponding to these four peaks were identified as isomers of C_5 -trihydroxydicarboxylic acids. This identification is
448 tentative due to the absence of authentic standards, except for peak eluting at 33.47, which was identified as pentaric acid
449 (Table 6) based on authentic standard. The spectra of BSTFA derivatives of the remaining three red peaks are only slightly
450 different from the pentaric acid spectrum (Figure 6); however, they elute at different retention times. The EI mass spectra
451 are also similar to those reported in the literature for a set of C_5 -aldaric acids-TMS derivatives including xylaric, arabinaric
452 and ribaric acids (Hinton et al., 2008; <https://pubchem.ncbi.nlm.nih.gov>). Figure 6 shows the structure of pentaric acid
453 and its four isomers (a), the spectra associated with BSTFA derivative of pentaric acid observed in BnOH SOA (b: EI
454 mode), (c: CI- CH_4 mode), and standard (d: EI mode). Figure 6 also shows the structure of the main fragments observed
455 in BSTFA derivative of pentaric acid in EI mode including m/z at 540, 525, 407, 292, 147, and 73 Da. Pentaric acid and
456 its isomers (aldaric acids) are reported to be formed from the oxidation of aldopentose (Hinton, 2008; Derrien et al., 2018),
457 but no evidence has been provided for its presence in SOA samples. In the present study, we successfully identified aldaric
458 acids from the oxidation of BnOH in SOA samples.

459
460 **Nitroaromatic compounds (NACs).** NACs of secondary origin are a possible contributor to urban OA and not only
461 adversely affect human health and the environment but impact the aerosol optical properties and the atmospheric radiation
462 balance. By understanding the sources of NACs in ambient particles and their chemical identities, we can evaluate their
463 impact on the climate, environment, and human health. Recently, the analytical capabilities associated with BSTFA
464 derivatization have been extended to NACs bearing hydroxyl and carboxylic acid groups (Jaoui et al., 2018). Mass spectra
465 of most silylated NACs, especially methane-Cl, are highly specific, reproducible, and produce characteristic fragments

466 useful in determining structural information and molecular weight, when authentic standards are not available (Jaoui et
467 al., 2018). In this study, a detailed analysis of mass spectra associated with peaks in chromatograms Figure 1c (GP) and
468 Figure 2 top (PP) reveals the presence of several peaks presenting similar fragmentation patterns as those reported by
469 Jaoui et al. (2018) for species bearing hydroxyl, carboxylic, nitro groups, and benzene ring. Figure 7 shows the portion
470 between 23 and 42 min of two +EI extracted ion chromatograms for the BSTFA derivatives at m/z 210, 165 (IS), 299 (IS),
471 300, 298, 372, 388 (merged in one chromatogram) associated with BnOH/NO_x (top) and BnOH/H₂O₂ (bottom). The EI
472 and/or CI mass spectra of selected nitroaromatic standards can be found in Jaoui et al. (2018), and additional representative
473 subset of the derivatives are displayed in Figures S7 (SI). For clarity, figure 7 inset shows an expanded portion of the top
474 chromatogram between 26.7 – 28 min. Table 7 contains proposed identification of NACs detected in this study, along
475 with molecular weights, formulae, main 5 intense ions associated with CI and EI mass spectra of the derivatives, proposed
476 structure, and the GP to PP peak area ratio.

477 NACs with the highest confidence assignment are those identified by comparing their retention times, EI, and CI
478 mass spectra with those of reference standards, and NACs with low levels of confidence are those (1) that have been
479 identified previously in ambient PM or in smog chamber studies, (2) their EI mass spectra exist in the literature, or (3)
480 their molecular weights and numbers of OH, COOH, and NO₂ groups are simply consistent with the CI and EI mass
481 spectrum (Jaoui et al., 2018). A total of fourteen peaks associated with NACs were detected in this study. 3-Nitrobenzyl
482 alcohol, 4-nitrocatechol, 2-hydroxy-5-nitro benzyl alcohol, and 2-nitrophenol were identified based on authentic
483 standards. Three peaks eluted at 33.76, 34.70, and 34.76 having similar mass spectra as 2-nitrophenol (main peak)
484 eluted at 35.62 min were detected. They were tentatively associated with homologous series of 2-nitrophenol
485 including 3-nitrobenzene-1,2,4-triol, 5-nitropyrogallol, and 4-nitro-1,2,3-benzenetriol (not shown in Table 7). Similarly,
486 three additional peaks having similar mass spectra as 2-hydroxy-5-nitrobenzyl alcohol were observed and were tentatively
487 associated with homologous series of 2-hydroxy-5-nitrobenzyl alcohol including 4-hydroxy-2-nitrobenzyl alcohol. The
488 EIC in figure 7 (top) includes a series of four peaks observed only in the PP eluting at 35.94, 36.60, 38.18 min, whose
489 mass spectra were consistent with the presence of molecular weight 185 and 401 for the underivatized and derivatized
490 compounds, respectively. Based on similarity of their mass spectra, they were tentatively identified as structural
491 homologue of 3,4-dihydroxy-5-nitrobenzyl alcohol (Table 7) with C₇H₇NO₅ formulae. As can be seen in figure 7 (bottom),
492 NACs peaks were not detected in BnOH/H₂O₂ SOA extract, consistent with the formation of NACs in the presence of
493 NO_x. All NACs were detected in both GPs and PP (Table 7), except 2-nitrophenol and 3,4-dihydroxy-5-

