**High-resolution regional emission inventory contributes to
the evaluation of policy effectiveness: A case study in Jiangsu
province, China**

26 **Abstract**

27 China has been conducting a series of actions on air quality improvement for the past
28 decades, and air pollutant emissions have been changing swiftly across the country.
29 Province is an important administrative unit for air quality management in China, thus
30 reliable provincial-level emission inventory for multiple years is essential for
31 detecting the varying sources of pollution and evaluating the effectiveness of emission
32 controls. In this study, we selected Jiangsu, one of the most developed provinces in
33 China, and developed the high-resolution emission inventory of nine species for
34 2015-2019, with improved methodologies for different emission sectors, best
35 available facility-level information on individual sources, and real-world emission
36 measurements. Resulting from implementation of strict emission control measures,
37 the anthropogenic emissions were estimated to have declined 53%, 20%, 7%, 2%,
38 10%, 21%, 16%, 6% and 18% for sulfur dioxide (SO₂), nitrogen oxides (NO_x),
39 carbon monoxide (CO), non-methane volatile organic compounds (NMVOCs),
40 ammonia (NH₃), inhalable particulate matter (PM₁₀), fine particulate matter (PM_{2.5}),
41 black carbon (BC), and organic carbon (OC) from 2015 to 2019, respectively. Larger
42 abatement of SO₂, NO_x and PM_{2.5} emissions were detected for the more developed
43 southern Jiangsu. Since 2016, the ratio of biogenic volatile organic compounds
44 (BVOCs) to anthropogenic volatile organic compounds (AVOCs) exceeded 50% in
45 July, indicating the importance of biogenic sources on summer O₃ formation. Our
46 estimates in annual emissions of NO_x, NMVOCs, and NH₃ were generally smaller
47 than the national emission inventory MEIC, but larger for primary particles. The
48 discrepancies between studies resulted mainly from different methods of emission
49 estimation (e.g., the procedure-based approach for AVOCs emissions from key
50 industries used in this work) and inconsistent information of emission source
51 operation (e.g., the penetrations and removal efficiencies of air pollution control
52 devices). Regarding the different periods, more reduction of SO₂ emissions was found
53 between 2015 and 2017, and of NO_x, AVOCs and PM_{2.5} between 2017 and 2019.
54 Among the selected 13 major measures, the ultra-low emission retrofit on power

55 sector was the most important contributor to the reduced SO₂ and NO_x emissions
56 (accounting for 38% and 43% of the emission abatement, respectively) for 2015-2017,
57 but its effect became very limited afterwards as the retrofit had been commonly
58 completed by 2017. Instead, extensive management of coal-fired boilers and
59 upgradation and renovation of non-electrical industry were the most important
60 measures for 2017-2019, accounted collectively for 61%, 49% and 57% reduction of
61 SO₂, NO_x and PM_{2.5}, respectively. Controls on key industrial sectors maintained the
62 most effective for AVOCs reduction for the two periods, while measures on other
63 sources (transportation and solvent replacement) became more important for recent
64 years. Our provincial emission inventory was demonstrated to be supportive for
65 high-resolution air quality modeling for multiple years. Through scenario setting and
66 modeling, worsened meteorological conditions were found from 2015 to 2019 for
67 PM_{2.5} and O₃ pollution alleviation. However, the efforts on emission controls were
68 identified to largely overcome the negative influence of meteorological variation. The
69 changed anthropogenic emissions were estimated to contribute 4.3 and 5.5 μg·m⁻³ of
70 PM_{2.5} concentration reduction for 2015-2017 and 2017-2019, respectively. While
71 elevated O₃ by 4.9 μg·m⁻³ for 2015-2017, the changing emissions led to 3.1 μg·m⁻³ of
72 reduction for 2017-2019, partly (not fully though) offsetting the meteorology-driven
73 growth. The analysis justified the validity of local emission control efforts on air
74 quality improvement, and provided scientific basis to formulate air pollution
75 prevention and control policies for other developed regions in China and worldwide.

76 **1. Introduction**

77 Severe air pollution is of great concern for fast industrialized countries like China,
78 especially in economically developed regions where an overlap of serious pollution
79 levels and dense populations has resulted in high exposure and adverse health
80 outcomes (Klimont et al., 2013; Hoesly et al., 2018). Emission inventory, which
81 contains complete information on the magnitude, spatial pattern, and temporal change
82 of air pollutant emissions by sector, is essential for identifying the sources of air

83 pollution and effectiveness of emission controls on air quality through numerical
84 modeling (Zhao et al., 2013). Improving the understanding of emission behaviors and
85 reducing the uncertainty of emission estimates have always been the main focus of
86 emission inventory studies, given the big variety of source categories, fast changing
87 mix of manufacturing and emission control technologies, and insufficient
88 measurements of real-world emissions. At the global and continental scales, emission
89 inventories have been developed by combining available information of large point
90 sources and improved surrogate statistics for area sources, e.g., Emissions Database
91 for Global Atmospheric Research (EDGAR, <https://edgar.jrc.ec.europa.eu/>, Crippa et
92 al., 2020) and Regional Emission Inventory in Asia (REAS,
93 <https://www.nies.go.jp/REAS/>, Kurokawa et al., 2020). As the largest developing
94 country in the world, China has been proven to contribute greatly to global emissions
95 (Klimont et al., 2013; Huang et al., 2014; Wiedinmyer et al., 2014; Miyazaki et al.,
96 2017).

97 Along with the improved methodology and increasing availability of emission source
98 and field measurement data, the applicability and reliability of recent Chinese
99 emission inventories (e.g., the Multi-resolution Emission Inventory for China, MEIC,
100 Zheng et al., 2018) have been considerably improved compared to the earlier
101 large-scale studies for Asia or the world. When the research focus switches to smaller
102 provincial and city scales, the uncertainty of national emission inventory may increase
103 attributed mainly to the insufficient information on detailed emission sources,
104 particularly for medium/small size stationary and area sources. Certain “proxies”
105 including population and economic densities were commonly applied to downscale
106 the emissions from coarser to finer horizontal resolution, based on the assumption that
107 those proxies were strongly associated with emission intensity. Such “coupling effect”,
108 however, has been demonstrated to be weakened for recent years. For example, a
109 great number of big industrial facilities have been gradually moved out of urban
110 centers, resulting in an inconsistency between emission and population hotspots.
111 Therefore, inappropriate application of those proxies could lead to great uncertainty in
112 emission estimation and thereby enhanced bias in air quality modeling (Zhou et al.,

113 2017; Zheng et al., 2017). For the urgent demand for preventing regional air pollution
114 and relevant health damage, therefore, development of high-resolution emission
115 inventories has been getting essential, especially in regions with developed industry,
116 large population and complex emission sources (Zheng et al., 2009; Shen et al., 2017;
117 Zhao et al., 2018). With increased proportion of point sources and more complete
118 facility-based information, the improved emission inventory could reduce the
119 arbitrary use of proxy-based downscaling technique and thereby the uncertainty of the
120 emission estimates (Zhao et al., 2015; Zheng et al., 2021).

121 For the past decade, China has been conducting a series of actions to tackle the
122 serious air pollution problem. With the mitigation of severe fine particulate matter
123 (PM_{2.5}) pollution set as a priority from 2013 to 2017, the National Action Plan on Air
124 Pollution Control and Prevention (NAPAPCP, State Council of the People's Republic
125 of China (SCC), 2013) pushed stringent end-of-pipe emission controls (e.g., the
126 “ultra-low” emission control for power sector) and retirement of small and
127 energy-inefficient factories (Zhang et al., 2019a; 2019b; Zheng et al., 2018). On top of
128 that, China announced the “Three-Year Action Plan to Fight Air Pollution”
129 (TYAPFAP) to further reduce PM_{2.5} and ozone (O₃) levels for 2018-2020 (SCC, 2018).
130 Substantially enhanced measures have been required for reducing industrial (e.g.,
131 application of “ultra-low” emission control for selected non-electrical industries) and
132 residential emissions (e.g., promotion of advanced stoves and clean coal during
133 heating seasons). Those measures have changed the air pollutant emissions and
134 thereby air quality over the country. Studies have been conducted to assess the
135 contribution of the nation actions to the improvement of air quality, based usually on
136 the national emission inventory. For example, Zhang et al. (2019a) estimated a
137 nationwide 30-40% reduction in PM_{2.5} concentration attributed to NAPAPCP from
138 2013 to 2017.

