18 **Abstract**

19 Reactive organic gases (ROGs), as important precursors of secondary pollutants, are
20 not well resolved as the chemical complexity challenged its quantification in many
21 studies. Here, a near-complete speciation of ROGs with 125 species was developed and
22 applied to evaluate their emission characteristics from residential solid fuel combustion.
23 ROGs identified by the present method accounted for ~90% of the “total” as the sum
24 of species by Gas Chromatography equipped with a Mass Spectrometer and a Flame
25 Ionization Detector (GC-MS/FID) and H₃O⁺/NO⁺ Proton Transfer Reaction Time-of-
26 Flight Mass Spectrometer (Vocus PTR-ToF-MS). The study further revealed that with
27 55 species, mainly oxygenated species, higher hydrocarbons with > 8 carbon atoms,
28 and nitrogen-containing ones, previously un- and under-characterized, ROG emissions
29 from residential coal and biomass combustion were underestimated by 44.3% ± 11.8%
30 and 22.7% ± 3.9%, respectively, which further amplified the underestimation of
31 secondary organic aerosols formation potential (SOAP) as high as 70.3% ± 1.6% and
32 89.2% ± 1.0%, respectively. The OH reactivity (OHR) of ROG emissions was also
33 undervalued significantly. The study highlighted the importance of acquiring

34 completely speciated measurement of ROGs from residential emissions, as well as
35 other processes.

36

37 **Highlights**

38 A near-complete speciation of ROGs emitted from residential combustion was
39 developed.

40 Oxygenated species, higher hydrocarbons and nitrogen-containing ones played larger
41 roles in the emissions of residential combustion comparing with the common
42 hydrocarbons.

43 ROG emissions from residential combustion were largely underestimated, leading more
44 underestimation of their OHR and SOAP.

45

46 **Keywords:** Chemical speciation, Reactive organic gases, Residential combustion,
47 Estimation bias

48 1. Introduction

49 Residential combustion, dominated by approximately 89% solid fuels in China
50 (Zhu et al., 2019), is responsible for ~23% and ~71% of the outdoor and indoor PM_{2.5}
51 concentrations, and ~67% of PM_{2.5}-induced premature deaths (Yun et al., 2020).
52 Reactive organic gases (ROGs), organic gases other than methane, from residential
53 combustion, have been shown to serve as key precursors for secondary organic aerosols
54 (SOA) (Huo et al., 2021) and ozone formation (Heald and Kroll, 2020; Heald et al.,
55 2020). Recommended 56 hydrocarbon species according to the Photochemical
56 Assessment Monitoring Station (PAMS), the most common ROG species, have been
57 recognized as the dominant ROGs from residential combustion in past years (Mo et al.,
58 2016). With the development of advanced detection technologies, more ROGs like
59 oxygenated volatile compounds (OVOCs) and higher alkanes with carbon atoms more
60 than 12, have been found to play important roles in the source emissions as well as in
61 the atmospheric chemistry (Yuan et al., 2017; Wang et al., 2020a; Chang et al., 2022;
62 Gao et al., 2022; Wang et al., 2022; Qu et al., 2021). A more complete chemical
63 description of ROGs emitted from residential coal and biomass combustion was
64 critically important to get more insights into their atmospheric effects.

65 Several studies attempting complete identification and quantification of ROGs
66 mainly emitted from biomass combustion have been conducted in the laboratory using
67 multiple trace-gas instruments in recent years (Gilman et al., 2015; Hatch et al., 2017),
68 which have mainly focused on emissions from various trees and other wildfire fuels.
69 Andreae (Andreae, 2021, 2019) summarized the ROG speciation and emission factors
70 of various kinds of combustion processes and concluded there were lack of results from
71 actual combustion processes like in field or household combustion and species such as
72 higher alkanes serving as important SOA precursors were not included in the previous
73 studies (Table S1)(Koss et al., 2018; Cai et al., 2019).

74 In this study, the ROGs emitted from typical Chinese household stoves with six
75 kinds of solid fuels were analyzed with the combination of a high mass resolution Vocus
76 Proton Transfer Reaction Time-of-Flight Mass Spectrometer (Vocus PTR-ToF-MS)
77 under two kinds of ion source (H₃O⁺ / NO⁺) and a gas chromatography system equipped
78 with a mass spectrometer and a flame ionization detector (GC-MS/FID). The Vocus

79 PTR-ToF-MS have a good sensitivity for most of OVOCs and aromatics as well as
80 some nitrogen-/sulfur-containing species in the mode of H_3O^+ (Wu et al., 2020), and
81 for higher alkanes in NO^+ mode (Wang et al., 2020a). GC-MS/FID has a wide detection
82 range of organics, and here is used for the detection of nonmethane hydrocarbons
83 (NMHCs) and some carbonyls. Accordingly, a near-complete speciation of ROGs
84 including 125 species results from the combined instrument data sets, further
85 supporting the evaluation of the roles of ROG emissions from residential combustion
86 in the formation potential of SOA and ozone in China.

