Abstract

The Tibetan Plateau (TP) is of great importance for weather and climate due to its role as heat and water resource. Relatively clean aerosol conditions over the Plateau makes the study on the aerosol-cloud-precipitation interactions in this pristine continental region distinctive. In order to investigate the impacts of aerosols on small-scale convection processes over the TP, a convective event with precipitation observed on 24 July 2014 in Naqu was selected to explore the influence of aerosols on the onset and intensity of precipitation. We use the Modern-Era Retrospective analysis for Research and Applications Version 2 (MERRA-2) reanalysis to derive the cloud condensation nuclei (CCN) number concentration, which can be regarded as the real-time background. These values are adopted to initialize the regional WRF 4.0 meteorological model and to simulate the onset of convective events and the formation of precipitation. Four sets of experiments, named clean (1/10 CCN), control (default setting), Tibetan Plateau (real CCN calculated from MERRA-2 reanalysis), and polluted (10 times CCN), were adopted for our simulations. A detailed analysis of microphysical processes shows that, with the increase in the aerosol number concentration, the conversion rate of cloud water to rain in clouds is enhanced at first. Under polluted situations, the conversion process of cloud water to rain is suppressed; however, the transformation of cloud water to graupel and the development of convective clouds are favored. As a result, the onset of the precipitation is delayed and cold-rain intensity increases.

Key words: Aerosol; Tibetan Plateau; Precipitation

Highlights:

- The evolution of convective events on the pristine continent under different atmospheric aerosol burden are examined.
- With the increase in the aerosol number concentration, the conversion of cloud water to rain in clouds is enhanced at first.
- Under polluted situations, the onset of the convective precipitation is delayed and the cold-rain intensity increases.

47 **1. Introduction**

48 The role of aerosol particles on the formation of convective clouds and related precipitation
49 remains a matter of extensive scientific investigations (Andreae et al., 2004; Fan et al., 2013; Freud
50 and Rosenfeld, 2012; Li et al., 2011; Rosenfeld et al., 2008; Sun and Zhao, 2021; Tao et al., 2012;
51 Zhao et al., 2020). Due to the complexity of the processes involved, the treatment of convective
52 cloud formation in weather forecast models remains uncertain, especially for the regions with
53 insufficient observational data (Ma et al., 2018). The Tibetan Plateau (TP) represents a clean region,
54 in which the aerosol optical depth baseline value is comparable to that in the Arctic and remote
55 ocean areas (Pokharel et al., 2019; Yang et al., 2021b). However, even though the TP is regarded
56 as a pristine continent, it is occasionally perturbed by the intrusion of dust particles originating in
57 the surrounding deserts and by black carbon particles produced by biomass burning in the regions
58 of South Asia and part of Africa (Zhu et al., 2019; Zhao et al., 2020; Yang et al., 2021b). The
59 analysis presented here in the climate-sensitive and environmentally fragile continental TP
60 characterized by frequent convective events, will hopefully be of interest for similar investigations
61 to be conducted in other areas of the world, which is about the aerosol perturbations on pristine
62 continent.

63 The Tibetan Plateau, with an average elevation of more than 4000 meters, covers
64 approximately a quarter of the Chinese territory (Wu et al., 2007; Yao et al., 2012). It greatly
65 influences weather and climate in East Asia and even globally due to its unique geographical
66 location and topography-induced thermal and dynamical effects (Pokharel et al., 2019). The water
67 vapor balance on the TP directly affects the water cycle over a large area of the plateau and the
68 surrounding areas due to high sensible heat and low air density (Duan et al., 2012; Fu et al., 2006;
69 Zhao et al., 2018). Convection on the Tibetan plateau is characterized by high frequency but low
70 intensity activity (Fu et al., 2006; Gao et al., 2016; Ye 1981). Aerosols can act as cloud
71 condensation nuclei (CCN) and ice nuclei (IN) that affect cloud microphysical processes and
72 thermal and dynamical conditions (IPCC, 2013; Redemann et al., 2021; Stevens et al., 2017; Yang
73 et al., 2021a). Relatively clean conditions with low levels of background aerosols, frequent
74 convection and induced precipitation make the study of aerosols' impact on convective
75 precipitation over the TP distinctive.

76 Aerosol observational sites over the TP are sparse. Ground-based observations include (1) the
77 two stations of the Automated Aerosol Observation Network (AERONET) in Nam Co and

78 Qomolangma (QOMS), (2) the stations of PM_{2.5} and PM₁₀ from the China Air Quality Online
79 Monitoring and Analysis Platform (CAWNET) of the Ministry of Environmental Protection at the
80 seven stations of Linzhi, Ali, Lhasa, Changdu, Naqu, Shannan, and Shigatse, and (3) the
81 concentrations of PM₁ at four stations from China Meteorological Administration (CMA)
82 Observation Network at Gongga, Lhasa, Xining, and Shangri-La. The monitoring of PM_{2.5} and
83 PM₁₀ on the TP were initiated in January 2013 at Lhasa, in January 2015 at Ali and Naqu, and in
84 January 2017 at Changdu, Shannan, Shigatse, and Linzhi. The CMA recorded PM₁ data at Gongga,
85 Lhasa, and Shangri-La data from January 2014 to December 2018, and at Xining, starting in 2018.
86 CMA used a GRIMM Model 1.180 aerosol spectrometer with observations every five minutes at
87 wavelengths ranging from 1 μm to 10 μm. A decade of measurements of aerosol optical properties
88 at two AERONET stations, Nam Co and QOMS on the Tibetan Plateau, shows that aerosol optical
89 depth (AOD) values were maximum in spring and minimum in autumn (Pokharel et al., 2019).
90 Due to the anisotropic reflection of the unique geographical surface in TP, the satellite retrieval of
91 aerosol properties is difficult (Zhao et al., 2020). The main aerosol types on the Tibetan Plateau
92 were further identified as continental background, biomass burning, and dust (Pokharel et al., 2019;
93 Yang et al., 2021b; Zhu et al., 2019; Zhao et al., 2020). Satellite observations from March to June
94 indicate that aerosols are transported from South Asia to the region close to the Himalaya (Liu et
95 al., 2008). In summer, aerosols from Northwest China and Central Asia are transported to the
96 northern Tibetan Plateau (Huang et al., 2007). In general, aerosol conditions over the TP
97 correspond mainly to a background situation. However, incoming pollution from South/East Asia
98 under the influence of the summer monsoon can cause relatively high disturbances in the area of
99 the Tibetan Plateau.

