17 **Abstract**

18 Despite its importance in controlling the abundance of methane (CH₄) and a myriad of other
19 tropospheric species, the hydroxyl radical (OH) is poorly constrained due to its large spatial
20 heterogeneity and the inability to measure tropospheric OH with satellites. Here, we present a
21 methodology to infer tropospheric column OH (TCOH) in the tropics over the open oceans using a
22 combination of a machine learning model, output from a simulation of the GEOS model, and satellite
23 observations. Our overall goals are to assess the feasibility of our methodology, to identify potential
24 limitations, and to suggest areas of improvement in the current observational network. The
25 methodology reproduces the variability of TCOH from independent 3D model output and of
26 observations from the Atmospheric Tomography mission (ATom). While the methodology also
27 reproduces the magnitude of the 3D model validation set, the accuracy of the magnitude when applied
28 to observations is uncertain because current observations are insufficient to fully evaluate the machine
29 learning model. Despite large uncertainties in some of the satellite retrievals necessary to infer OH,
30 particularly for NO₂ and HCHO, current satellite observations are of sufficient quality to apply the
31 machine learning methodology, resulting in an error comparable to that of *in situ* OH observations.
32 Finally, the methodology is not limited to a specific suite of satellite retrievals. Comparison of TCOH
33 determined from two sets of retrievals does show, however, that systematic biases in NO₂, resulting
34 both from retrieval algorithm and instrumental differences, lead to relative biases in the calculated
35 TCOH. Further evaluation of NO₂ retrievals in the remote atmosphere is needed to determine their
36 accuracy. With slight modifications, a similar methodology could likely be expanded to the extra-tropics
37 and over land, with the benefits of increasing our understanding of the atmospheric oxidation capacity
38 and, for instance, informing understanding of recent CH₄ trends.

39
40 **1 Introduction**

41 The hydroxyl radical (OH) dictates the lifetime of many tropospheric species, including carbon monoxide
42 (CO), methane (CH₄), and numerous volatile organic compounds (VOCs). Knowledge of OH is therefore
43 necessary to understand the abundance, distribution, and variability of these species. For instance,
44 Rigby et al. (2017) and Laughner et al. (2021) attribute recent trends and increases in CH₄ at least
45 partially to changes in OH abundance. Current constraints on OH are insufficient, however, to assess its
46 relative importance in controlling these trends (Turner et al., 2017).

47

48 Differences in OH distributions among chemistry transport (CTM) and chemistry climate models (CCM)
49 suggest that these models are insufficient to inform understanding of OH abundance and variability
50 without further observational constraints. OH abundance can differ by up to 80% among models
51 constrained with identical emissions in intercomparison projects (Voulgarakis et al., 2013; Nicely et
52 al.; Zhao et al., 2019; Murray et al., 2021). Variables such as the photolysis frequency of O₃ (JO¹D) (Nicely
53 et al., 2020), the NO_x lifetime (NO_x = NO + NO₂), and the oxidation efficiency of VOCs (Murray et al.,
54 2021) contribute to these inter-model variations in OH. Likewise, the response of OH to the El Niño
55 Southern Oscillation (ENSO), the dominant mode of OH variability on monthly and seasonal timescales
56 (Anderson et al., 2021; Turner et al., 2018), and other modes of internal climate variability can vary
57 widely among models (Anderson et al., 2021).

58
59 Despite this need for better constraints, observations of tropospheric OH are limited. The hydroxyl
60 radical has a lifetime of approximately 1s (Mao et al., 2009), resulting in large spatial heterogeneity in
61 both the horizontal and vertical. A strategic, representative in situ observational network is therefore
62 unfeasible. As a result, observations of OH are generally limited to intensive field campaigns (Miller and
63 Brune, 2022) that have narrow spatial and temporal coverage. While remotely-sensed OH observations
64 are available, those from satellites are limited to the stratosphere (e.g., Pickett et al., 2008), while
65 ground-based observations of total column OH are dominated by the stratospheric contribution (e.g.,
66 Burnett and Minschwaner, 1998).

67
68 Reference gases with well-characterized sources and an OH sink, such as methyl chloroform (MCF), can
69 be used to infer OH abundance (Lovelock, 1977). This methodology, however, generally yields no
70 information on spatial heterogeneity beyond the hemispheric scale (e.g., Montzka et al., 2011; Rigby et
71 al., 2017; Naus et al., 2019). For MCF in particular, recent declines in tropospheric abundance will soon
72 dictate the need for a new reference species (Liang et al., 2017).