494 nitrobenzyl alcohol and their isomers were observed only in the PP consistent with their low volatility. This result suggests
495 that NACs may be formed in the GP, and partition to the PP for those with low volatility, although PP reactions may
496 occur as suggested by Charan et al. (2020) who analyzed only PP. 4-Nitrocatechol and 2-nitrophloroglucinol were among
497 the largest NAC peaks observed in our study (Figure 7). All three experiments conducted in this study were analyzed for
498 NACs to probe reproducibility of the BSTFA method and showed consistent results. 2-Nitrophloroglycinol, 4-
499 nitrocatechol and other NACs has been reported in PM collected in Pico Mountain Observatory, Pico Island in the Azores
500 archipelago by Ikemori et al., (2019). A series of NACs have been reported recently by Charan et al. (2020) in BnOH
501 SOA using off-line UPLC/ESIQ-ToFMS (ultra-high-performance liquid chromatography electrospray ionization
502 quadruple time of flight mass spectrometry), and the structure assigned to formulas obtained from MassLynk software
503 was based on expected oxidation products and MS/MS analysis. These observations support the identification of NACs
504 reported in this study. 4-Nitrophenol was reported in the GP by Bernard et al., (2013) at low yield and by Charan et al.
505 2020 in SOA from the OH radical oxidation of BnOH but was not detected either in the GP or the PP in this study.

506

507 3.3. Mechanism of product formation

508 Based on known GP reactions for aromatic compounds, a schematic representation for the reaction of BnOH with
509 OH is presented in schemes 1-3. It is developed to understand the chemistry leading to the main GP and PP products
510 identified experimentally in this study including HOCs and NACs. These schemes incorporate the latest experimental,
511 quantum and kinetic developments of the fate of peroxy/alkoxy benzoyl radicals including autooxidation (Wang, 2015;
512 Sankar et al. 2014, and Namysl et al. 2020). The lines shown in these schemes are either one step or multistep pathways.
513 Rate constants at room temperature of BnOH with OH radical, O₃, and NO₃ radical of 2.8×10^{-11} , 6×10^{-19} (upper limit),
514 and $4.0 \times 10^{-15} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, respectively, have been reported in the literature (Harrison and Wells, 2009, 2012;
515 Bernard et al., 2013). This suggests that the day-time oxidation of BnOH will be mainly initiated by OH radicals. The
516 reaction for O₃ and NO₃ radical are not included in schemes 1-3, although they are expected to be formed as minor
517 products in our systems.

518 The reaction of BnOH with OH radicals is initiated primarily by H atom abstraction from the external CH₂ group
519 leading to BnAld, and OH addition to the aromatic *ipso* (C1) and *ortho* (C2 or C6) positions to form two alkyldihydroxy
520 adducts R1 and R2 (scheme 1). The OH addition to the *para* (C3, C5) and *meta* (C4) position was reported to be not
521 favourable based on theoretical study of Wang, (2015). Scheme 1 shows mechanistic pathways leading to the formation

522

523

524 **Scheme 1.** Initial reaction pathways proposed to produce selected products detected in this study (blue color) in the gas
 525 or PP (Table 5). R1-26OO and R2-13OO intermediates undergo further reactions leading to ring-opening products as
 526 shown in scheme 3.