139 Province is an important administrative unit for air quality management in China.
140 Given the heterogeneous economical and energy structures as well as atmospheric
141 conditions, there are usually big diversities in the strategies and actions of reducing
142 regional air pollution adopted by the local governments, leading to various progresses

143 of emission and air quality changes (Liu et al., 2022; Wang et al., 2021a). Limited by
144 incomplete or inconsecutive information on emission sources and lack of on-time
145 emission measurements, however, there were few studies on provincial-level emission
146 inventories for multiple years. Studies based on the national emission inventories
147 would be less supportive for policy makers to formulate the emission control
148 measures and to evaluate their effectiveness on emission reduction and air quality
149 improvement (An et al., 2021; Huang et al., 2021). Contrary to NAPAPCP that has
150 been noticed, moreover, few analyses have been conducted for TYAPFAP after 2017
151 due partly to lack of most recent emission data, preventing comparison and
152 comprehensive understanding of the effectiveness of emission controls for the two
153 phases. Jiangsu Province, located on the northeast coast of the Yangtze River Delta
154 region (YRD), is one of China's most industrial developed and heavy-polluted regions.
155 It contributed to 10.1% of the gross domestic product (GDP) in mainland China
156 (ranking the second place in the country), and 6.4%, 11.3% and 11.4% of national
157 cement, pig iron and crude steel production in 2020, respectively (National Bureau of
158 Statistics of China, 2021). MEIC indicated the emissions per unit area of
159 anthropogenic sulfur dioxide (SO₂), nitrogen oxides (NO_x), non-methane volatile
160 organic compounds (NMVOCs), PM_{2.5}, and ammonia (NH₃) in Jiangsu were 2.8, 6.5,
161 7.0, 4.5 and 4.8 times of the national average in 2017, respectively. Resulting from the
162 implementation of air pollution prevention measures, PM_{2.5} pollution in Jiangsu has
163 been alleviated since 2013, while the great changes in emissions due to varying
164 energy use and industry and transportation development have made it the province
165 with the highest O₃ concentration and the fastest growth rate of O₃ in YRD for recent
166 years (Zheng et al., 2016; Wang et al., 2017; Zhang et al., 2017a; Zhou et al., 2017).
167 In this study, therefore, we took Jiangsu as an example to demonstrate the
168 development of high-resolution emission inventory and its application on evaluating
169 the effectiveness of emission control actions. We integrated the methodological
170 improvements on regional emission inventory by our previous studies (Zhou et al.,
171 2017; Zhao et al., 2017; 2020; Wu et al., 2022; Zhang et al., 2019b; Zhang et al., 2020;
172 2021b), and compiled and incorporated best available facility-level information and

173 real-world emission measurements (see details in the methodology and data section).
174 A provincial-level emission inventory for 2015-2019 was then thoroughly developed
175 for nine gaseous and particulate species (SO₂, NO_x, NMVOCs, carbon dioxide (CO),
176 inhalable particulate matter (PM₁₀), PM_{2.5}, NH₃, black carbon (BC), and organic
177 carbon (OC)). The difference between our emission inventory and others, as well as
178 its main causes, was carefully explored. Using a measure-specific integrated
179 evaluation approach, we further identified the drivers of emission changes of SO₂,
180 NO_x, PM_{2.5} and anthropogenic volatile organic compounds (AVOCs), with an
181 emphasis on the impacts of 13 major control measures summarized from NAPAPCP
182 and TYAPFAP. Finally, air quality modeling was applied to assess the reliability of
183 our emission inventory and to quantify the contribution of emission controls to the
184 changing PM_{2.5} and O₃ concentrations for 2015-2017 within NAPAPCP and
185 2017-2019 within TYAPFAP, and the differentiated impacts of emission controls on
186 air quality were revealed for the two phases.

187 **2. Methodology and data**

188 **2.1 Emission estimation**

189 **2.1.1 Emission source classification**

190 We applied a four-level framework of emission source categories for Jiangsu emission
191 inventory, based on a thorough investigation on the energy and industrial structures in
192 the province. The framework included six first-level categories, covering all the social
193 and economic sectors in Jiangsu: power sector, industry, transportation, agriculture,
194 residential, and biogenic source (for NMVOCs only). Moreover, the framework
195 contained 55 second-level categories based on facility/equipment types and
196 economical subsectors, 240 third-level categories classified mainly by fuel, product,
197 and material types, and a total of 870 fourth-level categories including sources by
198 combustion, manufacturing and emission control technologies of emission facilities
199 (details on the first three level sectors are listed in Table S1 in the Supplement).

200 Compared to the guidelines of national emission inventory development (He et al.,
201 2018), 42 new categories (third-level) were added in this study, contained mainly in
202 the second-level categories including metal products and the mechanical equipment
203 manufacturing industries, non-industrial solvent usage from ship fittings and repairs,
204 household appliances, and housing retrofitting emissions. Those categories were
205 identified as important sources of NMVOCs emissions in Jiangsu. In particular, ship
206 coating emissions, coming mainly from solvent usage during spraying, cleaning and
207 gluing in a wide range of procedures, could account for nearly 20% of the solvent use
208 emissions in the YRD region (Mo et al., 2021). Therefore, the updated framework
209 provides a more complete coverage of source categories, thus considerably reduces
210 the bias of emission estimation due to missing potentially important emitters.

211 **2.1.2 Emission estimation methods**

212 We applied the “bottom-up” methodology (i.e., the emissions were calculated at the
213 finest source level (e.g., facility level if data allowed) and then aggregated to upper
214 categories/regions) to develop the high-resolution emission inventory for Jiangsu (and
215 its 13 cities, as shown in Figure S1 in the Supplement) 2015-2019. As mentioned in
216 Introduction, we have conducted a series of studies and made substantial
217 improvements on the methodology of regional emission inventory development by
218 source category or species, compared to the ones at larger spatial scales. Here we
219 integrated those improvements as briefly described below, and additional further
220 details can be found in corresponding published articles.

221 **Power plant** We developed a method of examining, screening and applying online
222 measurement data from the continuous emission monitoring systems (CEMS, Zhang
223 et al., 2019b) to estimate the emissions at the power unit/plant level. For units without
224 CEMS data, we applied the average flue gas concentrations obtained from CEMS for
225 units with the same installed capacity. The emissions were calculated based on the
226 annual mean hourly flue gas concentration of air pollutant obtained from CEMS and
227 the theoretical annual flue gas volume of each unit/plant:

$$E_{i,j} = C_{i,j} \times AL_j \times V_m^0 \quad (1)$$

where E is the emission of air pollutant; i , j and m represent the pollutant species, individual plant/unit, and fuel type, respectively; C is the annual average concentration in the flue gas; AL is the annual coal consumption, and V^0 is the theoretical flue gas volume per unit of fuel consumption, which depends on the coal type and can be calculated following the method in Zhao et al. (2010).

Industrial plant Emissions were principally calculated based on activity level data (production output or energy consumption) and emission factor (emissions per unit of activity level). For point sources with abundant information, we used a procedure-based approach to calculate the emissions of pollutants (Zhao et al., 2017). For example, we subdivided the iron and steel industry into sintering, pelletizing, iron making, steel making, rolling steel, and coking. The activity data and emission factors of each procedure were derived based on multiple information collected from enterprise regular report, statistics, and/or on-site investigation at the facility level (see Section 2.1.3). The emissions of air pollutants were calculated using Eq. (2):

$$E_i = \sum_{j,r} AL_{j,r} \times EF_{i,j,r} \times (1 - \eta_{i,j,r}) \quad (2)$$

where r is the industrial procedure; AL is the activity level; EF is the unabated emission factor; η is the pollutant removal efficiency of end-of-pipe control equipment.

Petrochemical industry Certain procedures in petrochemical industry have been identified as the main contributors to AVOCs emissions from the sector. For example, equipment leaks, storage tanks, and manufacturing lines were estimated to be responsible for over 90% of the total emissions (Ke et al., 2020; Liu et al., 2020; Yen and Horng, 2009). Through field measurements and in-depth analysis of different emission calculation methods, Zhang et al. (2021a) suggested that procedure-based method should provide better estimate of NMVOCs emissions for petroleum industries than the commonly approach that applied a full emission factor for the whole factory. In this study, therefore, we applied the procedure-based method for four key procedures (manufacturing lines, storage tanks, equipment leaks, and

257 wastewater collection and treatment system), with best available information from
258 on-site surveys and regular enterprise reports.

259 **Agriculture** Agricultural NH₃ emissions can be influenced by the meteorology, soil
260 environment, farming manners, and thus are more difficult to track compared to SO₂
261 and NO_x that are commonly from power and industrial plants. For example, high
262 temperature and top-dressing fertilization conducted in summer could elevate NH₃
263 volatilization from urea fertilizer uses in YRD. Our previous work (Zhao et al., 2020)
264 quantified the effects of meteorology, soil property and various agricultural processes
265 (e.g., fertilizer use and manure management) on YRD NH₃ emissions for 2014. Here
266 we expanded the research period and obtained the agricultural NH₃ emission
267 inventory for 2015-2019 in Jiangsu.

268 **Off-road transportation** In this work, we combined the method developed by Zhang
269 et al. (2020) and newly tested emission factors to estimate the emissions from off-road
270 machines in Jiangsu for multiple years. We developed a novel method to estimate the
271 emissions and their spatiotemporal distribution for in-use agricultural machinery, by
272 combining satellite data, land and soil information, and in-house investigation (Zhang
273 et al., 2020). In particular, the machinery usage was determined based on the spatial
274 distribution, growing and rotation pattern of the crops. Moreover, twelve construction
275 and agricultural machines with different power capacity and emission grades (China
276 I-III) were selected and emission factors were measured under various working loads
277 (unpublished).

278 **Biogenic source:** Located in the subtropics, Jiangsu has abundant broadleaf
279 vegetation, a main contributor to biogenic volatile organic compounds (BVOCs)
280 emissions. Our previous work (Wang et al., 2020b) evaluated the effect of land cover
281 data, emission factors and O₃ exposure on BVOCs emissions in YRD with the Model
282 of Emissions of Gases and Aerosols from Nature (MEGAN). Here we followed the
283 improved method by Wang et al. (2020b) and calculated BVOCs emissions with
284 integrated land cover information, local BVOCs emission factors, and influence of
285 actual O₃ stress in Jiangsu.