87 **2. Materials and methods**

88 **2.1 Sampling**

89 The ROG samples of the combustion of four typical biomass fuels (wood, corncob,
90 bean straw and corn straw) and two typical coals (anthracite, and briquette coals) (see
91 Fig. S1) were collected from the stack nozzles of household stoves by vacuumed
92 SUMMA canisters (Entech Inc., 3.2 L). During canister sampling, the combustion in
93 the stoves was in the stage of flaming visually, which was the common condition for
94 heating or cooking in the rural areas in northern China. Particles was removed by a
95 particle-filter with 5.0 μm pore size Teflon filter (PTFE). Temperatures (37 ± 17 °C) of
96 flue gas were monitored at the sampling location by a flue gas analyzer (Testo 350).
97 Wood and straws burned at an average temperature of 394°C (in the range of 231°C–
98 567°C) and 353°C (334°C–371°C), respectively, while the residential coals burned at a
99 higher temperature (514°C, 411°C–581°C), which were measured by an
100 infrared thermometer in the stove. There were 23 samples were collected in all in this
101 study, as shown in Fig. S1.

102 **2.2 Analysis**

103 All the samples stored in SUMMA canisters were detected with the combination
104 of Vocus PTR-ToF-MS (Vocus 2R, Tofwerk AG, Switzerland) and GC-MS/FID (TH-
105 300, Wuhan Tianhong Instruments, China) within 9 days. The effect of storage inside
106 the canister was evaluated using the standard samples with different storage duration in
107 the laboratory. The intercomparisons of different methods were carried out to ensure
108 the results were comparable. Accordingly, the measurement uncertainties of different

109 ROG species were estimated, as listed in Table S2. Details of the measurements were
110 as following.

111 **PTR-ToF-MS.** A commercial Vocus PTR-ToF-MS with H_3O^+ and NO^+ chemistry
112 was used to detect ROGs. The Vocus PTR-ToF-MS was operated at a mass resolving
113 power of $10000 \text{ m } \Delta\text{m}^{-1}$ (full width at half maximum, FWHM). A total of 1005 peaks
114 were extracted from raw spectral data by Tofware package v3.2.3 (Tofwerk Inc.),
115 including all peaks with mass to charge ratio (m/z) below 200 under H_3O^+ mode and
116 selected peaks under NO^+ mode (mainly higher alkanes). The peak assignment was
117 derived based on accurate m/z values, isotopic patterns and previous study results
118 (Pagonis et al., 2019). In all, 162 ions with a relative high degree of certainty
119 associated with previous reports (Pagonis et al., 2019; Cai et al., 2019; Koss et al., 2018)
120 were identified and had noticeable concentrations in the samples. These 162 masses
121 represent about 89% of the total extracted signal measured by Vocus PTR-ToF-MS,
122 assuming all the signals with the same sensitivity as acetone. Twenty-six out of 162
123 identified species were calibrated using customized cylinders (Linde Gas North
124 America LLC, USA) including benzene, toluene, styrene, m-xylene, 1,3,5-
125 trimethylbenzene, isoprene, alpha-pinene, methyl vinyl ketone, naphthalene, acrolein,
126 acetone, methyl ethyl ketone, 2-pentanone, acetaldehyde, furan, acetonitrile,
127 dichlorobenzene, ethyl acetate and C_8 – C_{15} n-alkanes. More details of the calibration
128 could be found in our previous studies (Gao et al., 2022; Wang et al., 2020b).
129 Sensitivities of C_{16} – C_{21} alkanes were assumed to be same as that of C_{15} n-alkane
130 according to Wang et al.(2022) (Wang et al., 2020a). For other measured species, we
131 used the method proposed by Sekimoto et al. (2017) to determine the relationship
132 between ROG sensitivity and kinetic rate constants for proton transfer reactions of
133 H_3O^+ with ROGs (Fig. S2), and the uncertainties of the concentrations for these
134 uncalibrated species were about 50% (Table S1) (Sekimoto et al., 2017).

135 **GC-MS/FID.** 57 NMHCs and 11 carbonyls were detected by GC-FID/MS
136 coupled with a cryogen-free preconcentration device, which were calibrated by gas
137 standards (Linde Gas North America LLC, USA) including 68 species as listed in Table
138 S2. Intercomparisons between GC-FID/MS and Vocus PTR-ToF-MS for overlapped
139 ROG species were carefully evaluated. Good agreements for aromatics and some

140 carbonyls were observed in all samples (Fig. S3).