100 Among the studies conducted in development over the TP, are the Third Tibetan Plateau
101 Atmospheric Scientific Experiment (TIPEX-II and TIPEX-III), initiated jointly by the China
102 Meteorological Administration (CMA), the Chinese Academy of Sciences (CAS), and the National
103 Natural Scientific Foundation of China (NSFC) (Zhao et al., 2018), and the Third Pole
104 Environment (TPE) Program, which was initially proposed and agreed upon by several participants
105 from China, India, Germany, Japan, Italy, Nepal, the Netherlands, Norway, Pakistan, US, Canada,
106 Tajikistan, and Switzerland (Yao et al., 2012). These studies highlighted the role of aerosol
107 characteristics and related impact on cloud and precipitation in the TP in relation with weather and
108 climate modification due to East Asia and South Asia anthropogenic emissions, and dust

109 mobilization in the Taklamakan Desert (Kang et al., 2019; Liu et al., 2019; Xu et al., 2015), but
110 also in relation with further impacts on the weather system in the downstream regions, e.g. Yangtze
111 Delta region, or/and Sichuan Basin (Lau et al., 2019; Liu et al., 2019; Liu et al., 2020; Zhao et al.,
112 2018; Zhao et al., 2020). It has been shown that cloud cover and radiation effects in pristine regions
113 are particularly sensitive to aerosols (Garrett et al., 2006). Further, aerosols on the Tibetan Plateau
114 can affect weather and climate directly by absorbing and scattering solar radiation, and indirectly
115 by modifying the nature of the clouds. Using a cloud-resolving weather research and forecasting
116 model, Zhou et al. (2017) found that the increase in the aerosol load over the plateau not only
117 contributes to enhanced updrafts in clouds, but also transports a larger number of ice phase
118 particles to the upper troposphere. Based on satellite observations and the reanalysis of the dataset,
119 Liu et al. (2019) studied the effect of aerosols on clouds over the Tibetan Plateau and the effect of
120 dust-contaminated convective clouds on precipitation in downstream areas. They identified an
121 effect of Taklamakan dust on convective clouds, which in turn causes heavy rainfall in downstream
122 areas. However, one should highlight that there are still some uncertainties in the satellite retrievals.
123 The findings of aerosol-related studies require situation-specific analyses since the northern and
124 southern parts of the Tibetan Plateau are characterized by different aerosol backgrounds and
125 composition with different climate systems and meteorological conditions. Using the aerosol
126 spectral radiative transfer model (SPRINTARS) and the non-hydrostatic Icosahedral Atmospheric
127 Model (NICAM), Liu et al. (2020) found that dust aerosol transported from the Taklamakan desert
128 delayed the onset of heavy rainfall in the northern Tibetan Plateau by 12 hours through the indirect
129 aerosol-cloud interaction, and enhanced the precipitation in the northern region. Aerosols may also
130 influence the Asian monsoon by affecting snow melting trends and TP surface temperature, which
131 in turn affects precipitation (Lee et al., 2013). The role of aerosols in the teleconnections between
132 the heat-pump and the stronger convection and precipitation in the TP or downstream regions (Wu
133 et al., 2016) also needs to be accounted for in the weather forecasting models (Liu et al., 2019;
134 Zhao et al., 2020).

135 Although after decades of efforts, our awareness of Tibetan Plateau aerosols and related
136 weather impact gradually increased, the confidence of current knowledge on aerosols over the TP
137 still needs further observational evidence, more in-depth physical analyse and model investigations.
138 In order to gain understanding on the formation of small-scale convection and related precipitation,
139 we analyze here a particular event that took place in Naqu (92.067° E, 31.483° N) on 24 July 2014.

140 As observational data are sparse, we use the Modern-Era Retrospective analysis for Research and
141 Applications Version 2 (MERRA-2) reanalysis to derive the cloud condensation nuclei, which can
142 be regarded as the real-time background. These values are adopted to initialize the regional WRF
143 4.0 meteorological model and to simulate the onset of convective events and the formation of
144 precipitation. Vertical soundings provide data on the state of the background atmosphere. The
145 purpose of the present study is to use available information in this region of the Tibetan Plateau to
146 assess the dependence of the evolution of convective events on the pristine continent under
147 different background atmospheric aerosol burden. Since data in the region of the Tibetan Plateau
148 are sparse, the study relies heavily on model simulations, and the outcome should therefore be
149 regarded as a preliminary and partial attempt to investigate a possible relationship between aerosol
150 and convective precipitation in this region. This methodology could then be applied in other
151 regions of the world with similar background environments.

152 The paper is organized as follows: Section 2 introduces the data and the methodology that are
153 adopted in the study; it also describes the convection event under investigation and presents the
154 experimental design for the numerical simulations. Section 3 compares the microphysical process
155 that characterize the different model experiments. Section 4 presents a summary and the
156 conclusions.

157

158 **2. Data and methods**

159

160 **2.1 Data**

161

162 **2.1.1 MERRA-2 data**

163 MERRA-2, a long-term global reanalysis that assimilates space-based observations of
164 aerosols (Randles et al., 2017), is an upgrade of the offline aerosol analysis data MERRAero based
165 on the GOCART model (Chin et al., 2002). GOCART emission sources include aerosols and gases
166 from biomass burning, fossil fuel combustion, natural emission sources (ocean, volcanic eruptions,
167 dust), etc. (Chin et al., 2013). The bias-revised AOD is obtained from the observations by the
168 Moderate Resolution Imaging Spectroradiometer (MODIS). Cloud-filtered Aerosol Robotic
169 Network (AERONET) AOD data are used as input in a neural network to integrate Moderate
170 Resolution Imaging Spectroradiometer (MODIS) radiances into the bias-corrected AOD. The

171 MERRA-2 Aerosol reanalysis data are additionally included in the NASA Earth Observing System
172 (EOS), NOAA Polar Operational Environmental Satellites (POES), and ground-based
173 observations (Randles et al., 2017). Note that uncertainties are incurred when satellite retrievals
174 are used over the TP, due to the complicated reflection of the land surface (Yang et al., 2020; Zhao
175 et al., 2020; Jiang et al., 2022). The dataset used in the present paper is the MERRA-2 aerosol
176 mixing ratio data MERRA-2 inst3_3d_aer_Nv for 23 July 2014, with a spatial resolution of 0.625°
177 $\times 0.5^\circ$ (longitude, latitude) on 72 vertical layers and with a temporal resolution of 3 hours.