286 **Other sources** Emissions from on-road vehicles and residential sectors were

287 estimated following our previous work (Zhou et al., 2017; Zhao et al., 2021), with
288 updated activity levels and emission factors.

289 **NMVOCs speciation** We updated NMVOCs speciation by incorporating the local
290 source profiles from field measures (Zhao et al., 2017; Zhang et al., 2021a) and
291 massive literature reviews of previous studies (Mo et al., 2016; Li et al., 2014; Huang
292 et al., 2021; Wang et al., 2020a). Compared with the widely used SPECIATE 4.4
293 database (<https://www.epa.gov/air-emissions-modeling/speciate>, Hsu et al., 2018), we
294 included new source profiles from local measurements for production of sugar,
295 vegetable oil and beer, and refined the source profiles for the use of paints, inks,
296 coatings, dyes, dyestuffs and adhesives in manufacturing industry (Zhang et al.,
297 2021a), and selected production processes of chemical engineering (Zhao et al., 2017).
298 Moreover, we applied more detailed profiles for some finer categories compared to
299 the coarser source categories in the guidelines of national emission inventory
300 development, for example, NMVOCs release during filling into petrol and diesel
301 release, metal surface treatment into water-based and solvent-based paints, and ink
302 printing into offset, gravure and letterpress printing. Those efforts made the NMVOCs
303 speciation more representative for local emission sources (Zhang et al., 2021a).

304 **2.1.3 Data compilation, investigation and incorporation**

305 In this study, we compiled, investigated and incorporated most available information
306 on emission sources to improve the completeness, representativeness and reliability of
307 provincial emission inventory. In particular, we collected officially reported
308 Environmental Statistics Database (ESD, 2015-2019) and the Second National
309 Pollution Source Census (SNPSC, 2017) for stationary sources (mostly power and
310 industrial ones). Both of them contained basic information on their location, raw
311 material and energy consumption, product output, and manufacturing and emission
312 control technologies. The former database was routinely reported for relatively big
313 point sources every year, but some information could be outdated or inaccurate
314 attributed to insufficient on-site inspection. Through wide on-site surveys, in contrast,

315 the latter database included much more plants, and provided or corrected crucial
316 information at facility level, such as removal efficiency of air pollutant control
317 devices (APCD). However, the database was developed for 2017 and could not track
318 the changes for recent years. Therefore, we further applied an internal database from
319 the Air Pollution Source Emission Inventory Compilation and Analysis System
320 (APSEICAS, <http://123.127.175.61:31000>), which was developed by Jiangsu
321 Provincial Academy of Environmental Sciences. Following the principal of SNPSC,
322 the information of APSEICAS has been collected and dynamically updated since 2018,
323 based mainly on in-depth investigation for individual enterprises conducted jointly by
324 themselves and local environmental administrators. We made cross validation and
325 necessary revision according to above-mentioned three databases, to ensure the
326 accuracy of information as much as possible.

327 As a result, we obtained sufficient numbers of point sources with satisfying
328 facility-level information for provincial-level emission inventory development
329 (57,457, 32,324 and 48,826 for 2017, 2018, and 2019, respectively). The shares of
330 coal consumption by those sources to the total ranged 90-94% for the three years. The
331 high proportions of point sources could effectively reduce the uncertainty in
332 estimation and spatial allocation of air pollutant emissions. For the remaining
333 industrial sources, the emissions were calculated by using the average emission factor
334 of each sector in each city, and were spatially allocated according to the distribution of
335 local industrial parks and GDP data extracted from a database of the Chinese
336 Academy of Sciences (CAS) for 2015 at a horizontal resolution of 1 km
337 (<https://www.resdc.cn/DOI/DOI.aspx?DOIid=33>).

338 Other information on area industrial sources, transportation, agricultural, and
339 residential sources were taken from economical and energy statistical yearbooks at
340 city level. Activity data that were not recorded (e.g., civil solvent usage, catering, and
341 biomass burning) were indirectly estimated from relevant statistics, including
342 population, building area, and crop yields.

343 **2.2 Analysis of emission change**

344 In this study, we summarized 13 major control measures adopted between 2015 and
345 2019, based on NAPAPCP, TYAPFAP and relative action plans promulgated by the
346 Jiangsu government (Figure S2 in the Supplement). Those included 1) ultra-low
347 emission retrofit of coal-fired power plants, 2) extensive management of coal-fired
348 boilers, 3) upgradation and renovation of non-electrical industry, 4) phasing out
349 outdated industrial capacities, 5) promoting clean energy use, 6) phasing out small
350 polluting factories, 7) construction of port shore power, 8) comprehensive treatment
351 of mobile source pollution, 9) VOCs emission control in key sectors, 10) application
352 of leak detection and repair (LDAR), 11) oil and gas recovery, 12) replacement with
353 low-VOC paints, 13) control of non-point pollution. We applied the method by Zhang
354 et al. (2019a) to quantify the benefits of those air clean actions on emission abatement.
355 Briefly, the emission reduction resulting from the implementation of a specific
356 measure was estimated by changing the parameters of emission calculation associated
357 with the measure within the concerned period, and keeping other parameters constant
358 (same as initial year). The emission reduction from each measure was then estimated
359 for 2015-2017 and 2017-2019. The provincial-level emission inventory developed in
360 Section 2.1 was adopted as the baseline of the emission estimates. It is worth noting
361 that the aggregated emission reduction from all the measures is not equal to the actual
362 reduction, as the factors leading to emission growth were not counted in this analysis.

363 **2.3 Air quality modeling**

364 **2.3.1 Model configurations**

365 To evaluate the provincial-level emission inventory, we used the Community
366 Multiscale Air Quality (CMAQ v5.1) model developed by US Environmental
367 Protection Agency (USEPA), to simulate the PM_{2.5} and O₃ concentrations in Jiangsu.
368 Four months representing the four seasons (January, April, July, and October) of each
369 year between 2015 and 2019 were selected as the simulation periods, with a spin-up

370 time of 7 days for each month to reduce the impact of the initial condition on the
371 simulation. As shown in Figure S1, three nested domains (D1, D2, and D3) were
372 applied with the horizontal resolutions of 27, 9, and 3 km, respectively, and the most
373 inner D3 covered Jiangsu and parts of the YRD region including Shanghai, northern
374 Zhejiang, and eastern Anhui. MEIC was applied for D1, D2, and the regions out of
375 Jiangsu in D3, and the provincial-level emission inventory was applied for Jiangsu in
376 D3. The emission data outside Jiangsu in D3 were originally from MEIC and
377 downscaled to the resolution of 3km×3km with the "proxy-based" approach. The
378 Carbon Bond Mechanism (CB05) and AERO5 mechanisms were used for the
379 gas-phase chemistry and aerosol module, respectively.

380 The meteorological field for the CMAQ model was obtained from the Weather
381 Research and Forecasting model (WRF v3.4). Meteorological initial and boundary
382 conditions were obtained from the National Centers for Environmental Prediction
383 (NCEP) datasets for the assimilation in simulations. Ground observations at 3-h
384 intervals were downloaded from National Climatic Data Center (NCDC) to evaluate
385 the WRF modelling performance, and statistical indicators including bias, index of
386 agreement (IOA), and root mean squared error (RMSE) were calculated (Yang et al.,
387 2021a). The discrepancies between simulations and ground observations were within
388 an acceptable range (Table S2 in the Supplement).

389 In order to evaluate the model performance of CMAQ, we collected ground
390 observation data of hourly PM_{2.5} and O₃ concentrations at the 110 state-operating air
391 quality monitoring stations within Jiangsu (<https://data.epmap.org/page/index>, see the
392 station locations in Figure S1). Correlation coefficients (R), normalized mean bias
393 (NMB) and normalized mean errors (NME) between observation and simulation for
394 each month were calculated to evaluate the performance of CMAQ modeling:

$$395 \quad NMB = \frac{\sum_{p=1}^n (S_p - O_p)}{\sum_{p=1}^n O_p} \times 100\% \quad (3)$$

$$396 \quad NME = \frac{\sum_{p=1}^n |S_p - O_p|}{\sum_{p=1}^n O_p} \times 100\% \quad (4)$$

397 where S_p and O_p are the simulated and observed concentration of air pollutant,
398 respectively, and n indicates the number of available data pairs.

399 We further compared the modeling performance using provincial-level emission
400 inventory in D3 with that using MEIC in D2. Basically, the proxies of total population
401 and GDP were poorly correlated with gridded emissions dominated by point sources,
402 and the proxy-based methodology would result in great uncertainty in downscaling
403 emissions and thereby air quality modeling from coarser to finer resolution. For
404 example, Zheng et al. (2017) suggested a much larger bias for high-resolution
405 simulation (additional 8-73% at 4 km) than that at coarser resolution (3-13% for 36
406 km) when MEIC was applied in predicting surface concentrations of different air
407 pollutants. Our previous work in YRD also demonstrated that downscaling national
408 emission inventory with the proxy-based method resulted in clearly larger bias in
409 high-resolution (3 km) air quality modeling than the provincial-level emission
410 inventory with more point sources included (Zhou et al., 2017). To avoid expanding
411 the modeling bias, therefore, we did not directly downscale MEIC into the entire D3,
412 and the improvement of provincial emission inventory could be demonstrated with
413 better model performance (in D3) than MEIC (in D2).