73
74 Multiple studies have attempted to constrain OH through the creation of proxies and the application of
75 satellite retrievals of OH drivers. Murray et al. (2014) showed that global OH strongly correlated with a
76 combination of JO¹D, water vapor (H₂O_(v)), and the tropospheric sources of reactive nitrogen and carbon
77 in the GEOS-Chem model. Murray et al. (2021) demonstrated that OH correlated with this proxy in
78 multiple CTMs, although the relationship differs strongly among models. Wolfe et al. (2019) developed
79 a proxy for OH based on formaldehyde (HCHO) production and loss rates. They applied that proxy to
80 satellite HCHO observations to estimate OH columns in the remote troposphere, a region where HCHO
81 abundance is low and the satellite retrievals are reflective of the *a priori* (Zhu et al., 2016). Using
82 machine learning, chemical transport model output, and retrievals of NO₂ and HCHO, Zhu et al. (2022a)
83 developed a method to estimate surface OH in North American urban areas. Finally, Pimlott et al.
84 (2022) used a steady state approximation of OH, including primary production from H₂O and O₃ and loss
85 from CO, CH₄, and O₃, to estimate OH between 600 and 700 hPa using observations from IASI (Infrared
86 Atmospheric Sounding Interferometer). A logical next step, building on the results of these studies, is
87 the development of a methodology to constrain OH that ingests multiple satellite retrievals,
88 encompasses the breadth of OH chemical and dynamical drivers, and spans a significant enough portion
89 of the globe to inform variability and trends in CH₄ and CO loss.

90
91 Combining machine learning, chemical transport model (CTM) output, and satellite data has the
92 potential to constrain tropospheric column OH (TCOH). A variety of machine learning techniques, such
93 as neural networks (Nicely et al., 2017; Nicely et al., 2020; Kelp et al., 2020), self-organizing maps
94 (Stauffer et al., 2016), random forest regression (Keller and Evans, 2019), and gradient boosted
95 regression trees (GBRTs) (Ivatt and Evans, 2020; Zhu et al., 2022a; Anderson et al., 2022) show promise in

96 helping to solve problems in atmospheric chemistry. In particular, Zhu et al. (2022a) and Anderson et al.
97 (2022) demonstrated the ability of GBRTs to predict OH from a chemical transport model with
98 reasonable accuracy. GBRT models (Elith et al., 2008; Chen and Guestrin, 2016) use an ensemble of
99 decision trees to predict the value of a target based on multiple inputs, even for targets with highly non-
100 linear dependencies on the inputs.

101

102 Here, we present a methodology to infer clear sky TCOH in the tropics from space-based observations of
103 its chemical and dynamical drivers with the goal of assessing the feasibility of our methodology,
104 identifying potential limitations, and suggesting areas of improvement in the current observational
105 network. We train a GBRT model using output from a simulation of the NASA GEOS (Goddard Earth
106 Observing System) model, and then estimate TCOH in the actual atmosphere at the satellite overpass
107 time using inputs from a suite of satellite retrievals. In Section 2, we describe the methodology for
108 generating the machine learning model as well as the satellite retrievals used to constrain TCOH. We
109 then evaluate the suitability of MERRA2 GMI as a training dataset (Sect. 3) and, in Section 4, present a
110 satellite-constrained OH product for one month from each season. Finally, in Section 5, we explore
111 potential methodological limitations and benefits, including lack of validation data, the impacts of
112 observational uncertainties, and the ability to use different satellites and retrievals as inputs to the GBRT
113 model.

114

115 **2 Description of the methodology to generate the GBRT model and of the associated datasets**

116 Our overall aim is to demonstrate the feasibility of our approach to constrain TCOH with satellite-based
117 observations over broad regional scales. As a first step, we restrict our analysis to latitudes equatorward
118 of 25° and regions over water. We chose to focus initially on this domain as it has appreciable OH
119 concentrations and simplified chemistry, as compared to regions with large biogenic and anthropogenic
120 VOC emissions. Nevertheless, this portion of the atmosphere accounts for 50 – 60% of global CO and
121 CH₄ loss. In this section, we describe the creation of the machine learning model used to predict TCOH
122 (Sect. 2.1) for this region as well as the satellite products used as inputs to the machine learning model
123 (Sect. 2.2).

124

125 **2.1 Creation of the TCOH model**

126 **2.1.1 Creation of the GBRT training dataset**

127 For the machine learning model training dataset, we use a subset of output from the MERRA2 GMI
128 simulation (<https://acd-ext.gsfc.nasa.gov/Projects/GEOSCCM/MERRA2GMI/>). MERRA2 GMI is a 40 year
129 (1980 – 2019) simulation of the NASA GEOS model run in replay mode (Orbe et al., 2017) with MERRA2
130 (Modern Era Retrospective analysis for Research and Applications, version 2) meteorology (Gelaro et al.,
131 2017). The simulation has a resolution of c180 on the cubed sphere (approximately 0.625° longitude by
132 0.5° latitude) with 72 vertical layers and uses the Global Modeling Initiative (GMI) chemical mechanism
133 (Duncan et al., 2007; Strahan et al., 2007). Output is available at daily- and monthly-averaged resolution,
134 as well as instantaneous values corresponding with the overpass times of the satellites described in
135 Section 2.2. Anderson et al. (2021) and Strode et al. (2019) provide detailed information about the
136 simulation, including emissions.