141 **Loss in storage.** To determine the possible artifacts caused by the SUMMA
142 canister storage, standard samples with concentration of 5 ppbv containing 81 species
143 were prepared into clean vacuum SUMMA canisters and detected within 2h as well as
144 on days 1, 2, 4, 7, 10 and 14 after preparation. The detailed compounds and deviations
145 were shown in Table S2 and Fig. S4. Generally, on the 10th day, the relative deviations
146 were within 20% for 71 out of the 81 standard compounds, and the rest 10 compounds
147 like diethylbenzene, terpenoids and long-chain alkanes had the relative deviations
148 within 49%. The concentration of the standard sample was lower than most of the
149 concentrations of species in source samples. Thus, the estimated loss in the storage in
150 this study was the upper bound for the source samples. For acids and alcohols with
151 larger loss in the canisters potentially due to the functional groups of -COOH and -OH,
152 the measured concentrations in the samples were excluded from the results, and
153 especially there were no standard gases used to evaluate the loss during storage. The
154 estimated total uncertainty of ROGs were in the range of 4%–50%, which included the
155 uncertainties of storage and detection, as listed in Table S2.

156 **Speciation.** Finally, 87 out of the 162 species measured by Vocus PTR-ToF-MS
157 were used in this study, including 31 overlapped species with those by GC-FID/MS
158 (Fig. 1). Since isomers can't be distinguished by Vocus PTR-ToF-MS, GC-FID/MS
159 measured concentrations for overlapped ROG species were used in this study.
160 Combining with other 37 species detected by GC-MS/FID, a total of 124 species were
161 used in this study, including 27 alkanes, 9 alkenes, 1 alkyne, 16 aromatics, 6 biogenic
162 volatile organic compounds (BVOCs), 9 polycyclic aromatic hydrocarbons (PAHs), 14
163 higher alkanes, 15 carbonyls, 10 furans (furan and its homologues and derivatives), 9
164 phenols (phenol and its homologues and derivatives) and 8 nitrogen-containing
165 compounds. Other species detected by Vocus PTR-ToF-MS but not included in the
166 follows were mainly acids, alcohols and species with more than 2 oxygen atoms,
167 accounting for about 8% (ranging from 2% to 17% in different samples) of the total
168 ROG masses as shown in Fig. S5.

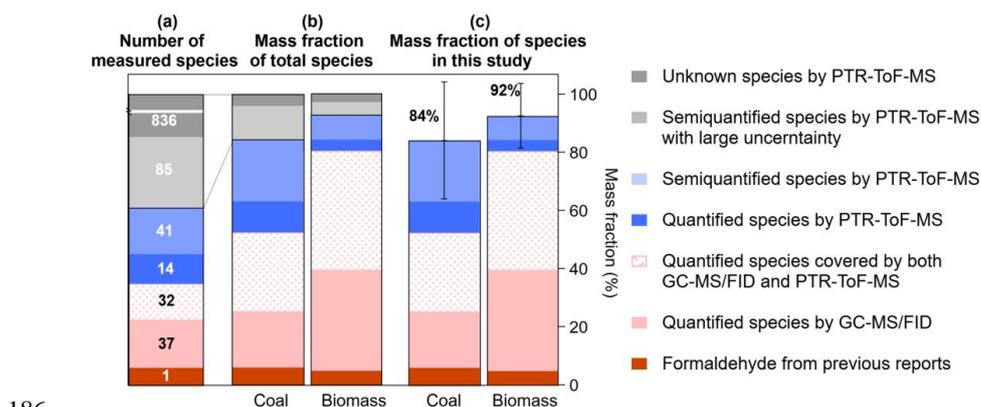

169 **Formaldehyde**, a very important species from combustion (Zarzana et al., 2017)
170 but not measured in this study, was assumed to account for ~7% and ~5% in all

171 discussed species for coal and biomass combustion in this study, respectively, according
172 to the previous reported results (Cai et al., 2019; Stockwell et al., 2015; Stockwell et
173 al., 2016). Specifically, the emission ratio of formaldehyde ($ER_{\text{HCHO, ref}}$) from anthracite
174 coal combustion (2.13 g/g,benzene) and straws (2.85 g/g,benzene) could be obtained
175 from Cai et al. (2019) and Stockwell et al. (2016). Considering the emission ratio of the
176 species covered by both previous studies and the current work were consistent as shown
177 in Fig. S6, the mass fraction of formaldehyde ($f_{\text{HCHO, cal}}$) in ROG emissions from coal
178 combustion of this work could be calculated using the previously reported $ER_{\text{HCHO, ref}}$
179 and the currently measured mass fraction of benzene (f_{benzene}) as follows:

$$180 \quad f_{\text{HCHO, cal}} = \frac{ER_{\text{HCHO, ref}} \times f_{\text{benzene}}}{1 + ER_{\text{HCHO, ref}} \times f_{\text{benzene}}} \quad (1)$$