414 **2.3.2 Emission and meteorological factors affecting the variation of PM_{2.5} and O₃**

415 Besides the baseline simulations conducted for 2015, 2017, and 2019, we set up two
416 extra scenarios, the meteorological variation (VMET) and the anthropogenic emission
417 variation (VEMIS), to assess the impacts of emission and meteorological changes on
418 the interannual variations of PM_{2.5} and O₃ concentrations, and to reveal their varying
419 contributions for different periods, as summarized in Table S3 in the supplement.
420 VMET used the varying meteorological fields for the three years but fixed the
421 emission input at the 2017 level, and was thus able to quantify the impact of changing
422 meteorological conditions on PM_{2.5} and O₃ concentrations. For example, the
423 difference between 2015 and 2017 in VMET indicated the contribution of changing
424 meteorology to variation of air pollutant concentration. Similarly, the emission
425 variation scenario (VEMIS) used the varying emission inventory for the three years
426 but fixed meteorological fields at the 2017 level, and was thus able to quantify the

427 impact of changing emissions on PM_{2.5} and O₃ concentrations. The contributions
428 between 2015 and 2017, and those between 2017 and 2019, could then be compared
429 to evaluate the effectiveness of emission control on air quality for the two periods.
430 Notably the anthropogenic emission change in the modeling scenario referred to that
431 for entire D3, and thus the contribution of emission control to the changing air quality
432 was from both Jiangsu and nearby regions. Given the clearly larger emission intensity
433 for the former compared to the latter (An et al., 2021), the contribution of local
434 emissions was expected to be more important on the air quality than regional transport.
435 Moreover, the BVOCs emissions were selected in accordance with the used
436 meteorological field for the given year, thus the interannual changes of BVOCs
437 emissions were counted in the contribution of changing meteorology.

438 **3. Results and discussions**

439 **3.1 Air pollutant emissions by sector and region**

440 **3.1.1 Anthropogenic emissions by sector and their changes**

441 From 2015 to 2019, the total emissions of anthropogenic SO₂, NO_x, AVOCs, NH₃,
442 CO, PM₁₀, PM_{2.5}, BC, and OC in Jiangsu were estimated to decline 53%, 20%, 6%,
443 10%, 7%, 21%, 16%, 6% and 18%, down to 296, 1122, 1271, 422, 7163, 565, 411, 32,
444 and 36 Gg in 2019, respectively (Table S4 in the Supplement). On top of SO₂ and
445 NO_x, NMVOCs has been incorporated into national economic and social
446 development plans with emission reduction targets in China since 2015, because of its
447 harmful impact on human health and important role on triggering O₃ formation. The
448 central government required the total national emissions of SO₂, NO_x, and AVOCs to
449 be cut by 15%, 15%, and 10% during the 13th Five-Year Plan period (2015-2020),
450 respectively (Zhang et al., 2022). Our estimates show that the actual SO₂ and NO_x
451 emission reductions were larger than planned in Jiangsu, due to the implementation of
452 stringent pollution control measures. However, AVOCs emissions did not decline
453 considerably within the research period, resulting from less penetration of efficient

454 APCD, and more fugitive leakage that were difficult to capture. As shown in Figure 1,
455 the GDP and vehicle population grew by 40% and 24%, respectively, while coal
456 consumption declined slightly during 2015-2019. Along with stringent emission
457 reduction actions, the provincial emissions of SO₂, NO_x and PM_{2.5} were gradually
458 decoupling from those economical and energy factors, while CO was still strongly
459 influenced by the change of coal consumption.

460 We present the sectoral contribution to anthropogenic emissions and their interannual
461 changes in Figure 2 and Figure 3, respectively. Industrial sector was identified as the
462 major contributor to SO₂, CO, AVOCs, PM₁₀, and PM_{2.5} emissions, of which the
463 contribution accounted averagely for 50%, 62%, 64%, 68%, and 61% during
464 2015-2019, respectively (Figure 2a, c, d, f and g). The sector was found to drive the
465 reductions in emissions of SO₂, NO_x, CO, PM₁₀, PM_{2.5} and BC. In particular, the
466 benefit of emission controls on industrial sector after 2017 was found to clearly
467 elevate and to surpass that of power sector for SO₂, NO_x, PM₁₀ and PM_{2.5} (Figure 3a,
468 b, f and g).

469 The power sector, accounting for more than half of provincial coal burning though,
470 was not the most important contributor to the emissions of any pollutant (Figure 2).
471 Upgrading the units with advanced APCDs, phasing-out outdated boilers, and
472 retrofitting for ultra-low emission requirement significantly reduced SO₂, NO_x, and
473 particulate emissions from the power sector (Liu et al., 2015; Zhang et al., 2021b).
474 With the completion of the ultra-low emission retrofit in 2017, the declines of
475 emissions for most species slowed down for the power sector (Figure 3). The results
476 indicated that the potential for further emission abatement from end-of-pipe controls
477 has been very limited for the sector, unless an energy transition with less coal
478 consumption is sustainably undertaken in Jiangsu.

479 The transportation sector averagely accounted for 51%, 17%, 14% and 42% of NO_x,
480 CO, AVOCs and BC emissions, respectively (Figure 2b, c, d, and h). The growth of
481 vehicle population resulted in a 38% increase in the annual NO_x emissions from
482 transportation from 2015 to 2019, faster than that of any other sector (Figure 3b).
483 Similarly, a 20% and 25% increase were found for transportation CO and BC

484 emissions (Figure 3c and h), respectively. Therefore, the rapid development of
485 transportation in economically developed Jiangsu has expanded its contribution to air
486 pollutant emissions for those species, particularly after the emissions from large
487 power and industrial plants have been effectively curbed. However, the
488 implementation of China V emission standard (equal to Euro V,
489 <https://publications.jrc.ec.europa.eu/repository/handle/JRC102115>) for motor vehicles
490 since 2018 effectively slowed down the growth of transportation NO_x emissions: The
491 annual growth rate was estimated to decrease from 12% for 2015-2017 to 5% in
492 2018-2019. Meanwhile, a downward trend was also found for transportation AVOCs
493 emissions since 2018 (Figure 3d). Those results show that emission controls for
494 transportation could be crucial for limiting the key precursors of ozone production
495 (Geng et al., 2021; Zhang et al., 2019a).

496 The residential sector was the most important source of OC, contributing averagely 68%
497 to total emissions within 2015-2019 (Figure 2i), and was the second most important
498 source of PM₁₀ (18%, Figure 2f) and PM_{2.5} (24%, Figure 2g). It dominated the
499 abatement of OC emissions, attributed to the reduced bulk coal and straw burning
500 (Figure 3i). The agricultural sector dominated NH₃ emissions (91%, Figure 2e), and
501 the small decline resulted mainly from the reduced use of nitrogen fertilizer (13%)
502 from 2015 to 2019 (Figure 3e).

503 It is worth noting that the PM_{2.5} and OC emissions decreased faster than BC (Figure
504 2g-i). As mentioned above, the reduction in primary PM_{2.5} resulted mainly from the
505 improved energy efficiencies and emission controls in industry, and promotion of
506 clean stoves and replacement of solid fuels with natural gas and electricity in
507 residential sources. For OC, in particular, the reduced use of household biofuel and
508 the prohibition of open biomass burning led to considerable emission abatement (18%
509 from 2015 to 2019). However, the lack of specific APCDs and increasing heavy-duty
510 diesel vehicles partly offset the benefit of emission controls for other sources,
511 resulting relatively small reduction in BC emissions (6%). Besides air quality issue,
512 the slower decline of BC than OC raised the regional climate challenge, as the former
513 has a warming impact while the latter a cooling one.

514 3.1.2 City-level emissions and spatial distribution

515 Figure 4 and Table S5 in the supplement shows the average annual emissions of SO₂,
516 NO_x, AVOCs, NH₃, and PM_{2.5} for the five years by city. In further discussions, we
517 classified the 13 cities in Jiangsu as the southern cities (Nanjing, Zhenjiang,
518 Changzhou, Wuxi, and Suzhou), central cities (Yangzhou, Taizhou, and Nantong) and
519 northern cities (Xuzhou, Suqian, Lianyungang, Huaian, and Yancheng) (their
520 distributions are shown in Figure S1). Clearly larger emissions of most species were
521 found in southern Jiangsu cities with more developed industrial economy and
522 transportation (Figure 4a-e, see the detailed emission data by year in Table S5). The
523 SO₂ emissions per unit area were calculated as 7.7, 3.3, and 2.4 ton·km⁻² for the
524 southern, central and northern cities, respectively. The analogous numbers were 23.0,
525 11.7, and 8.1 ton·km⁻² for NO_x, 22.5, 13.2, and 8.1 ton·km⁻² for AVOCs, and 7.3, 5.2,
526 and 2.9 ton·km⁻² for PM_{2.5}, respectively. As shown in Figure S3 in the Supplement,
527 the regions along the Yangtze River are of largest densities of power and industrial
528 plants. In contrast, higher NH₃ emissions were found for the central and northern
529 cities with abundant agricultural activities (Figure 4e). Figure S4 in the Supplement
530 illustrates the spatial distributions of emissions for selected species for 2019, at a
531 horizontal resolution of 3km. Besides industrial sources, the spatial patterns of NO_x,
532 BC, CO and AVOCs were also influenced by the road net, suggesting the role of
533 heavy traffic on emissions. Particulate matter emissions were mainly distributed in
534 urban industrial regions, while OC was more found in the broader central and
535 northern areas, attributed partly to the contribution from residential biofuel use.