178

179 **2.1.2 Precipitation and sounding data**

180 The Station-Satellite combined $0.1^\circ \times 0.1^\circ$ hourly precipitation data (Shen et al., 2014) are
181 provided by the China Meteorological Administration Information Center, while the ground
182 precipitation observations are obtained from the Naqu automatic station. Note that some unrealistic
183 rainfall centers are depicted over western China due to the sparse automatic weather station
184 network (Shen et al., 2014). The sounding data are taken from the China Meteorological Data
185 Network National Meteorological Science Data Center (<http://data.cma.cn>).

186

187 **2.2 Method**

188

189 **2.2.1 The calculation for cloud condensation nuclei (CCN)**

190 In the Thompson Aerosol-aware scheme (Thompson and Eidhammer, 2014), the number
191 concentration of cloud droplets is not fixed, but is derived from a series of calculations and look-
192 up tables of the CCN and IN input calculated from the mixing ratio of different aerosol species.
193 This scheme takes into account the activation of cloud condensation nuclei to form cloud droplets.
194 Further, the aerosol background mixing ratios are used to calculate the cloud droplet number
195 concentration. The input MERRA-2 inst3_3d_aer_Nv data contains the following variables: mass
196 mixing ratios of sea salt (SS, five bins), sulfate (SO_4), organic carbon (OC), black carbon (BC),
197 and dust (DU, five bins). The characteristic particle sizes, density parameters, and particle size
198 ranges were obtained with reference to the aerosol radius distribution file of MERRA-2 (Chin et
199 al., 2002). We assume that dust particles larger than $0.5 \mu\text{m}$ are ice-friendly aerosols and that all
200 remaining aerosol species except black carbon are water-friendly aerosols. The aerosol number
201 concentrations are calculated at the WRF pre-processing stage by assuming a log-normal

202 distribution with characteristic diameter and geometric standard deviation in the concentration
 203 (Thompson and Eidhammer, 2014). Since the aerosol radius distribution file of MERRA-2
 204 provides the particle size intervals for different bins of sea salt and dust particles, the integration
 205 of the probability density function is determined between the lower and the upper limits of the
 206 radius. The details of the aerosol parameters are shown in Table 1.

207
 208 **Table 1** Aerosol particle radius, standard deviation, and density

Aerosol type	Density (kg m ⁻³)	Mean radius (μm)	Radius lower (μm)	Radius upper (μm)	Standard deviation (μm)
Sulfate	1700	0.350	0.005	0.500	2.030
Organic carbon	1800	0.350	0.005	0.500	2.200
	2500	0.730	0.100	1.000	2.000
	2650	1.400	1.000	1.800	2.000
Dust (5 bins)	2650	2.400	1.800	3.000	2.000
	2650	4.500	3.000	6.000	2.000
	2650	8.000	6.000	10.000	2.000
	2200	0.079	0.030	0.100	2.030
Sea salt (5 bins)	2200	0.316	0.100	0.500	2.030
	2200	1.119	0.500	1.500	2.030
	2200	2.818	1.500	5.000	2.030
	2200	7.772	5.000	10.000	2.030

209 The total mass density calculation equation is derived by:

210

$$\int_{r_{lower}}^{r_{upper}} \frac{10^{-18}N}{r \ln \sigma_g \sqrt{2\pi}} \exp \left[\frac{-1}{2 \ln^2 \sigma_g} (\ln r - \ln r_g)^2 \right] \frac{4}{3} \pi r^3 \rho dr = M \quad (1)$$

211

212 where N is the number concentration (unit: # kg⁻¹), r is the integral radius (unit: μm), σ_g is the
 213 geometric standard deviation (unit: μm), and r_g is the median radius (unit: μm), ρ is the particle
 214 density (unit: kg m⁻³). The probability density integral for selected bin needs to be multiplied to
 215 the probability P in the corresponding bin, and it is calculated as:

216

$$P = \frac{\int_{r_{lower}}^{r_{upper}} \frac{1}{r \ln \sigma_g \sqrt{2\pi}} \exp \left[\frac{-1}{2 \ln^2 \sigma_g} (\ln r - \ln r_g)^2 \right] dr}{\int_0^{\infty} \frac{1}{r \ln \sigma_g \sqrt{2\pi}} \exp \left[\frac{-1}{2 \ln^2 \sigma_g} (\ln r - \ln r_g)^2 \right] dr} \quad (2)$$

217

218 Since ice-friendly aerosols contain only dust aerosol particles with a radius greater than 0.5 μm in
 219 model, the percentage of particles with a radius greater than 0.5 μm of the total number of particles
 220 in the interval is also calculated after the number concentration is derived for the first dust bin. The
 221 number concentration of ice-friendly aerosol N_i and of water-friendly aerosol
 222 concentration N_w are calculated by Eq. (3) and (4), respectively:

$$N_i = N_{dust1} * P(r_{lower} = 0.5 \mu\text{m}) + \sum_{i=2}^5 N_{dusti} \quad (3)$$

223

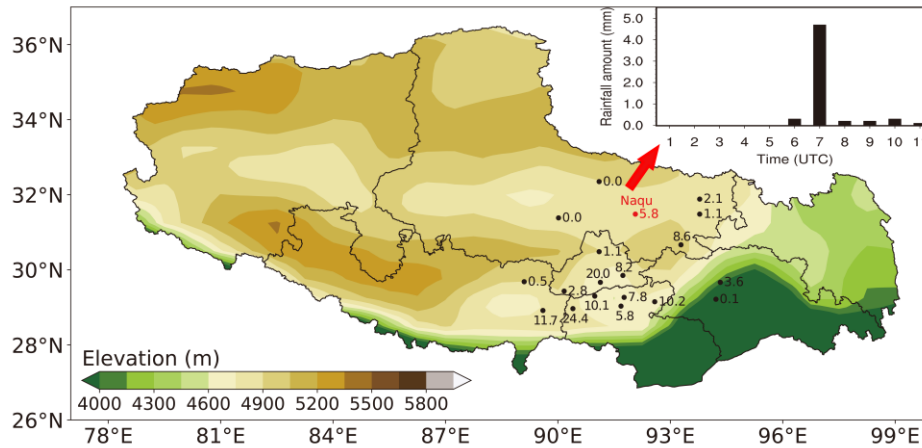

$$N_w = N_{SO4} + N_{OC} + \sum_{i=1}^5 N_{ssi} \quad (4)$$

224 Here N_{dusti} is the number concentration of dust aerosol particles for five specific bins, N_{SO4} is the
 225 sulfate number concentration, N_{OC} is the organic carbon number concentration, and N_{ssi} is the
 226 number concentration of sea salt particles for five specific bins. The data are interpolated to the
 227 simulation area, and finally written to the WRF Pre-Processing System (WPS).