181 Finally, all the species included in this study were sketched in Fig. 1, as well as
182 their mass fractions in ROG emissions from residential combustion which would be
183 discussed in detail below. Briefly, although only 125 out of more than 1000 species
184 were included in the speciation of ROGs from residential combustion emissions, they
185 have contributed $89 \pm 20\%$ and $92 \pm 11\%$ of the total ROGs from residential combustion.

186

187 **Figure 1.** The number and mass fraction of species measured by GC-MS/FID and
188 Vocus PTR-ToF-MS. (a) Number of measured species by GC-MS/FID and Vocus PTR-
189 ToF-MS. (b) Average mass fraction of all measured species from coal combustion and
190 biomass combustion samples. (c) Mass fraction of selected 125 species in this study.
191 The result of formaldehyde was cited from previous studies (Cai et al., 2019; Stockwell

192 et al., 2015). All the quantified species were calculated by standard matters. The
193 semiquantified species were measured by Vocus PTR-ToF-MS (H_3O^+) by the method
194 proposed by Sekimoto et al. (2017) to determine the relationship between ROG
195 sensitivity and kinetic rate constants for proton transfer reactions of H_3O^+ with ROGs.
196 Among the above semiquantified species, species with the functional groups of -OH
197 and -COOH as well as those with more than two oxygen atoms had relatively large
198 uncertainty due to the potential loss in the storage. The unknown species were detected
199 by Vocus PTR-ToF-MS (H_3O^+) and were semiquantified by the sensitivity of acetone.

200 **3. Results and discussions**

201 **3.1 A near-complete speciation of ROGs from residential combustion**

202 ROG compositions emitted from typical residential combustion using two types of
203 coals (anthracite, and briquettes) and four types of biomasses (wood, corncob, corn
204 straw and bean straw) are shown in Fig. 2. The measured ROG profiles for each kind
205 of fuel had a good correlation ($R > 0.6$) (Fig. S7), and the average result was used here.

206 Generally, ROGs emitted from the residential combustion can be divided into three
207 groups based on the element composition, including hydrocarbons, oxygenated species,
208 and nitrogen-containing species. Differing from the previously studies which mainly
209 stressed the dominant role of hydrocarbons (Mo et al., 2016; Stockwell et al., 2015;
210 Wang et al., 2014), the contribution of oxygenated species (36.8%–56.8%) was
211 comparable with that of hydrocarbons (40.8%–48.7%) in this study. It was expected as
212 24 more oxygenated species mainly including furans, phenols and carbonyls were
213 measured by Vocus PTR-ToF-MS in our study, which were un- and under-characterized
214 in previous studies using GC methods. Besides hydrocarbons and oxygenated species,
215 nitrogen-containing species mainly included acetonitrile and acrylonitrile also played a
216 considerable role in ROG emissions from residential combustion, with the proportions
217 ranging from 5.7% to 14.5%, which have been previously reported (Cai et al., 2019).

218 Here, we defined the species previously un- and under-characterized by GC
219 methods as newly identified species and could be measured only using Vocus PTR-