536 According to Table S5, faster declines in annual SO₂, NO_x and PM_{2.5} emissions for
537 southern cities (59%, 23%, and 24% from 2015 to 2019, respectively) could be found
538 than for northern cities (53%, 18%, and 8%, respectively). In contrast, AVOCs
539 emissions were estimated to increase by 10% in southern cities while decrease by 27%
540 in northern cities. The fractions of southern cities to the total provincial emissions
541 decreased from 2015 to 2019 except for AVOCs and NH₃, indicating more benefits of
542 stringent measures on emission controls for relatively developed regions (Figure 4f).

543 Figure 5 illustrates the changes in the spatial distribution of major pollutant emissions
544 from 2015 to 2019 in Jiangsu. It can be found that the areas with large emission
545 reduction for SO₂, NO_x, and PM_{2.5} were consistent with the locations of super
546 emitters of corresponding species (Figure 5a-c). Facing bigger challenges in air
547 quality improvement, the economically developed southern Jiangsu has made more
548 efforts on the emission controls of large-scale power and industrial enterprises, and
549 achieved greater emission reduction than the less developed northern Jiangsu.
550 Different pattern in the spatial variation of emissions was found for AVOCs (Figure
551 5d). There was a big development of industrial parks for chemical engineering along
552 the riverside of Yangtze River in the cities of Suzhou, Nantong, and Wuxi in southern
553 Jiangsu. The elevated solvent use and output of chemical products of those large-scale
554 enterprises resulted in the growth of AVOCs emissions. In northern Jiangsu, in
555 contrast, small-scale chemical plants have been gradually closed, and the emissions
556 were thus effectively reduced. There is a great need for substantial improvement of
557 emission controls for the key regions and sectors for further abatement of AVOCs
558 emissions.

559 **3.1.3 Enhanced contribution of biogenic sources to total NMVOCs**

560 Table 1 summarizes AVOCs and BVOCs emissions by month and year. Different from
561 AVOCs that decreased slowly but continuously from 2015 to 2019, a clearly growth
562 of annual BVOCs emissions was estimated between 2015 and 2017, followed by a
563 slight reduction till 2019. The peak annual BVOCs emissions reached 213 Gg in 2017.
564 The interannual variation of BVOCs was mainly associated to that of temperature and
565 short-wave radiation (Wang et al., 2020b). Influenced by meteorological conditions
566 and vegetation growing, BVOCs emissions were most abundant in July, less in April
567 and October and almost zero in January. Within the province, there was a general
568 increasing gradient from southeast to northwest in BVOCs emissions (Figure S5 in
569 the Supplement). The rapid development of industrial economy in southern Jiangsu
570 has led to the expansion of urban centers and less vegetation cover, which limited the

571 BVOCs emissions.

572 We calculated the ratio of BVOCs to AVOCs emissions by month and year (Table 1).

573 Dependent on the trends of both BVOCs and AVOCs emissions, the annual ratio

574 increased from 11.1×10^{-2} in 2015 to 15.8×10^{-2} in 2017, and stayed above 15×10^{-2}

575 afterwards. There is also a clear seasonal difference in the ratio, with the averages for

576 the five years estimated at 0×10^{-2} , 8×10^{-2} , 52×10^{-2} , and 3×10^{-2} for January, April, July

577 and October, respectively. Since 2016, the ratio of BVOCs to AVOCs emissions

578 exceeded 50×10^{-2} in July, indicating that the O_3 pollution in summer could be

579 increasingly influenced by BVOCs. Regarding the spatial pattern, larger ratios were

580 commonly found in northern Jiangsu, with a modest growth for recent years (Figure

581 6). Moreover, greater growth of the ratio was found in part of southern Jiangsu where

582 AVOCs emissions were rapidly declining (e.g., Nanjing and Zhenjiang). The

583 evolution indicated that biogenic sources became more influential in O_3 production

584 even for some regions with developed industrial economy, along with controls of

585 anthropogenic emissions. Due to the relatively high level of ambient NO_2 from

586 anthropogenic emissions, a broad area of Jiangsu was identified with a mixed or

587 VOC-limited regime in terms of O_3 formation (Jin and Holloway, 2015), indicating

588 the impacts of NMVOCs (including BVOCs) on the ambient O_3 concentration. In the

589 future, the BVOCs emissions may further increase with the elevated temperature,

590 improved afforestation and vegetation protection, and they will probably play a more

591 important role on summer O_3 pollution once the controls of AVOCs emissions are

592 pushed forward (Ren et al., 2017; Gao et al., 2022a).

593 **3.2 The comparisons between different emission inventories**

594 **3.2.1 Assessment of emission amounts**

595 We compared our provincial-level emission inventory with previous studies on
596 emissions in Jiangsu in terms of the total and sectoral emissions through examinations
597 of activity data, emission factor, removal efficiency and other parameters. The
598 influence of data and methods on emission estimation was then revealed.

599 Table 2 compares our emission estimates, by year and species, with available global
600 (EDGAR, Crippa et al., 2020), continental (REAS, Kurokawa et al., 2020), national
601 (MEIC), and regional emission inventories (Li et al., 2018; Sun et al., 2018; Zhang et
602 al., 2017b; Simayi et al., 2019; An et al., 2021; Gao et al., 2022b; Yang et al., 2021a),
603 official emission statistics of Jiangsu Province
604 (<http://sthjt.jiangsu.gov.cn/col/col183555/index.html>), and an emission estimate with
605 the “top-down” approach, i.e., constrained by satellite observation and inverse
606 chemistry transport modelling (Yang et al., 2019). In particular, we stressed the
607 differences in emissions by sector among our study, MEIC and An et al. (2021) for
608 2017 as an example (Figure 8).

609 The annual SO₂ emissions in our provincial inventory were close to those in REAS
610 (2015), MEIC, Yang et al. (2021a), and official statistics for most years, but much
611 smaller than those reported by EDGAR, Sun et al. (2018) and Li et al. (2018). The
612 emissions in this work were 32% higher than the MEIC for 2017, with the biggest
613 difference (62% higher in this work) for power sector (Figure 8). It results mainly
614 from the discrepancies in the penetration and SO₂ removal efficiency of flue gas
615 desulfurization (FGD) systems applied in the two emission inventories. For example,
616 Zhang et al. (2019a) assumed that the penetration rate of FGD in the coal-fired power
617 sector reached 99.6% in 2017, with the removal efficiency estimated at 95%.
618 According to our unit-based investigation, the removal efficiencies in the power
619 sector were typically less than 92%, owing to the aging devices, low flue gas
620 temperature and other reasons. The main differences between this work and the YRD

621 emission inventory by An et al. (2021) existed in the industrial sector, attributed partly
622 to insufficient consideration of the comprehensive emission control regulations of
623 coal-fired boilers in Jiangsu in the past few years in An et al. (2021).

624 The estimates of NO_x emissions from MEIC, EDGAR and Sun et al. (2018) were
625 14-38% higher than ours, while the official statistics were much lower than ours,
626 attributed mainly to the absence of emissions from traffic sources in the statistics. The
627 major difference between MEIC and our provincial inventory existed in the power
628 and industrial sector, and the total emissions in the former were 56% larger than the
629 latter (Figure 8). For example, the emission factors for coal-fired power plants in this
630 study were derived from CEMS (0.03-2.8 g·kg⁻¹ coal), much smaller than those from
631 applied in MEIC and another research (2.88-8.12 g·kg⁻¹ coal, Zhang et al., 2021b).
632 Similarly, the smaller emission factors for industrial boilers derived based on on-site
633 investigations were commonly smaller than previous studies, leading to an estimation
634 of 45% smaller than MEIC for industrial sector in 2017. Correspondingly, some
635 modeling and satellite studies suggested that the NO_x emissions in previous studies
636 were overestimated partly due to less consideration of improvement in NO_x control
637 measures for coal burning sources (Zhao et al., 2018; Sha et al., 2019). Constrained by
638 satellite observation, the top-down estimation by Yang et al. (2019) was 10% and 22%
639 smaller than our provincial emission estimation and MEIC for 2016.

640 As mentioned in Section 2.1.2, AVOCs emissions for certain industrial sources in this
641 study were estimated with a procedure-based approach, which took the removal
642 efficiencies of different technologies into account (Zhang et al., 2021a). Therefore, the
643 annual AVOCs emissions in the provincial inventory were commonly much smaller
644 than others. Without sufficient the local information, for example, Simayi et al. (2019)
645 applied the national average removal efficiencies of AVOCs in furniture
646 manufacturing, automotive manufacturing and textile dyeing industries at 18%, 28%,
647 and 30%, clearly lower than 21%, 42%, and 43% in our inventory, respectively. As a
648 result, the AVOCs emissions from industrial source in the former were 45% higher
649 than the latter.