228

229 2.2.2 Case selection

230 The typical convective precipitation event in Naqu, a city in the relatively flat plateau with a
 231 simple meadow surface, on 24 July 2014 is selected for simulation. A mesoscale precipitation
 232 event with a large-scale impact occurred in the central plateau, while the center of the precipitation
 233 area was concentrated in the southern part of the central plateau. The elevation of the central
 234 plateau ranges from 4600 to 5200 meters. As shown in Fig.1, Naqu is located at the northern edge
 235 of this precipitation, and the 24-hour accumulated precipitation amount in Naqu reaches 5.8 mm.
 236 On 24 July, the hourly precipitation amount in 07:00 (UTC) at Naqu station reached 4.7 mm, which
 237 is of medium intensity.

238

239 **Figure 1.** 24-hour accumulated precipitation in Tibet and the hourly precipitation in Naqu on 24
 240 July 2014.

241 From the sounding data map at 00:00 UTC (08:00 at Beijing Time) on 24 July 2014 (Fig. 2a),
 242 the temperature dew point difference in Naqu (red solid line minus green solid line) was less than
 243 4°C, which means that a wet layer was formed between 400-500 hPa. A relatively dry area was
 244 present above 300 hPa, and the whole layer formed an "inverted trumpet" with a dry upper layer
 245 superimposed on a wet lower layer, which is conducive of producing an unstable development of
 246 convection. In Fig. 2b, which corresponds to 12:00 UTC (20:00 at Beijing Time) on the same day,
 247 the relative humidity of the air in the upper troposphere increased significantly and the relative dry
 248 layer disappeared; the whole atmosphere was in a near-saturated state and gradually became stable.
 249 This suggests that the convection developed during 00:00 UTC to 12:00 UTC on 24 July 2014.

250

251 **Figure 2.** T-logP sounding data from Naqu station at (a) 00:00 UTC and (b) 12:00 UTC on 24
 252 July 2014 (black solid line: temperature-pressure curve (laminar curve); green solid line: dew point
 253 pressure curve; red solid line: state curve; grey solid line (diagonal): isotherm; grey solid line
 254 (straight): isobaric line; blue dashed line: wet adiabatic line; red dashed line: dry adiabatic line;
 255 green dashed line: saturation mixing ratio; light blue dashed line: 0°C isotherm).

256

257 **2.2.3 Model setup**

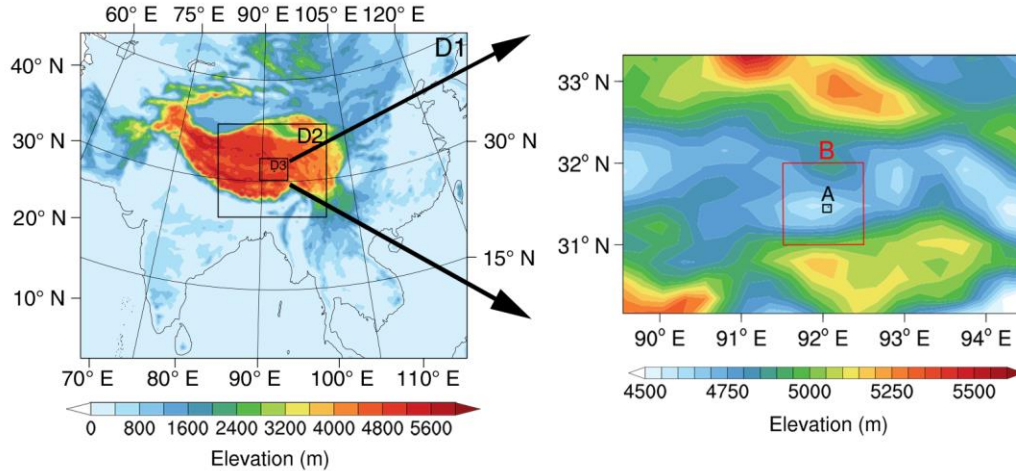

258 The Weather Research Forecast (WRF) model is one of the most commonly used
 259 meteorological research and numerical weather forecasting systems. It provides users with a wide
 260 choice of formulations for atmospheric processes, and can run on a variety of computer platforms
 261 (<http://www2.mmm.ucar.edu/wrf/users/>). The model version used in this paper is WRF-V4.0, and
 262 the basic model settings are shown in Table 2. The integration of 24 hours starts at 00:00 UTC on
 263 24 July 2014. A triple nesting grid with spacing of 25 km, 5 km and 1 km, respectively, and an
 264 integration step of 60 seconds for the outer layer is applied, as shown in Fig.3. The precipitation
 265 in the 0.1°x 0.1° area around Naqu (31.4-31.5° N, 92.0-92.1° E, area A) and the distribution of the
 266 aerosol number concentration in the 1°x 1° area around Naqu (31-32° N, 91.5-92.5° E, area B) are
 267 examined in our detailed analysis.

268

269 **Table 2** Model basic settings

Model basic settings	
Model version	WRF 4.0
Initial field	FNL
Simulation period	24 July 2014 00:00 - 25 July 2014 00:00
Step length	60 s
Number of nesting levels	3 levels
Grid size	25:5:1
Center point	Latitude: 28.0 ° N, Longitude: 92.0 ° E

270

271
 272 **Figure 3.** Color-filled map of the height field for simulated region (area A is marked with black
 273 rectangle, and area B is marked with red rectangle).