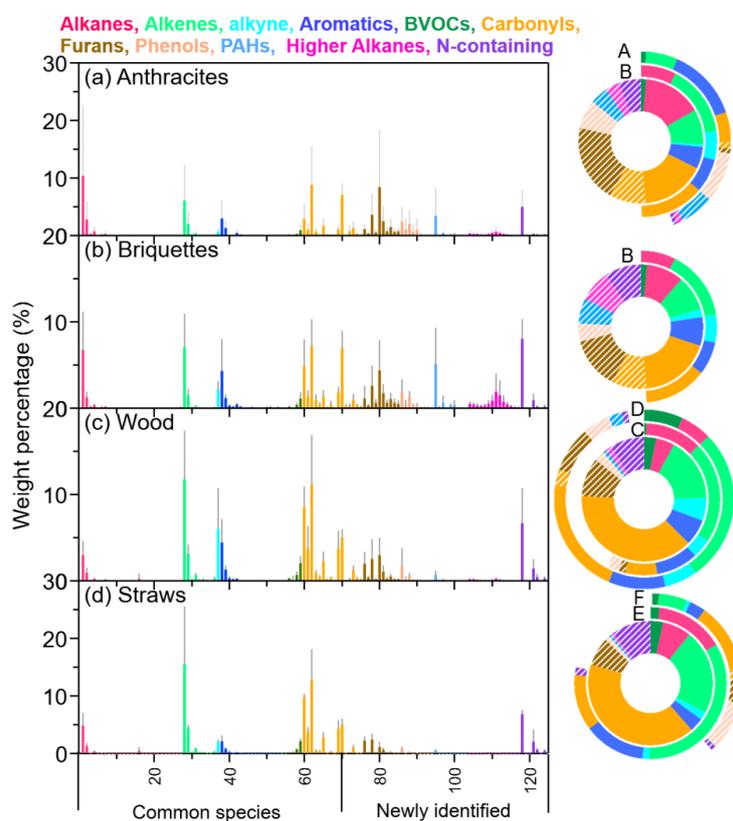

220 ToF-MS in this study, and as a result 55 of 125 species were newly identified species.
221 As shown in Fig. 2, these newly identified species mainly including furans and phenols
222 contributed $44.3\% \pm 11.8\%$ of the total ROGs for coal emissions and $22.7\% \pm 3.9\%$ of
223 the total ROGs for biomass emissions. We also compared our results with the previous
224 reports, and for comparison the previous speciation was scaled by the total fraction of
225 the previously reported species in the total ROGs measured in this study. As shown in
226 Fig. 2 and Fig. S5, the fraction of reported species in previous studies was comparable
227 to the present result. In particular, as Fig. 2(c) shown, the present composition of ROGs
228 from residential wood combustion was close to that of Black Spruce combustion
229 simulated in laboratory by multiple advanced trace-gas instruments, which reported
230 464–551 species (~173 molecules) in all (Hatch et al., 2017). It further confirmed that
231 the obtained ROG characterization with the combination of Vocus PTR-ToF-MS and
232 GC-FID/MS were nearly complete. Our study underscored the importance of the
233 completely speciated measurement of the ROG emissions from residential combustion
234 especially for coal combustion.

235 Large difference was observed between the ROG speciation of coal and biomass
236 combustion but not significant among different types of coal or biomasses, as shown in
237 Fig. 2. Specifically, the alkenes mainly ethylene and propene dominated hydrocarbons
238 emitted from biomass combustion, while alkanes were the most hydrocarbons from coal
239 combustion. Especially, coal combustion emitted considerable higher alkanes including
240 8–21 carbon atoms and gaseous PAHs (mainly including 2–3 benzene rings), primarily
241 generated by pyrolysis of the volatile matter in coal (Du et al., 2020), accounting for
242 8.3%–14.8% of ROGs much higher than the minor fractions (0.4%–2.4%) for biomass
243 combustion emissions. In terms of oxygenated species, coal combustion emitted
244 considerable furans ($16.8\% \pm 3.2\%$) and phenols ($6.1\% \pm 1.5\%$) mainly formed through
245 pyrolysis of polymers in coal (Liu et al., 2017; Morgan and Kandiyoti, 2014), which
246 together played a comparable role with carbonyls ($26.9\% \pm 6.8\%$) in ROGs. In
247 comparison, carbonyls ($40.6\% \pm 6.6\%$) were the dominant oxygenated species in ROG
248 emissions from biomass combustion, mainly originated from products of biomass
249 pyrolysis and pyrosynthesis (Morgan and Kandiyoti, 2014). A slightly higher

250 proportion of phenols and furans from wood combustion ($12.8\% \pm 3.0\%$) than straw
251 combustion ($8.7\% \pm 2.8\%$) were observed, possibly resulting from the higher
252 composition of lignin in wood (Collard and Blin, 2014). Considerable terpenes were
253 also observed in ROG emissions from residential coal ($1.5 \pm 0.2\%$) and biomass (3.2%
254 $\pm 0.5\%$) combustion.

255

256 **Figure 2.** Source profiles and compositions of the four types of residential fuels
257 including (a) anthracites, (b) briquettes, (c) wood and (d) straws (average of corncob,
258 bean straws and corn straws) as well as those of the previous results. A. anthracites
259 combustion in stove from Cai et al., 2019; B. residential coal combustion simulation in
260 lab from Mo et al., 2016; C. hardwood combustion simulation in lab from Stockwell et
261 al., 2016; D. Black Spruce combustion simulation from lab experiments reported by
262 Hatch et al., 2017; E. wood combustion simulation from Wang et al., 2014; F. rice straw
263 combustion simulation from Stockwell et al., 2015 (Cai et al., 2019; Mo et al., 2016;

264 Wang et al., 2014; Stockwell et al., 2016; Hatch et al., 2017; Stockwell et al., 2015).
265 The measured species corresponding to the numbers of horizontal axis are listed in
266 Table S2. The shaded parts of pie charts represent the newly identified species.