650 NH₃ emissions in the provincial emission inventory were commonly smaller than

651 others. In particular, the estimate was less than half of that by An et al. (2021) for
652 2017 (Figure 8). The big difference resulted mainly from the methodologies. As
653 indicated by our previous study (Zhao et al., 2020), the method characterizing
654 agricultural processes usually provided smaller emission estimates than that using the
655 constant emission factors. The former detected the emission variation by season and
656 region, and was more supportive for air quality modeling with better agreement with
657 ground and satellite observation. Compared with Infrared Atmospheric Sounding
658 Interferometer (IASI) observation, for example, application of the emission inventory
659 characterizing agricultural processes in CMAQ reduced the monthly NMEs of vertical
660 column density of NH_3 from 44%-84% to 38%-60% in different seasons for the YRD
661 region (Zhao et al., 2020).

662 For PM emissions, our estimates were larger than MEIC, Gao et al. (2022b), An et al.
663 (2021) and official emission statistics, but smaller than EDGAR, REAS, and Yang et
664 al. (2021a). The discrepancies resulted mainly from the inconsistent penetration rates
665 and removal efficiencies of dust collectors determined at national level and from
666 on-site surveys at provincial level. Taking cement as an example, all the plants were
667 assumed to be installed with dust collectors, and the national average removal
668 efficiency was determined at 99.3% in MEIC (Zhang et al., 2019a), clearly larger than
669 that in Jiangsu from plant-by-plant surveys (93%). The PM_{10} and $\text{PM}_{2.5}$ emissions
670 from the industrial sector in this study were 197 and 113 Gg higher than MEIC for
671 2017 (Figure 8).

672 **3.2.2 Assessment of interannual variability**

673 Figure 7 compares the interannual trends of SO_2 and NO_x emissions estimated in this
674 study with those in available global (EDGAR) and national emission inventories
675 (MEIC), as well as those of annual averages of ambient concentrations for
676 corresponding species collected from the state-operating observation sites in Jiangsu.
677 Different from other inventories, the global emission inventory EDGAR could not
678 reflect the rapid decline of SO_2 and NO_x emissions of Jiangsu for recent years. It is

679 probably due to the lack of information on the gradually enhanced penetrations and
680 removal efficiencies of APCDs use in power and industrial sectors in EDGAR.
681 Therefore, we mainly compared the interannual variability of emissions in our
682 provincial inventory and MEIC.

683 Both MEIC and our provincial inventory show the continuous declines in SO₂ and
684 NO_x emissions for Jiangsu from 2015 to 2019, which could be partly confirmed by
685 the ground observation. In general, quite similar trends were found for the two
686 inventories, suggesting similar estimations in the interannual variation of total
687 emissions at the national and provincial scales. However, there are some discrepancies
688 between the two. Compared to MEIC, as shown in Figure 7a, a slower decline in SO₂
689 emissions between 2015 and 2017 was estimated by our provincial inventory, but a
690 faster one between 2017 and 2019. In other words, MEIC describes a more optimistic
691 emission abatement for earlier years. The ultra-low emission retrofit on power sector
692 started from 2015 in Jiangsu, which was expected to significantly reduce the
693 emissions of coal-fired plants to the level of gas-fired ones. Through investigations
694 and examinations of information on APCD operations for individual sources, we
695 cautiously speculated that the benefit of the retrofit might not be as large as expected
696 at the initial stage. This could be partly supported by the correspondence between
697 online monitoring of SO₂ emissions for individual power plants and satellite-derived
698 SO₂ columns around them when the ultra-low emission retrofit was required (Karplus
699 et al., 2018). From 2017 to 2019, we were more optimistic on the emission reduction,
700 attributed partly to larger benefit of emission controls on non-electric industries.
701 Similar case with less discrepancy could also be found for NO_x emission (Figure 7b).

702 **3.3 Analysis of driving force of emission change from 2015 to 2019**

703 The actual reductions of annual SO₂, NO_x, AVOCs, NH₃, and PM_{2.5} emissions were
704 estimated at 331, 289, 77, 46, and 80 Gg from 2015 to 2019, respectively in our
705 provincial emission inventory. We analyzed the emission abatement and its driving
706 forces for two periods, 2015-2017 and 2017-2019, to represent the different influences

707 of individual measures on emissions for NAPAPCP and TYAPFAP. As shown in
708 Figure S6 in the Supplement, the actual emission reductions of SO₂ and NH₃ during
709 2015-2017 (211 and 34 Gg respectively) exceeded those during 2017-2019 (120 and
710 12 Gg, respectively). As the retrofit of ultra-low emission technologies for the power
711 sector and the modification of large-scale intensive management of livestock farming
712 in Jiangsu were basically completed between 2015 and 2017. The reductions of
713 annual NO_x, AVOCs, and PM_{2.5} emissions during 2017-2019 were much larger (209,
714 72, and 57 Gg, respectively) than those during 2015-2017 (80, 5, and 23 Gg,
715 respectively), implying bigger benefits of TYAPFAP on emission controls of those
716 species.

717 Figure 9 summarizes the effect of individual measures on net emission reduction for
718 the two periods. There were some common measures for SO₂, NO_x and PM_{2.5}
719 emission controls, thus, they were further discussed together below. During
720 2015-2017, the ultra-low emission retrofit of coal-fired power plants was identified to
721 be the most important driving factor for the reductions of SO₂ and NO_x emissions,
722 responsible for 38% and 43% of the abatement for the two species, respectively. By
723 the end of 2017, more than 95% of the coal-fired power plants in Jiangsu were
724 equipped with FGD and selective catalytic/non-catalytic reduction (SCR/SNCR), and
725 91% of coal-fired power generation capacity met the ultra-low emission standards (35,
726 50 and 10 mg·m⁻³ for SO₂, NO_x and PM concentration in the flue gas, respectively;
727 Zhang et al., 2019a). Through the information cross check and incorporation based on
728 different emission source databases as mentioned in Section 2.1.3, the average
729 removal efficiencies of SO₂ and NO_x in the coal-fired power plants were estimated to
730 increase from 89% and 50% in 2015 to 94% and 63% in 2017, respectively.

731 The extensive management of coal-fired boilers was the second most important driver
732 for SO₂ and NO_x reduction and the most important driver for PM_{2.5}, contributing to
733 24%, 20% and 37% of the emission reductions for corresponding species, respectively.
734 The main actions included the elimination of 100 MW of coal-fired power generation
735 capacity and the enhanced penetrations of SO₂ and particulate control devices on large
736 coal-fired industrial boilers since the improved enforcement of the latest emission

737 standard (GB 13271–2014).

738 The upgradation and renovation of non-electrical industry contributed 18%, 15%, and
739 28% to the emission reductions for SO₂, NO_x, and PM_{2.5}, respectively. Till 2017,
740 more than 80% of steel-sintering machines and cement kilns were equipped with FGD
741 and SCR/SNCR systems. The average removal efficiency in the steel and cement
742 production increased from 48% and 43% in 2015 to 60% and 57% in 2017 for SO₂,
743 and from 45% and 38% in 2015 to 54% and 40% in 2017 for NO_x, respectively (as
744 shown in Figure S7 in the Supplement).

745 Phasing out outdated capacities in key industries including crude steel (8 million tons),
746 cement (9 million tons), flat glass (3 million weight-boxes), and other
747 energy-inefficient production capacity contributed 11%, 6%, and 11% to the emission
748 reductions of corresponding species, respectively. Given their relatively small
749 proportions to total emissions, the contributions of other emission reduction measures
750 were less than 10%, such as promoting clean energy, phasing out small and polluting
751 factories, and the construction of port shore power.

752 The driving forces of emission abatement have been changing for the three species
753 since implementation of TYAPFAP. The potential for further reduction of SO₂ and
754 NO_x emissions were narrowed through the end-of-pipe treatment in the power sector,
755 and the ultra-emission retrofit on the sector was of very limited influence on the
756 emissions during 2017-2019. Measures on the non-electric sector brought greater
757 benefits on emission reduction. Extensive management of coal-fired boilers and
758 upgradation and renovation of non-electrical industry maintained as the most
759 important driving factors for the reduction of SO₂, NO_x, and PM_{2.5} emissions (33%,
760 20%, and 26% for the former and 28%, 29% and 33% for the latter, respectively).
761 After 2017, small coal boilers (≤ 30 MW) were continuously shut down and remaining
762 larger ones (≥ 60 MW) were all retrofitted with ultra-low emission technology.
763 Through the ultra-low emission retrofit, the average removal efficiencies of NO_x in
764 the steel and cement production increased from 54% and 40% in 2017 to 70% and 61%
765 in 2019, respectively.

766 Regarding AVOCs, the emission reduction resulted mainly from the implementation

767 of controls on the key sectors, which accounted for 63% and 34% of the reduced
768 emissions for 2015-2017 and 2017-2019, respectively. Besides, application of LDAR
769 was the second most important measure for 2015-2017, with the contribution to
770 emission reduction reaching 23%. The results also showed that AVOCs emission
771 reductions from all the concerned measures in 2017-2019 (152Gg) were higher than
772 those in 2015-2017 (116 Gg). Although more abatement in total AVOCs emissions
773 was found for 2017-2019 (Figure S6), the contributions of above-mentioned two
774 measures reduced clearly in the period. Some other measures were identified to be
775 important drivers of emission reduction, including control on mobile sources (e.g.,
776 implementation of the China V emission standard for on-road vehicles) and
777 replacement with low-VOCs paints. In our recent studies, we evaluated the average
778 removal efficiency of AVOCs in industrial sector was less than 30% (Zhang et al.,
779 2021a), and organic solvents with low-VOCs content accounted for less than 30% of
780 total solvent use (Wu et al., 2022). Therefore, there would still be great potential for
781 further reduction of AVOCs emissions through improvement on the end-of-pipe
782 emission controls and use of cleaner solvents.