274 The simulation uses the RRTMG long-wave and short-wave radiation scheme (Iacono et al.,
 275 2008), the Mellor-Yamada-Janjic planetary boundary layer scheme (Dyer et al., 1970), the Eta
 276 similarity near-surface layer scheme, and the Noah-MP land surface scheme (Niu et al., 2011).
 277 The Grell-Freitas cumulus convective parameterization scheme (Grell et al., 2013) is adopted for
 278 the outer two grids while the cumulus scheme is turned off in the inner grid. The physical parameter
 279 schemes are shown in Table 3. The microphysical scheme selected in this paper is the Thompson
 280 aerosol-aware scheme (Thompson et al., 2014), in which the default is set as the control run
 281 (Control); the Clean and Polluted schemes multiply the default cloud condensation nuclei number
 282 by 1/10 and 10 times, respectively; the TP uses the MERRA-2 aerosols on 23 July 2014. The
 283 experimental settings are described in Table 4.

284

285 **Table 3** Physical parameter scheme settings

Physical parameter scheme settings	
Microphysical scheme	Thompson aerosol-aware scheme
Long wave radiation scheme	RRTMG Longwave
Shortwave radiation scheme	RRTMG Shortwave
Land surface	Noah-MP
Planetary boundary layer scheme	Mellor-Yamada-Janjic
Cumulus parameterization scheme	Grell-Freitas (the inner layer turns off)

286

287 **Table 4** Experimental settings

Marker	Microphysical settings	Settings
Control	'use_aero_icbc' is set to false	Default NaCCN, NaIN setting
Clean	'use_aero_icbc' is set to false	1/10*NaCCN, NaIN
Polluted	'use_aero_icbc' is set to false	10*NaCCN, NaIN
TP (slightly polluted)	'use_aero_icbc' is set to true	MERRA-2 aerosol reanalysis

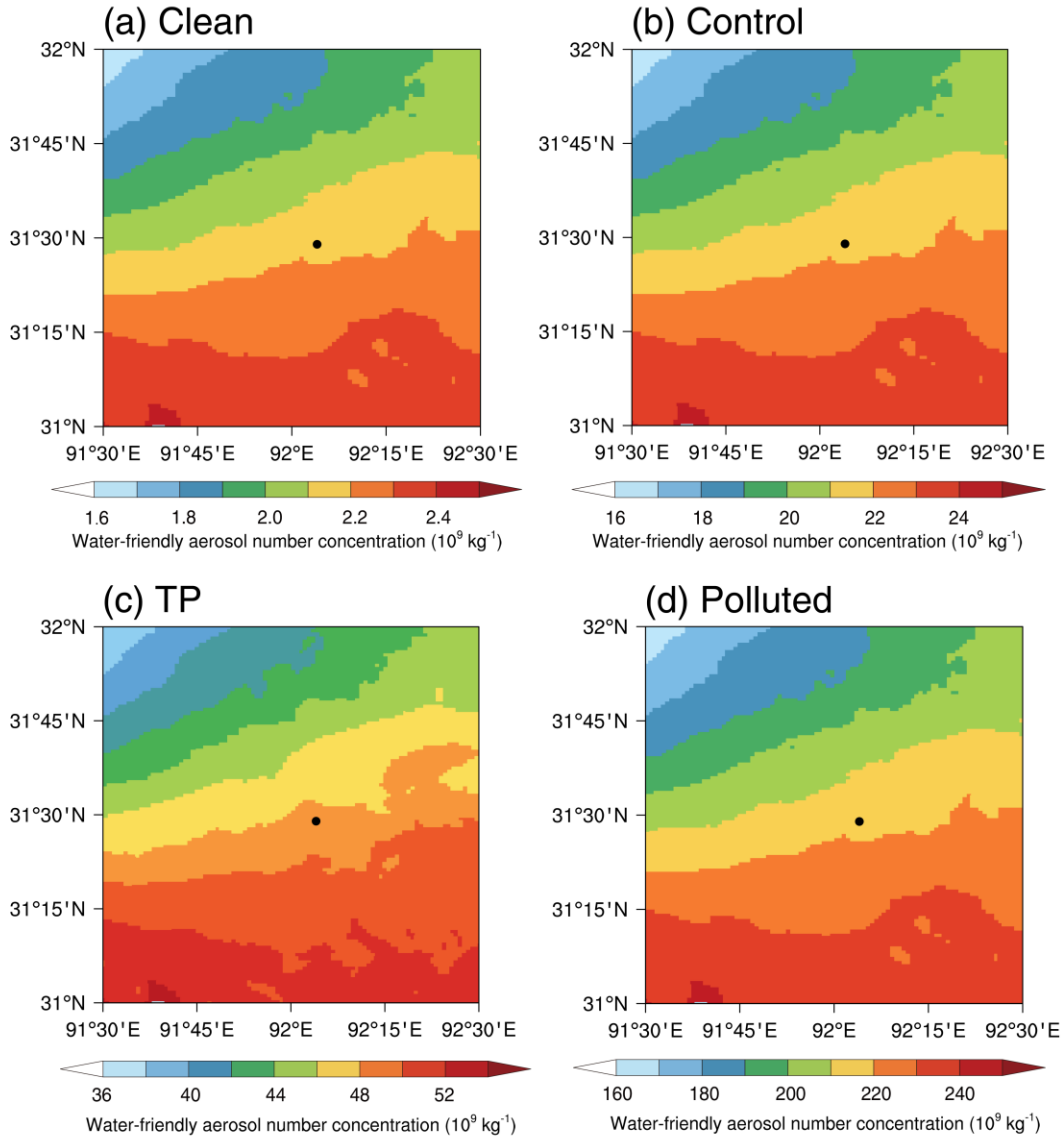

288

289 **3. Results**

290

291 **3.1 Aerosol and cloud analysis**

292 Figure 4 compares the spatial distribution of the vertically averaged water-friendly aerosol
 293 number concentration from (a) clean, (b) control, (c) TP, and (d) polluted cases at 00:00 on 24 July
 294 2014. It shows that, at the simulation start time, the number concentration of the water-friendly
 295 aerosols in TP simulation (Fig. 4c) is almost 2 times than that of default simulation (Fig. 4b), which
 296 can be regarded as slightly polluted situation. In this way, the dependence of the evolution of the
 297 convective event that took place in Naqu (92.067° E, 31.483° N) on 24 July 2014, are examined
 298 under different background atmospheric aerosol burden, which are almost 1/10, 1 time, 2 times,
 299 10 times of the default CCN setting for Clean, Control, TP (slightly polluted), and Polluted,
 300 respectively.