267 3.2. SOAP and OHR underestimation from newly identified species

268 To further understanding the role of residential combustion emitted ROGs in
269 atmospheric chemistry, the OH reactivity (OHR) and formation potential (SOAP) of
270 per unit mass (or concentration) of ROGs emitted from residential combustion was
271 calculated based on the source profiles. OHR is defined here as the sum of OH reactivity
272 of each species, calculated by product of ROG species weight percentage ($W_{\text{ROG}i}$) in
273 emissions from residential combustion and corresponding OH reaction rate ($k_{\text{OH}+\text{ROG}i}$)
274 (Carter, 2008; Koss et al., 2018), as presented in Eq. (2) below. SOAP is the sum of
275 SOAP of each species and calculated by multiplying proportion of ROG species with
276 according SOA yields based on the reported approach (Ng et al., 2007; Lim and
277 Ziemann, 2009), as presented in Eq. (3) below.

$$278 \quad \text{OHR} = \sum W_{\text{ROG}i} \times k_{\text{OH}+\text{ROG}i} \quad (2)$$

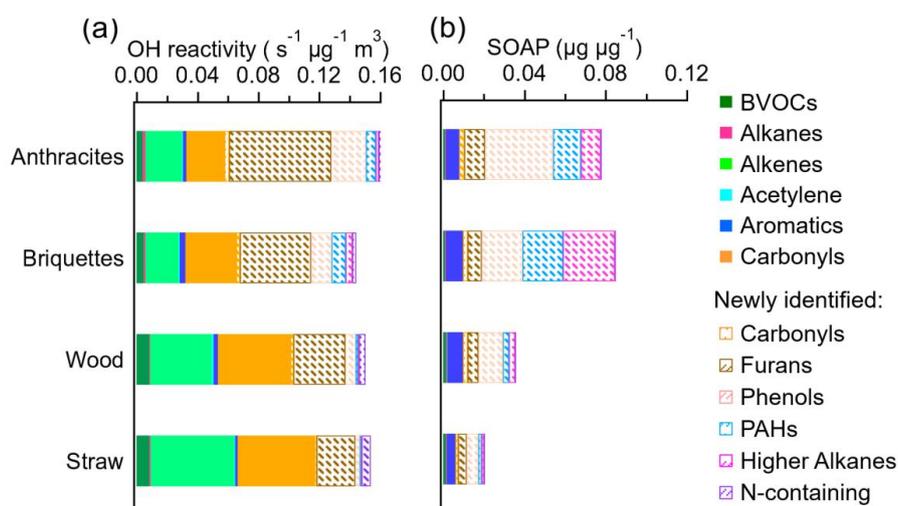

$$279 \quad \text{SOAP} = \sum W_{\text{ROG}i} \times \text{Yield}_{\text{ROG}i} \quad (3)$$

280 Figure 3 shows the OHR and SOAP of per unit mass (or concentration) ROG
281 emissions. The OHR for coal and biomass emissions were quite similar ($0.14\text{--}0.16 \text{ s}^{-1}$
282 $\mu\text{g}^{-1} \text{ m}^3$) but with different compositions, which was expected as the differences of their
283 ROG compositions. The OHR was dominated by oxygenated species (39.6%–73.7%)
284 and alkenes (15.0%–48.2%), and the contribution of other species was within the range
285 of 9.3%–17.1%. The newly identified ROG species dominated the OHR of coal
286 combustion with the fractions of $64.2\% \pm 7.8\%$ and $54.6\% \pm 9.3\%$ for anthracites and
287 briquettes combustion, respectively, due to the large contribution of furans, phenols,
288 PAHs, and higher alkanes in ROGs. In comparisons, the previously reported species
289 contributed more to OHR of biomass combustion than that of newly identified species.
290 The ratio of OHR between newly identified and previously reported ROGs was 1.20–
291 1.80 for coals and 0.22–0.51 for biomass, much higher than the ratios of their emissions
292 ($0.79\text{--}0.81$ for coals and $0.20\text{--}0.36$ for biomass). It meant that the OHR of ROG
293 emissions from residential coal and biomass combustion was underestimated by 59.4%

294 $\pm 4.8\%$ and $26.2 \pm 6.8\%$, respectively, without the newly identified species.