783 In summary, expanding the end-of-pipe treatment (e.g., the ultra-low emission retrofit)
784 from power to non-electricity industry and phasing out the outdated industrial
785 capacities have driven the declines of emissions for most species. Along with the
786 limited potential for current measures, more substantial improvement of energy and
787 industrial structures could be the option for further emission reduction in the future.

788 **3.4 Effectiveness of emission controls on the changing air quality**

789 **3.4.1 Simulation of the O₃ and PM_{2.5} concentrations**

790 The CMAQ model performance was evaluated with available ground observation.
791 The observed concentrations of PM_{2.5} (hourly) and O₃ (the maximum daily 8-h
792 average, MDA8) were compared with the simulations using the provincial emission
793 inventory and MEIC for the selected four months for 2015-2019, as summarized in
794 Table S6 and Table S7 in the Supplement. Overall, the simulation with the provincial

795 inventory shows acceptable agreement with the observations, with the annual means
796 of NMB and NME ranging -21% – 2% and 43% –52% for PM_{2.5}, and -26% – -14%
797 and 30% – 41% for O₃. The analogous numbers for MEIC were -23% – -5% and 47%
798 – 53% for PM_{2.5}, and -26% – -6% and 33% – 46% for O₃, respectively. Most of the
799 NMB and NME were within the proposed criteria ($-30\% \leq \text{NMB} \leq 30\%$ and $\text{NME} \leq 50\%$,
800 Emery et al., 2017). Better performance was achieved using the provincial inventory,
801 implying the benefit of applying refined emission data on high-resolution air quality
802 simulation.

803 Besides O₃ and PM_{2.5}, better model performances were also found for SO₂ and NO₂
804 with the provincial emission inventory than MEIC, as shown in Table S8 in the
805 Supplement. For 2017, the monthly NMB and NME ranged -38% – -24% and 43% –
806 53% for SO₂, and 22% – 40% and 38% – 61% for NO₂. The analogous numbers for
807 MEIC were 35% – 68% and 84% – 114% for SO₂, and 50% – 133% and 65% – 138%
808 for NO₂, respectively (unpublished data provided by MEIC development team,
809 Tsinghua University).

810 Figure 10 compares the observed and simulated (with the provincial inventory)
811 interannual trends in PM_{2.5} and MDA8 O₃ concentrations from 2015 to 2019 (see the
812 simulated spatiotemporal evolution in Figures S8 and S9 in the Supplement).
813 Satisfying correlations between observed and simulated concentrations were found for
814 both PM_{2.5} and MDA8 O₃, with the squares of correlation coefficients (R^2) estimated
815 at 0.81 and 0.86 within the research period, respectively. The good agreement
816 suggests the simulation with high-resolution emission inventory was able to well
817 capture the interannual changes in air quality at the provincial scale.

818 Both observation and simulation indicated a declining trend of PM_{2.5} concentrations,
819 with the annual decreasing rates estimated at -5.4 and -4.2 $\mu\text{g}\cdot\text{m}^{-3}\cdot\text{yr}^{-1}$, respectively
820 (Figure 10a). The decline reflected the benefit of improved implementation of
821 emission control actions as well as the influence of meteorological condition change.
822 In general, higher concentrations were found in winter and lower in summer. A
823 rebound in PM_{2.5} level was notably found in winter after 2017, attributed possibly to

824 the unfavorable meteorological conditions that were more likely to exacerbate air
825 pollution (e.g., the reduced wind speed as shown in Table S2) for recent years. In
826 contrast to PM_{2.5}, MDA8 O₃ was clearly elevated from 2015 to 2019, with the annual
827 growth rates estimated at 4.6 and 7.3 $\mu\text{g}\cdot\text{m}^{-3}\cdot\text{yr}^{-1}$, by observation and simulation
828 (Figure 10b). Higher concentrations were found in spring and summer and lower in
829 autumn and winter. Besides the impact of emission change, the O₃ concentrations can
830 be greatly influenced by the varying meteorological factors such as the decreased
831 relative humidity and wind speed for recent years in YRD region (Gao et al., 2021;
832 Dang et al., 2021). In addition, the recent declining PM_{2.5} concentration in eastern
833 China reduced the heterogeneous absorption of hydroperoxyl radicals (HO₂) by
834 aerosols and thereby enhanced O₃ concentration (Li et al., 2019). If such aerosol
835 effect was considered in CMAQ modeling, the increasing rate of annual O₃
836 concentration would possibly be further overestimated. The complex impacts of
837 various factors on air quality triggered the separation of emission and meteorological
838 contributions to the changing PM_{2.5} and O₃ levels in Section 3.4.2.

839 The common underestimation of O₃ should be stressed, partly resulting from the bias
840 in the estimation of precursor emissions. In this study, the enhanced penetrations
841 and/or removal efficiencies of NO_x control devices might not be fully considered in
842 the emission inventory development, in particular for the non-electric industry,
843 leading to possible overestimation of NO_x emissions. Moreover, underestimation of
844 AVOCs emissions could exist, due to incomplete counting of emission sources,
845 particularly for the uncontrolled fugitive leakage. As most of Jiangsu was identified as
846 a VOC-limited region for O₃ formation (Wang et al., 2020b; Yang et al., 2021b), the
847 overestimation of NO_x and underestimation of AVOCs could result in underestimation
848 in O₃ concentration with air quality modeling. Compared to MEIC, the improved
849 provincial emission inventory partly corrected the overestimation of NO_x emissions
850 and NO₂ concentrations (Table S8), and helped reduce the bias of O₃ concentration
851 simulation. Furthermore, a larger underestimation in O₃ was revealed before 2017
852 (Figure 8b), attributed partly to less data support on the emission sources and thereby
853 less reliability in the emission inventory, compared with more recent years.

854 **3.4.2 Anthropogenic and meteorological contribution to O₃ and PM_{2.5} variation**

855 As shown in Figure 11, in the baseline simulation that accounted for the interannual
856 changes of both anthropogenic emissions and meteorology, the provincial-level PM_{2.5}
857 concentration (geographical mean) was calculated to decrease by 4.1 $\mu\text{g}\cdot\text{m}^{-3}$ in
858 2015-2017 and 1.7 $\mu\text{g}\cdot\text{m}^{-3}$ in 2017-2019, and MDA8 O₃ increase by 17.0 $\mu\text{g}\cdot\text{m}^{-3}$ in
859 2015-2017 and 3.2 $\mu\text{g}\cdot\text{m}^{-3}$ in 2017-2019. Smaller variations were found for more
860 recent years for both species. With VEMIS and VMET, the contributions of the two
861 factors were identified and discussed in the following. It should be noted that the air
862 quality changes in baseline did not equal to the aggregated contributions in VEMSI
863 and VMET due to non-linearity effect of the chemistry transport modeling, and the
864 main goal of the analysis was to compare the relative contributions of the two factors.
865 As shown in Figure 11a, similar patterns of driving factor contributions to PM_{2.5} were
866 found during 2015-2017 and 2017-2019. While meteorological conditions
867 consistently promoted the formation of PM_{2.5}, the continuous abatement of
868 anthropogenic emissions completely offset the adverse meteorological effects and
869 contributed to the declines in PM_{2.5} concentrations. Although less reduction in PM_{2.5}
870 concentration was found for 2017-2019 due mainly to the worsened meteorology,
871 emission abatement was estimated to play a greater role on reducing PM_{2.5}
872 concentration (5.5 $\mu\text{g}\cdot\text{m}^{-3}$ in VEMIS) compared to 2015-2017 (4.3 $\mu\text{g}\cdot\text{m}^{-3}$), implying
873 the higher effectiveness of recent emission control actions on PM_{2.5} pollution
874 alleviation.

875 The O₃ case is different (Figure 11b). Both the changing emissions and meteorology
876 favored MDA8 O₃ increase for 2015-2017, consistent with previous studies (Wang et
877 al., 2019; Dang et al., 2021). The contribution of meteorology was estimated at 11.9
878 $\mu\text{g}\cdot\text{m}^{-3}$ (VMET), larger than that of emissions at 4.9 $\mu\text{g}\cdot\text{m}^{-3}$ (VEMIS). As shown in
879 Figure S6, the abatement of annual NO_x emissions in Jiangsu was estimated at 104
880 Gg, while very limited reduction was achieved in AVOCs emissions. Declining NO_x
881 emissions thus elevated O₃ formation under the VOC-limited conditions particularly
882 in urban areas in Jiangsu.