301
 302 **Figure 4.** Vertically averaged water-friendly aerosol number concentration from (a) clean, (b)
 303 control, (c) TP, and (d) polluted cases at 00:00 on 24 July 2014 in the $1^\circ \times 1^\circ$ area around Naqu
 304 ($31\text{-}32^\circ \text{N}$, $91.5\text{-}92.5^\circ \text{E}$, area B). The dot represents the position of Naqu.

305 Since the precipitation is interrupted at 11:00 UTC (Fig. 1), the analysis focuses on the
 306 vertical distribution of the hydrometeor categories from 00:00 to 11:00 UTC on 24 July 2014. The
 307 mean precipitation in the $0.1^\circ \times 0.1^\circ$ area surrounding Naqu ($31.4\text{-}31.5^\circ \text{N}$, $92.0\text{-}92.1^\circ \text{E}$, area A)
 308 is selected for a time series analysis. Figure 5 shows that the precipitation starts at 06:00 and the
 309 hourly maximum precipitation occurs at 08:00. Afterwards, the precipitation intensity gradually
 310 decreases and ends up at 11:00. All four simulations show a decreasing precipitation rate occurring

311 after 09:00. The maximum precipitation intensity is predicted to happen at 07:00 in the clean and
 312 TP simulations; it occurs at 08:00 and at 09:00 in the control and the polluted simulations,
 313 respectively. The timing of the maximum precipitation rate is delayed and the precipitation
 314 intensity is enhanced as air pollution heavily increases. Comparing the simulation results for clean
 315 and polluted conditions, we find that the time at which precipitation starts is later in polluted air
 316 than in clean situation. However, the amount of precipitation was significantly enhanced. This
 317 suggests that an increase in atmospheric aerosol load leads to a delayed onset, but an increased
 318 intensity of the precipitation.

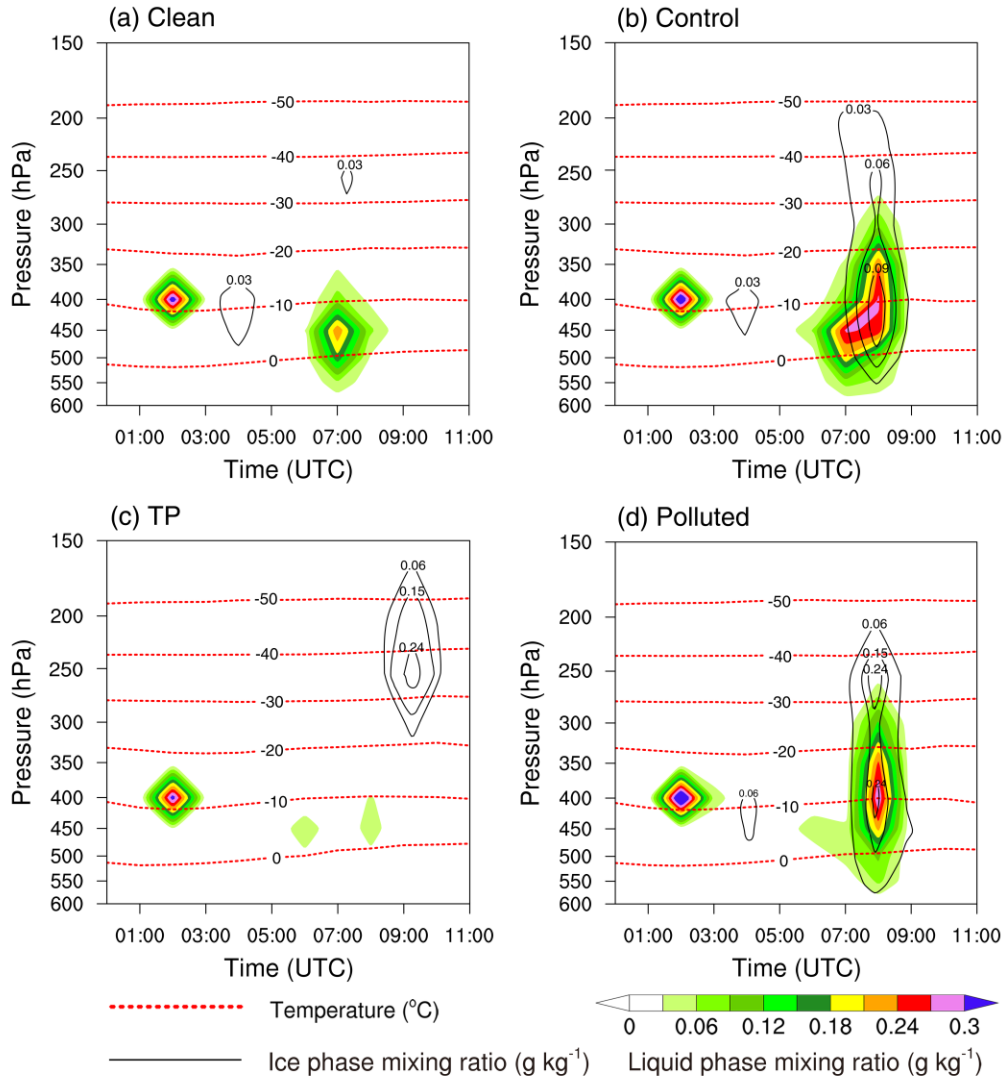

319
 320 **Figure 5.** Time series of hourly precipitation rate (mm) in area A (31.4-31.5°N, 92.0-92.1°E) from
 321 00:00 to 11:00 UTC on 24 July 2014.