295 SOAP derived from per unit mass ROG emissions of coal combustion was 0.078–
296 $0.085 \mu\text{g } \mu\text{g}^{-1}$, much higher than that from biomass combustion ($0.016\text{--}0.035 \mu\text{g } \mu\text{g}^{-1}$).
297 Nevertheless, for all samples, newly identified ROGs accounted for over 70% of the
298 SOAP. SOAP was dominated by newly identified oxygenated species like phenols
299 which contributed $47.6\% \pm 12.4\%$ and $56.7\% \pm 7.0\%$ to SOAP of emissions from coal
300 and biomass combustion, respectively, and higher alkanes and PAHs also played
301 important roles in SOAP emissions from coal combustion. The ratios of SOAP derived
302 from newly identified ROGs and previously reported ROGs were 7.8–8.8 and 2.2–2.7
303 for coals and biomass, respectively, much higher than those of mass percentages. These
304 results indicated that for both coal and biomass combustion, the measurement of newly
305 identified ROGs would be greatly affected on SOA estimation. The field study has
306 found that newly identified ROGs like higher alkanes and PAHs contributed more than
307 60% of SOA formation from measured precursors in ambient air (Wang et al., 2020a).
308 Our study of ROG emissions could donate to the explanation of the high SOA formation
309 in atmosphere to some extent. In other words, failure to include newly identified ROGs
310 in emission inventories and SOA models could lead to significant underestimation of
311 residential contribution to SOA production.

312

313 **Figure 3.** OH reactivity and SOA formation potential (SOAP) of per unit mass (or
314 concentration) of ROG emissions for coal and biomass combustion. The shaded parts

315 of bar charts represent the newly identified species.

316 **3.3 ROG emissions from residential combustion in China**

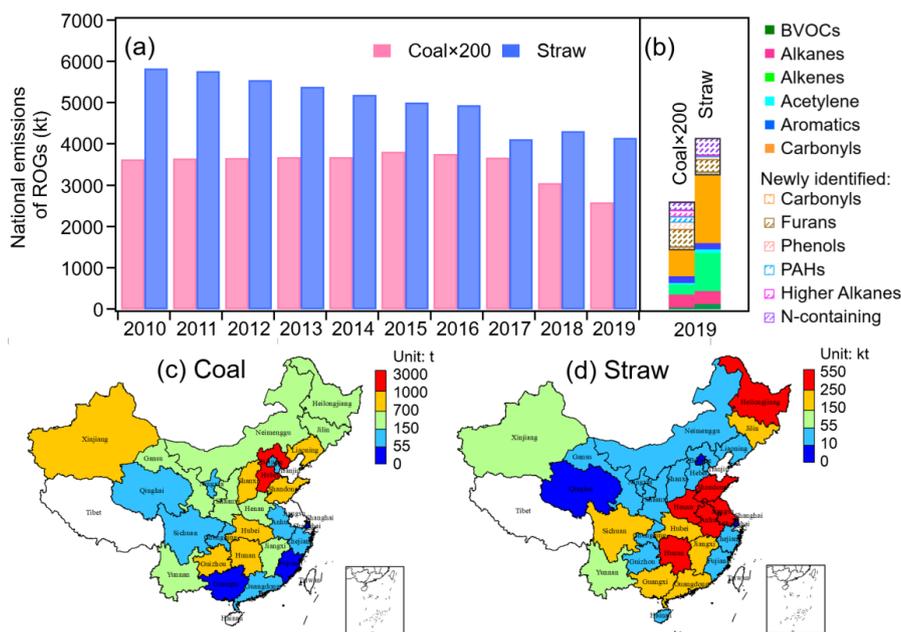

317 ROG emissions could generally be calculated through multiplying the activity data
318 by the emission factors which were not measured in this study. However, the emission
319 factors of most of the common ROG species like hydrocarbons in the emissions from
320 residential combustion have been reported in previous studies (Cai et al., 2019;
321 Stockwell et al., 2015). Hence, the emission factor of the newly identified ROG species
322 in this study could be estimated by the reported emission factor (EF) of the previously
323 reported species combining with their emission ratio (ER) in residential combustion.
324 Here, the benzene as well as its reported EF was used for the purpose above, and we
325 also tested other species with reported EFs (Fig. S8). There were no significant
326 differences (-39%–4% for straws and 6%–26% for coals) of the estimated EFs of newly
327 identified ROG species among different tests, which further confirmed our results were
328 comparable with the previous studies but with more ROG species measured, as shown
329 in Fig. S8. The ER of other ROG species to benzene was the ratio of their concentrations
330 in the sample, and the average ER in different samples of each type of fuel was used in
331 this study, as listed in Table S3. Notably, the EFs of anthracite and straw combustion
332 were used below to estimate the ROG emissions of residential coal and straw
333 combustion in China mainland.