527 of stable products (blue) including BnAld, 4-hydroxybenzyl alcohol, 2-hydroxybenzyl alcohol, phenol, formaldehyde,
528 and catechol. The initial branching ratios shown in scheme 1 are those reported by Wang (2015), obtained by combining
529 quantum chemistry calculations and experimental work from the literature. BnAld was observed in this study in the
530 presence and absence of NO_x, and its secondary chemistry may lead in part to oxygenated compounds observed in this
531 study (Bernard et al., 2013). Due to large number of possible intermediates formed (Wang, 2015), only selected pathways
532 energetically favourable leading to some products observed in this study are considered. We refer the readers to Wang
533 (2015) paper for an in-depth theoretical analysis of mechanistic pathways leading to the formation of selected reaction
534 products. The adduct R1 reacts rapidly through addition of O₂ to the ortho (C2) to produce peroxy radicals R1-2OO, The
535 O₂ addition to para position (C4) leading to R1-4OO peroxy radicals (not shown in Scheme 1) was found to be
536 endothermic, therefore negligible (Wang, 2015). Radicals R1-2OO undergo intramolecular H-shifts or ring closures to
537 form a stable bicyclic intermediate R1-26OO (red). Similarly, R2 reacts rapidly with O₂ to form peroxy radical R2-1OO
538 intermediate, which itself undergoes intramolecular H-shifts or ring closures to form a stable bicyclic intermediate R2-
539 13OO (red). R1-26OO and R2-13OO intermediates undergo further reactions leading to ring-opening products as shown
540 in scheme 3 below. 2-Hydroxybenzyl alcohol was proposed by Wang (2015) to form through the reaction of R2 with O₂
541 involving rapid direct H-abstraction. A possible formation pathway of phenol is decomposition of the peroxy radicals R1-
542 2OO and R2-1OO through CH₂OH radical elimination (Bernard et al., 2013). CH₂OH radical reacts rapidly with O₂ to
543 produce formaldehyde. Catechol was proposed to originate from the reaction of OH radicals with phenol (Atkinson et al.,
544 1992) and with 2-hydroxybenzyl alcohol (Bernard et al., 20013).

545 NACs observed in this study (Table 7) are expected to be formed through reaction of OH radicals with BnOH in the
546 presence of NO₂. Scheme 2 briefly summarizes the main mechanistic pathways leading to BnOH NACs, which follow
547 similar chemistry as those reported for toluene, benzene, and xylenes (Jenkin et al., 2003; Vidovic et al., 2018) and
548 summarized by Wang et al., (2019). The steps shown in scheme 2 are multi-steps and the reader should consult the
549 reference papers above for more in depth information. NACs are proposed to originate from secondary reactions of
550 catechol, 1,3,5-trihydroxy benzene, and 4-hydroxybenzyl alcohol with OH radicals in the presence of NO₂ (scheme 2).
551 These intermediates are proposed to be originated from R1, R2, and R3 adducts. Additional pathways could be initiated
552 via less well understood aqueous-phase nitration (Krofllic et al., 2018). 4-Nitrocatechol is proposed to be initiated through
553 the reaction of catechol with OH radicals in the presence of NO_x (Finewax et al., 2018). 4-Hydroxy-2-nitrobenzyl alcohol
554 is proposed to be likely originated from the alkyldihydroxy-para-adduct formed from the OH addition to para position

555 (scheme 2). 2-Nitrofloroglucinol and 3,4-dihydroxy-5-nitrobenzyl alcohol follow similar reactions involving R3 adduct,
 556 OH radicals, and NO₂. According to Wang (2015) calculation, at high NO₂ (100 ppbv) the reaction of R1 with NO₂ can
 557 compete to a minor degree with the reaction with O₂, therefore R1 possibly forms minor amounts of nitrobenzyl alcohol.

558

559

560 **Scheme 2.** Proposed mechanism for selected NAC species observed in this study.

561 HOCs were detected in the PP from the oxidation of BnOH in both low and high NO_x systems (Table 6). Mechanistic
 562 pathways based on theoretical studies leading to several HOCs (e. g. HOMs) from the atmospheric oxidation of biogenic
 563 and aromatic hydrocarbons have been reported recently in the literature involving unimolecular reaction through
 564 autoxidation, and peroxy and/or alkoxy radical isomerization (Wang, 2015; Jaoui et al., 2021; Piletic and Kleindienst,
 565 2022). The formation of selected HOCs observed in this study is consistent with the following pathways proposed in
 566 scheme 3 involving R2-1300 radical as the starting material. R1-26OO adduct undergoes similar reactions leading to
 567 butenedial and 2,3-epoxy-butenedial as shown in scheme S1 (SI). Tartaric acid, 2,3,5-trihydroxy-4-oxo-pentanoic acid,
 568 and pentaric acid, observed in this study for the first time, are proposed to be initiated by the oxidation of butenedial/2,3-
 569 epoxy-butenedial, 5-hydroxy-4-oxo-2-pentenal, and 4-hydroxy-2,3-epoxypentandial (scheme 3). The mechanism

570

571

Scheme 3. Proposed mechanism for selected highly oxygenated compounds observed in this study.