322
 323 **3.2 Hydrometeor categories and microphysical processes analysis**

324 In order to analyze the influence of aerosols on water condensate at different heights, the time
 325 series of the vertical distribution of liquid phase water condensate and ice phase water condensate
 326 from clean, control, TP, and polluted are shown in Fig. 6 a, b, c, and d, respectively. Note that,
 327 compared to urban areas, the baseline aerosol burden in TP is pristine, and the clean simulation
 328 here represents extremely clean condition. From 01:00 to 03:00, the liquid phase water condensate
 329 existed in all four simulated cases, and were mainly distributed between the pressure levels of 350
 330 and 450 hPa. During this time, no precipitation was produced or the amount of precipitation was
 331 small. The analysis of the vertically pointing Ka-band cloud radar observation at Naqu, also shows

332 that only scattered clouds existed at the height between 5 and 7 km before 05:00 UTC (Cheng et
333 al., 2022).

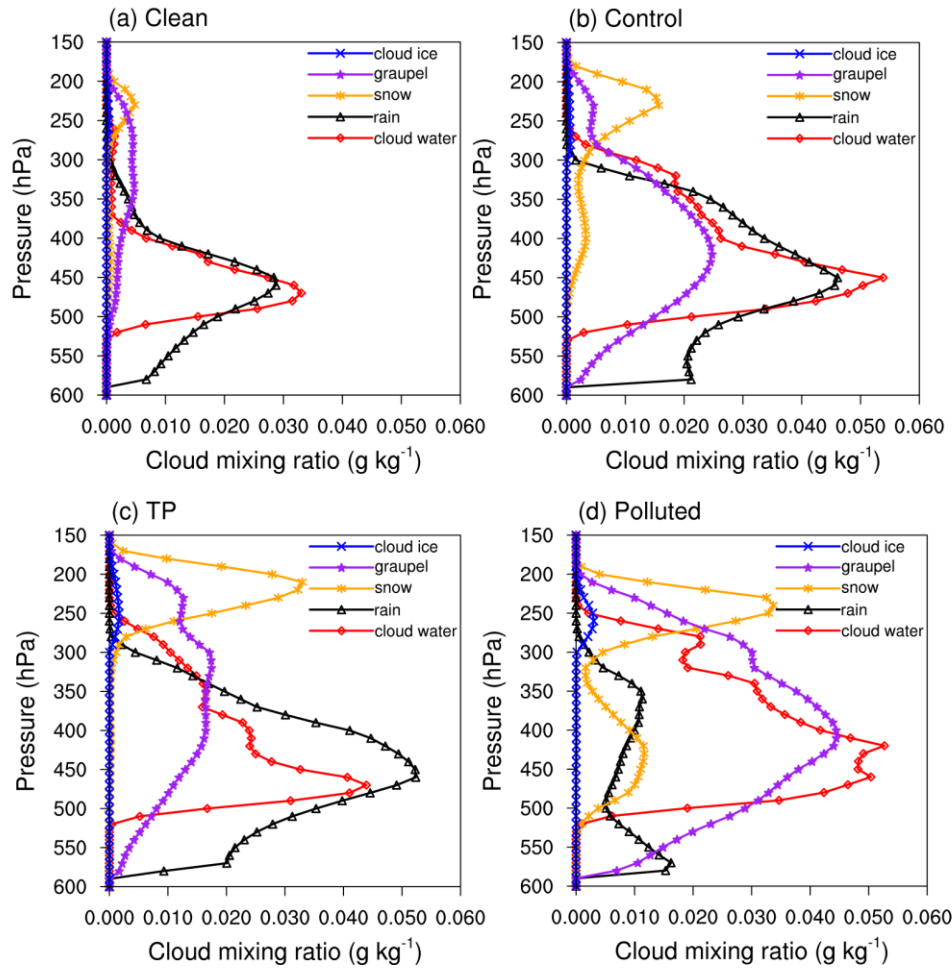

334 From 05:00 UTC, in the clean simulation (Fig. 6a), the liquid phase water condensate is mainly
335 distributed in the lower layers and its abundance starts to increase, which indicates the warm-based
336 convective cloud formed; while there little ice phase water condensate is presented. Compared to
337 the clean simulation, in the control scenario (Fig. 6b), the amount of liquid phase water condensate
338 formed in the control case is higher and the maximum value locates at a higher altitude. At the
339 same time, the ice phase water condensate increases. It indicates shifting from clean to control
340 scenario, the convective cloud invigorates and precipitation increases with increasing aerosol
341 number concentration. In the TP simulation (Fig. 6c), in which the water-friendly aerosols
342 background is 2 times of that in the control simulation (Fig. 6b), but not in the polluted simulation,
343 the amount of liquid phase water condensate decreases sharply. This indicates the rain already
344 started (Fig. 5). It also suggests that the precipitation intensity increases and the precipitation starts
345 earlier with the increase of aerosol loading when the atmosphere is slightly polluted. This may be
346 explained by aerosol-limited environment and the higher coalescence efficiency due to the
347 secondary droplet activation in convective clouds, especially in relatively clean areas (Efraim et
348 al., 2022). In the polluted scenario (Fig. 6d), the liquid phase water condensate in the polluted case
349 does not change substantially, however, the onset time is delayed. Under polluted situations, the
350 warm cloud precipitation does not occur easily, and the cloud development is more vigorous. As
351 a result, the onset time of the precipitation is delayed. The ice phase water condensate increased
352 substantially. In the polluted case, more ice phase water condensate is formed in both upper and
353 lower layers (Fig. 6d); while in the TP case (Fig. 6c), there is more ice phase water condensate
354 only in the upper layers. This suggests that, with the increase of aerosol loading, the ice cloud
355 precipitation increases. As a result, the onset time of the precipitation is delayed, but the
356 precipitation intensity increases. This is consistent with the impact of aerosols on convective
357 precipitation as derived from observations in south-east China (Jiang et al., 2016; Wu et al., 2016;
358 Yang et al., 2018).

359
 360 **Figure 6.** Time series of the vertical distribution of the mean liquid phase and ice phase water
 361 condensate mixing ratio in **(a)** clean, **(b)** control, **(c)** TP, and **(d)** polluted simulations in area A
 362 (31.4-31.5°N,92.0-92.1°E), in g kg^{-1} , with red dashed lines as isotherms.