334 Accordingly, the national ROG emissions of residential combustion were estimated
335 combining with the residential coal consumption and the crop straw combustion data
336 in China. Specifically, the data of residential coal consumption from 2010 to 2019 were
337 from the China Energy Statistical Yearbook (National Bureau of Statistics, 2010-2022),
338 which included the data of each province in China mainland in each year. The data of
339 crop straw combustion from 2010 to 2019 (Table S4) were from Report of Prospects
340 and Investment Strategy Planning Analysis on China Straw Refuse Treatment Industry
341 (2022-2027) (Qianzhan Industrial Research Institute, 2022), which only reported the
342 total amount of the whole China mainland and included both the household and field
343 combustion. The province data of crop straw combustion in 2017 (Table S5) were used
344 to study the spatial distribution in this study, which were from Second National
345 Pollution Source Census Bulletin (Ministry of Ecology and Environment of the People's

346 Republic of China et al., 2020).

347 The spatial and temporal distribution of ROG emissions from residential
348 combustion was presented in Fig. 4. The total emissions of ROG from residential
349 coal combustion and crop straw combustion were 14 kt and 4384 kt in 2019, respectively,
350 and as expected these values were underestimated by $44.3\% \pm 11.8\%$ and $22.7\% \pm 3.9\%$,
351 respectively, due to fewer species were included previously. Unexpectedly, the ROG
352 emissions from crop straw combustion were two orders of magnitude higher than those
353 of coal combustion, which included those both from household and field combustion.
354 Notably, the straw combustion emissions were stable after 2017 comparing with the
355 gradual decrease from 2010 to 2017, mainly due to the limitation of straw utilization
356 (Zhu et al., 2019). In comparison, ROG emissions of residential coal combustion began
357 to decrease after 2017 benefiting from the clean heating action in the north of China
358 (National Development and Reform Commission, 2017). Spatially, the hot areas of
359 ROG emissions from residential coal combustion were mainly in the North China Plain
360 (NCP)(Yang et al., 2020), while those of straw combustion were mainly in the main
361 food-production bases of China like the northeastern China, the southern NCP, and
362 Jiangsu, Anhui, and Hunan provinces.

363

364 **Figure 4.** Emissions of ROGs from residential coal and straw combustion in China. (a)
365 Annual variation of national ROG emissions and (b) the speciation of ROG emissions
366 in 2019 from residential coal and straw combustion. The black boxes indicate the
367 emissions of newly identified species. (c, d) Spatial distribution of ROG emissions from
368 coal combustion in 2019 and straw combustion in 2017 respectively. The blank parts
369 on the map indicate the provinces with missing data.

370 4. Conclusions

371 In this study, a near-complete chemical description of ROGs emitted from
372 residential coal and biomass combustion was developed to get more insights into their
373 atmospheric effects. ROGs identified by the present method accounted for ~90% of the
374 “total” as the sum of species by Gas Chromatography equipped with a Mass
375 Spectrometer and a Flame Ionization Detector (GC-MS/FID) and $\text{H}_3\text{O}^+/\text{NO}^+$ Proton
376 Transfer Reaction Time-of-Flight Mass Spectrometer (Vocus PTR-ToF-MS). Among
377 the near-complete description of ROGs, 55 species un- and under-characterized in
378 previous studies using GC methods were analyzed intensively by Vocus PTR-ToF-MS,
379 mainly including oxygenated species (carbonyls, furans, phenols), higher hydrocarbons
380 (PAHs, higher alkanes) with carbon atoms more than 8 as well as nitrogen-containing
381 compounds.

382 For the nearly complete ROGs dividing into three categories by the element
383 composition, oxygenated species played a similar major role with hydrocarbons, and
384 nitrogen-containing species dominated by acetonitrile and acrylonitrile were also
385 considerable in ROG emissions from residential combustion. Especially, coal
386 combustion emitted considerable higher alkanes including 8–21 carbon atoms, gaseous
387 PAHs (mainly including 2–3 benzene rings), furans and phenols, differently biomass
388 combustion emitted more carbonyls and terpenes.

389 Considering the newly discovered species, it is observed that approximately half
390 and a quarter of the ROG emissions from coal and biomass combustion are
391 underestimated. Combining with the spatial-temporal consumption of residential coal
392 and biomass combustion in China, ROG emissions of residential combustion were
393 estimated. The ROG emissions from straw combustion were two orders of magnitude
394 higher than those from coal combustion with negligible decline in recent years as the

395 limited straw utilization ratio, which suggested the biomass combustion would be the
396 only important residential emissions with the continuous replacement of residential coal
397 in rural of China. Given the newly identified species more reactive or with higher SOA
398 yields, amplified underestimation of OHR and SOAP were observed for both coal
399 combustion ($59.4\% \pm 4.8\%$ and $89.2\% \pm 1.0\%$) and biomass combustion ($26.2 \pm 6.8\%$
400 and $70.3\% \pm 1.6\%$). These results highlighted the importance of the completely
401 speciated measurement of the ROG emissions from residential combustion.