572
573 leading to butenedial/2,3-epoxybutanal, 5-hydroxy-4-oxo-2-pentanal (scheme S1) was reported by Wang (2015) from
574 the OH oxidation of BnOH, therefore is not shown in scheme 3. Tartaric acid present in the PP at high level (Figure 4), is
575 proposed to be formed through the oxidation of butenedial and/or 2,3-epoxybutanal through classical oxidation of
576 aldehydes and alkenes to carboxylic acid (not shown in scheme 3). Similarly, 2,3,5-trihydroxy-4-oxo-pentanoic acid and
577 pentaric acid are proposed to arise from the oxidation of 5-hydroxy-4-oxo-2-pentenal, and 4-hydroxy-2,3-
578 epoxy-pentanedial, respectively following similar mechanistic pathways reported by Jaoui et al. (2021) for the formation
579 of methyltartaric acid from 4-hydroxy-2-methyl-but-2-enal involving peroxy and alkoxy radical isomerization (not
580 reported here). In this study, a new mechanism is proposed in scheme 3 leading to the formation of 4-hydroxy-2,3-
581 epoxy-pentanedial, which is the starting material for pentaric acid formation. It involves several intermediate steps
582 including unimolecular H migration (e.g., 1,5-H shift), ring opening and decomposition. Formaldehyde and glyoxal
583 observed in this study are also shown in scheme 3.

584

585 **4. Summary**

586 In the present manuscript, laboratory experiments were conducted to investigate SOA formation from the oxidation
587 of benzyl alcohol in the presence and absence of NO_x. Chamber aerosol collected under these conditions has been
588 analyzed for organic mass to organic carbon ratio, and aerosol yield. In addition, the chemical composition of the gas
589 phase and SOA was analyzed using derivative-based methods followed by gas chromatography-mass spectrometry and
590 high-performance liquid chromatography analysis of the derivative compounds. More than 50 oxygenated organic
591 compounds in the gas and particle phases were identified. While a detailed non-targeted analysis has been made, our
592 primary focus has been to examine highly oxygenated and nitroaromatic compounds. The major components include ring-
593 opening products with high oxygen to carbon ratio (e. g. malic acid, tartaric acid, arabic acid, 2,3,5-trihydroxy-4-oxo-
594 pentanoic acid, and pentaric acid) and ring-retaining products (e. g. benzaldehyde, benzoic acid, catechol, 3-nitrobenzyl
595 alcohol, 4-nitrocatechol, 2-hydroxy-5-nitrobenzyl alcohol, 2-nitrophloroglucitol, 5-(hydroxymethyl)- 3-nitro-1,2-benzyl
596 diol). The presence of some of these products in the gas and particle phases simultaneously provides evidence of their
597 gas/particle partitioning. These oxygenated oxidation products made dominant contributions to the SOA particle
598 composition in both low and high NO_x systems. Yields, organic mass to organic carbon ratio, and proposed reaction
599 schemes for selected compounds are provided.

600 Finally, a set of reaction pathways are proposed that accounts for selected reaction products observed in this study
601 from BnOH photooxidation in the presence of OH radicals, including NACs and HOCs. The proposed mechanism is
602 based on (1) theoretical studies reported previously in the literature and (2) mechanisms associated with aromatics
603 oxidation (e.g., benzene, toluene, xylenes...). New pathways were proposed for the formation of newly observed highly
604 oxygenated compounds tartaric acid, 2,3,5-trihydroxy-4-oxopentanoic acid, and pentaric acid. Butenedial/2,3epoxy-
605 butandial, 5-hydroxy-4-oxo-2-pental, and 4-hydroxy-2,3-exopentanedial were proposed as the starting intermediate
606 species leading to these highly oxygenated compounds. While theoretical studies involving unimolecular reactions were
607 developed focusing mainly on ring-containing products (Wang, 2015, Piletic and Kleindienst, 2022), similar theoretical
608 investigations focusing on linear species (Jaoui et al., 2021) as HOCs reported in this study will help strengthen the
609 pathways proposed here.

610 The results of this study potentially have atmospheric implications for areas impacted by benzyl alcohol including
611 urban and indoor areas and contribute to understanding the formation of ambient SOA from oxygenated anthropogenic
612 precursors. Nitroaromatics are pollutants of concern due to their toxicity, light-absorption properties, and relatively long
613 residence times in the environment. HOCs may partition into pre-existing particles or be involved in new particle
614 formation.

F1: BnOH/NO_x E1: methanol extract F2: BnOH/H₂O₂ E2: methanol extract

1011

Figure 2. Portion of GC-MS total ion chromatograms (EI mode) of particle-phase extracts: (top) BSTFA derivatized sample from ER-889 (presence of NO_x), (middle) BSTFA derivatives from ER-892 (absence of NO_x), (bottom) effect of mixture changes in filter and methanol extract appearance: BnOH/NO_x filter (F1); BnOH/H₂O₂ (F2). The same volume of air was sampled on each filter.

1013

1014 **Figure 3.** Positive EI mass spectra of BSTFA derivatives of selected ring-containing products: benzoic acid, benzene-1,2-diol, 4-
 1015 hydroxybenzoic acid; and 2-hydroxybenzyl alcohol.