363 In order to analyze the evolution of microphysical quantities and processes, considering that
 364 precipitation mainly occurs between 06:00 and 11:00, various water condensate particles in area
 365 A are averaged between 06:00 and 11:00. Five water condensate mixing ratios varying with height
 366 are obtained for cloud water, cloud ice, rain, snow, and graupel are shown in Fig. 7. The water
 367 condensate mixing ratios for clean, control, TP, and polluted simulations are presented in Fig. 7a,
 368 b, c, and d, respectively. At 150-300 hPa, snowfall occurs in all four scenarios, and the proportion
 369 of snowfall increases as pollution increases. At 300-500hPa, compared with the clean simulation
 370 (Fig. 7a), the water condensate mixing ratio of cloud water, cloud ice, rain, snow, and graupel

371 increase with the increased aerosol burden in the control simulation (Fig. 7b). Compared with the
372 control simulation (Fig. 7b), the mixing ratio of rain increases while both of cloud water and
373 graupel decrease in the TP simulation (Fig. 7c). This suggests that, as aerosol loading increases,
374 the conversion process of cloud water to rain invigorates. In the polluted scenario (Fig. 7d), the
375 mixing ratios of cloud water, graupel, and snow are characterized by larger values than in the other
376 three scenarios, while the mixing ratio of rain has the smallest value. It indicates that the conversion
377 process of cloud water to rain is suppressed, but the conversion of cloud water to graupel is favored.
378 At 500-600 hPa, which is near the surface, rainfall is dominant in the clean case (Fig. 7a), while
379 graupel in addition to rainfall are visible in other simulations (Fig. 7b, c, and d). This suggests that,
380 with the increase of aerosol burden, the conversion process of cloud water to rain in clouds is
381 suppressed, but the generation of ice phase particles is favored. The proportion of surface graupel
382 to the total precipitation increases from 6.913%, 7.833%, 14.004%, and 26.376% in clean, control,
383 TP, and polluted, respectively. It also indicates that the development of convective clouds is more
384 vigorous under the polluted scenario.

385
 386 **Figure 7.** Mean water condensate mixing ratio as a function of height for (a) clean, (b) control, (c)
 387 TP, and (d) polluted cases in aera A (31.4-31.5°N,92.0-92.1°E) from 06:00 to 11:00 UTC on 24
 388 July 2014, units: g kg^{-1} .

389 The vertical distributions of the number concentration of cloud water, rain and snow for the
 390 four scenarios (which is not shown here) show similar results, which indicates the increase of
 391 aerosol number concentration tends to increase the cloud droplet number concentration but to
 392 decrease the cloud droplet scale, suppresses the warm cloud rainfall and invigorates cloud
 393 development (Fig. 8), producing more ice phase substances. The melting of ice phase particles
 394 increases the cold-rain precipitation, which delays the onset of the precipitation and increases
 395 precipitation intensity. It is consistent with the findings that in polluted scenario, the increase in
 396 aerosols suppress the warm-rain process but enhance the growth of graupel and increase the cold-
 397 rain (Rosenfeld et al., 2000; Tao et al., 2012).

398
 399 **Figure 8.** Updrafts in clouds in area A (31.4-31.5°N,92.0-92.1°E) averaged from 06:00 to 11:00
 400 UTC on 24 July 2014, in units of m s^{-1} .

401
 402 **4. Summary and discussion**

403
 404 Aerosol studies on the Tibetan Plateau are constrained by a small number of stations and
 405 observations, and by a limited amount of satellite data. The aerosol optical thickness in this region
 406 is generally smaller than in other regions, with only a few cases exceeding 0.1, which also explains
 407 the low availability of aerosol satellite data in the region. Although the region can be viewed as a
 408 region with a background aerosol situation, air masses transported by summer winds from South
 409 Asia can cause relatively strong local disturbances. Therefore, it is an ideal region to examine the
 410 aerosol impact on convective precipitation and on the downstream weather. The unique
 411 topography and the relatively pristine aerosol background levels above the Tibetan Plateau
 412 motivate us to explore the impact of high aerosol episodes on the formation of local convective
 413 precipitation events.

414 The Weather Research and Forecasting (WRF) model 4.0 version with Thompson aerosol-
 415 aware microphysical scheme was used to explore the influence of aerosols on convective
 416 precipitation processes. A specific convective precipitation event in Naqu, on the central Tibetan
 417 Plateau that occurred on 24 July 2014 was selected in our study. Four sets of experiments, named

418 clean (1/10 CCN), control (default setting), Tibetan Plateau (real CCN calculated from MERRA-
419 2 reanalysis), and polluted (10 times CCN), were retained for our simulations. A detailed analysis
420 on microphysical processes suggests that, with the increase of the aerosol number concentration,
421 the conversion of cloud water to rain inside clouds is enhanced at first, while in polluted situation,
422 the conversion process of cloud water to rain is suppressed. At the same time, the generation of
423 ice phase particles and the development of convective clouds are enhanced. In polluted situation,
424 the onset of the precipitation is delayed; however, rainfall occurs with higher intensity.

425 Since the air in the plateau area is relatively clean, the response of precipitation could be
426 sensitive to aerosol perturbation. However, the errors associated with the observations over the
427 Tibetan Plateau are large and sensitive to convective precipitation during the initial phase of the
428 event. Under such circumstances, our study has adopted a compromise approach to discuss the
429 effect of aerosols on convective precipitation in the relatively clean highlands.

430 The treatment of aerosols in the model can be chosen according to the air quality situation at
431 a particular time. If the air is clean, initial conditions for the simulated aerosol concentrations can
432 be chosen to be close to the actual observations; in a polluted situation, the background field for
433 the WRF simulation can be generated according to the real-time aerosol reanalysis method as
434 described in the paper, especially before year 2015. More sustained and comprehensive
435 observations over the Tibetan Plateau are a prerequisite for better understanding the aerosol impact
436 on precipitation formation in this region. More factors, such as latent heat, sensible heat, surface
437 topography, aerosol types, etc. should be carried out as comprehensive analysis in this region. At
438 the same time, approaches to determining measurement representation error (Asher et al., 2022)
439 for model evaluation should be established in the pristine region.

440 **Data Availability**

441 The Station-Satellite combined $0.1^\circ \times 0.1^\circ$ hourly precipitation data (Shen et al., 2014) are
442 provided by the China Meteorological Administration Information Center, and the ground
443 precipitation observations are obtained from the Naqu automatic station. The sounding data are
444 taken from the China Meteorological Data Network National Meteorological Science Data Center.
445 All the data is available at (<http://data.cma.cn>).

446

447 **Acknowledgments**