883 During 2017-2019, the meteorological condition played a more important role on the
884 O₃ growth (14.3 μg·m⁻³), attributed mainly to the decreased relative humidity and
885 wind speed for recent years (Table S2). In contrast, the changing emissions were
886 estimated to restrain the O₃ growth by 3.1 μg·m⁻³, implying the effectiveness of
887 continuous emission controls on O₃ pollution alleviation. As shown in Figure S6, a
888 much larger reduction in AVOCs emissions was achieved in Jiangsu during
889 2017-2019 compared to 2015-2017, and the greater NO_x emission reduction might
890 have led to the shift from VOC-limited to the transitional regime across the province
891 (Wang et al., 2021b). The emission controls thus helped limit the total O₃ production.
892 Although the reduction in precursor emissions was not able to fully offset the effect of
893 adverse meteorology condition, its encouraging effectiveness demonstrated the
894 validity of current emission control measures, and actual O₃ decline can be expected
895 with more stringent control actions to overcome the influence of meteorological
896 variation.

897 **4. Conclusion remarks**

898 In this study, we developed a high-resolution emission inventory of nine air pollutants
899 for Jiangsu 2015-2019, by integrating the improvements in methodology for different
900 sectors and incorporating the best available facility-level information and real-world
901 emission measurements. We evaluated this provincial-level emission inventory
902 through comparison with other studies at different spatial scales and air quality
903 modeling. We further linked the emission changes to various emission control
904 measures, and evaluated the effectiveness of pollution control efforts on the emission
905 reduction and air quality improvement.

906 Our study indicated that the emission controls indeed played an important role in
907 prevention and alleviation of air pollution. Through a series of remarkable actions in
908 NAPAPCP and TYAPFAP, the annual emissions in Jiangsu declined to varying
909 degrees for different species from 2015 to 2019, with the largest relative reduction at
910 53% for SO₂ and smallest at 6% for AVOCs. Regarding different periods, larger

911 abatement of SO₂ emissions was found between 2015 and 2017 but more substantial
912 reductions of NO_x, AVOCs and primary PM_{2.5} between 2017 and 2019. Our estimates
913 in SO₂, AVOCs and NH₃ emissions were mostly smaller than or close to other studies,
914 while those for NO_x and primary PM_{2.5} were less conclusive. The main reasons for
915 the discrepancies between studies included the modified methodologies used in this
916 work (e.g., the procedure-based approach for AVOCs and the agricultural process
917 characterization for NH₃) and the varied depths of details on emission source
918 investigation (e.g., the penetrations and removal efficiencies of APCD). Air quality
919 modeling confirmed the benefit of refined emission data on predicting the ambient
920 levels of PM_{2.5} and O₃, as well as capturing their interannual variations.

921 For 2015-2017 within NAPAPCP, the ultra-low emission retrofit on power sector was
922 most effective on SO₂ and NO_x emission reduction, but the expansion of emission
923 controls to non-electricity sectors, including coal-fired boilers and key industries
924 would be more important for 2017-2019. AVOCs control was still in its initial stage,
925 and the measures on key industrial sectors and transportation were demonstrated to be
926 effective. Along with the gradually reduced potential for emission reduction through
927 end-of-pipe treatment, adjustment of energy and industrial structures should be the
928 future path for Jiangsu as well as other regions with developed industrial economy.
929 Air quality modeling suggested worsened meteorological conditions from 2015 to
930 2019 in terms of PM_{2.5} and O₃ pollution alleviation. The continuous actions on
931 emission reduction, however, have been taking effect on reducing PM_{2.5} concentration
932 and restraining the growth of MDA8 O₃ level.

933 The analysis justified the big efforts and investments by the local government for air
934 pollution controls, and demonstrated how the investigations of detailed underlying
935 data could help improve the precision, integrity and continuity of emission inventories.
936 Such demonstrations were more applicable at regional scale (smaller countries and
937 territories) instead of national scale due to the huge cost and data gap for the latter.
938 Furthermore, the work showed how the refined emission data could efficiently
939 support the high-resolution air quality modeling, and highlighted the varying and
940 complex responses of air quality to different emission control efforts. Therefore, the

941 study could shed light for other highly polluted regions in China and worldwide, with
942 diverse stages of regional economical development and air pollution controls.
943 Limitations remain in the current study. Attributed to insufficient data support, there
944 was little improvement on emission estimation for some sources compared to previous
945 studies, e.g., on-road transportation and residential sector. Those sources may play an
946 increasingly important role on emissions and air quality along with stringent controls
947 on power and industrial sectors, and thus need to be better stressed in the future. The
948 temporal profiles of emissions for most source categories were not improved due to
949 the difficulty in capturing the real-time variation of activity for individual emitters
950 (e.g., the operation and energy consumption of industrial plant). It could be a reason
951 for the bias in air quality modeling. Given the limited access on emission source
952 information, moreover, the emission data for nearby regions around Jiangsu were not
953 refined in this work. Such limitation might lead to some bias in analyzing the
954 effectiveness of emission controls on air quality, as regional transport could account
955 for a considerable fraction of PM_{2.5} and O₃ concentrations. Should better regional
956 emission data get available, more analysis needs to be conducted to separate the
957 effectiveness of local emission controls and efforts from nearby regions. Due to huge
958 computational tasks through air quality modeling, the individual emission control
959 measures were not directly linked to the ambient concentration, and their
960 effectiveness on air quality improvement cannot be obtained in details. Advanced
961 numerical tools, e.g., the adjoint modeling, are recommended for further in-depth
962 analysis.

963 **Data availability**

964 The gridded emission data for Jiangsu Province 2015-2019 can be downloaded at
965 <http://www.airqualitynju.com/En/Data/List/Datadownload>

966 **Author contributions**

967 CGu developed the methodology, conducted the research and wrote the draft. YZhao

968 and LZhang developed the strategy and designed the research, and YZhao revised the
969 manuscript. ZXu provided the support of air quality modeling. YWang, ZWang and
970 HWang provided the support of emission data processing. SXia, LLi, and QZhao
971 provided the support of emission data.

972 **Competing interests**

973 The authors declare that they have no conflict of interest.

974 **Acknowledgments**

975 This work received support from the Natural Science Foundation of China
976 (42177080), the Key Research and Development Programme of Jiangsu Province
977 (BE2022838), and Jiangsu Provincial Fund on PM_{2.5} and O₃ Pollution Mitigation (No.
978 2019023). We appreciate Qiang Zhang, Guannan Geng, and Nana Wu from Tsinghua
979 University (the MEIC team) for national emission data and evaluation.

1252

1253 **Figure captions**

1254 Figure 1. Emission trends, underlying social and economic factors. Coal consumption
1255 is achieved by Chinese Energy Statistics (National Bureau of Statistics, 2016-2020).
1256 The GDP, population, and vehicle population data come from the National Bureau of
1257 Statistics, (2016-2020). Data are normalized by dividing the value of each year by
1258 their corresponding value in 2015.

1259 Figure 2. Anthropogenic emissions by sector and year. The species include (a) SO₂, (b)
1260 NO_x, (c) CO, (d) AVOCs, (e) NH₃, (f) PM₁₀, (g) PM_{2.5}, (h) BC, and (i) OC. Emissions
1261 are divided into five sectors: power, industry, transportation, residential, and
1262 agriculture.

1263 Figure 3. Changes in emissions by sector and year. The species include (a) SO₂, (b)
1264 NO_x, (c) CO, (d) AVOCs, (e) NH₃, (f) PM₁₀, (g) PM_{2.5}, (h) BC, and (i) OC. The 2015
1265 emissions are subtracted from the emission data for each year to represent the
1266 additional emissions compared to 2015 levels.

1267 Figure 4. The city-level emissions and spatial distribution include (a) SO₂, (b) NO_x, (c)
1268 AVOCs, (d) PM_{2.5}, and (e) NH₃; and (f) the proportions of emission by different
1269 regions for 2015 and 2019. The blue line indicates the Yangtze River. The map data
1270 provided by Resource and Environment Data Cloud Platform are freely available for
1271 academic use (<http://www.resdc.cn/data.aspx?DATAID=201>), © Institute of
1272 Geographic Sciences & Natural Resources Research, Chinese Academy of Sciences.

1273 Figure 5. Difference in the spatial distribution of major pollutant emissions between
1274 2015 and 2019 for (a) SO₂, (b) NO_x, (c) PM_{2.5}, and (d) AVOCs. The black circles
1275 represent the locations of top 10 emitters for corresponding species in each panel. The
1276 blue line indicates the Yangtze River.

1277 Figure 6. The ratios of BVOCs to AVOCs emissions in July: (a) 2015, (b) 2017, and (c)
1278 2019.

1279 Figure 7. Comparison of interannual trends with MEIC, EDGAR, and ground-based
1280 observations: (a) SO₂ and (b) NO_x (NO₂).

1281 Figure 8. Comparison of Jiangsu emissions for 2017 with MEIC and An et al. (2021).
1282 The air pollutants from left to right are SO₂, NO_x, VOCs, NH₃, and PM_{2.5},
1283 respectively.

1284 Figure 9. Contributions of individual measures to emission reductions in SO₂, NO_x,
1285 VOCs, and PM_{2.5} for 2015-2017 (the left column) and 2017-2019 (the right column).

1286 Figure 10. The monthly averages of (a) PM_{2.5} and (b) MDA8 O₃ from CMAQ
1287 simulation and ground observation for January, April, July and October from 2015 to
1288 2019. The slopes of linear regressions in the panels indicate the annual variation rates
1289 for corresponding species.

1290 Figure 11. The concentration changes during 2015-2017 and 2017-2019 from CMAQ
1291 for (a) PM_{2.5} and (b) O₃ (VEMIS and VMET: meteorological conditions and
1292 emissions fixed at 2017 level, respectively).