137

138 The training target for the machine learning model is TCOH. In Anderson et al. (2022), we developed a
139 GBRT parameterization trained on MERRA2 GMI output to predict in situ OH concentrations using 27
140 inputs, only a small fraction of which are observable from space. That parameterization, designed to be
141 integrated into the GEOS modeling framework, performed better when there was a separate model for
142 each month as opposed to one model for all months. While that GBRT model is not appropriate for the
143 application described here, we employ a similar approach, creating a separate set of TCOH training

144 targets for each month. We use instantaneous OH output from MERRA2 GMI at 14:00 local time for
145 each day of a given month across the years 2005 to 2019, to correspond with the satellite record. We
146 omitted data from 2017 to evaluate model performance. For a given month and year, we calculate daily
147 tropospheric column values across the grid, filtering out columns where the maximum cloud fraction in
148 that column was greater than 30%, yielding approximately 43,000 valid grid boxes per day. For each
149 year, we then average these values to monthly resolution. This results in approximately 600,000 total
150 training targets for each month over the 15-year period.

151
152
153

Table 1: Input variables to the machine learning model and the corresponding satellite retrieval used to create the satellite OH product.

Variable	Satellite retrieval	Original horizontal and temporal resolution	Reference
Total O ₃ column	OMI TOMS-Like L3 version 3	0.25° × 0.25°, daily	McPeters et al. (2015)
Tropospheric NO ₂ column	OMI GSFC L3 version 4	0.25° × 0.25°, daily	Lamsal et al. (2021)
CO column	MOPITT L3 version 8	1.0° × 1.0°, monthly	Deeter et al. (2019)
HCHO column	OMI SAO L3 version 3	0.1° × 0.1°, daily	González Abad et al. (2015)
H ₂ O _(v) column	AIRS L3 version 6	1.0° × 1.0°, monthly	Susskind et al. (2014)
Sea surface temperature	MUR L4 version 4.2	0.25° × 0.25°, daily	Chin et al. (2017)
Aerosol optical depth at 550 nm	MODIS Aqua L3 collection 6	0.5° × 0.5°, daily	Levy et al. (2013)
H ₂ O _(v) layers: 925 – 850 hPa, 850 – 700 hPa, 700 – 600 hPa, 600 – 500 hPa, 500 – 400 hPa, 400 – 300 hPa, and 300 - 250 hPa	AIRS L3 version 6	1.0° × 1.0°, monthly	Susskind et al. (2014)
Solar zenith angle	N/A		
Latitude	N/A

166

We selected the input variables for the machine learning model (Table 1) based on their relevance to OH chemistry and variability as well as our current ability to observe the variable with satellites. Performance was similar for a model including total column ozone only and for a model also including the tropospheric column. We therefore use total column ozone because of the uncertainties inherent in separating the column into two parts in the satellite retrieval. We chose the water vapor layers to correspond with the Atmospheric Infrared Sounder (AIRS) layers product. Layers are averages over the indicated pressure range, and we denote the layer names by the highest pressure in that range. We include sea surface temperatures (SST) as a proxy for the Indian Ocean Dipole and ENSO, which has a strong impact on OH variability in the tropics (Anderson et al., 2021; Turner et al., 2018). In addition, we include latitude and solar zenith angle as previous work has shown that these variables can explain a large fraction of the spatial OH variability (Duncan et al., 2000; Anderson et al., 2022).

167
168
169
170
171
172

We sampled the MERRA2 GMI output to create the training dataset in the same manner as for the TCOH targets. The inputs to the machine learning model each correspond to the same model column as the OH target. All column values are instantaneous and taken from 14:00 to correspond with satellite overpass times, except for CO, which is for 10:00, corresponding with the Measurement of Pollution in the Troposphere (MOPITT) overpass time. Model performance was similar when using CO output at 14:00 and 10:00, likely because of limited diurnal variability in CO column in the study region. SSTs are

173 monthly averages of 24-hour averaged values, and we calculated solar zenith angle at the surface for
174 noon on the 15th of a given month.

175

176 **2.1.2 Creation and tuning of the GBRT model**

177 We used the XGBoost package (Chen and Guestrin, 2016) version 0.81 in Python version 3.6 to create a
178 GBRT model of TCOH for each month using the training datasets from MERRA2 GMI. For each month,
179 we used 90% of the dataset for model training and the remainder for model validation. As mentioned in
180 Section 2.1.1, we also used MERRA2 GMI output from 2017, which was omitted from the training
181 dataset, as further validation.

182

183 To maximize parameterization performance while also balancing the potential of overfitting, we tuned
184 hyperparameters, including the learning rate, the maximum tree depth, and the number of trees. We
185 chose hyperparameter values that minimized the parameterization root mean square error (RMSE) of
186 the training dataset. We set the learning rate, which controls the magnitude of change when adding a
187 new tree, to 0.1, while we varied the maximum tree depth and number of trees from 6 to 22 and from
188 10 to 150, respectively. For both maximum tree depth and number of trees, RMSE initially dropped
189 significantly with increasing value, representing sharp improvement in parameterization performance.
190 RMSE values eventually plateaued, increasing parameterization runtime without noticeably improving
191 performance. A combination of a maximum tree depth of 18 and 100 trees balanced performance with
192 model training and run time.

193

194 To determine whether the inputs to the machine learning model improved or hindered performance, we
195 performed a “leave one out” analysis. Using 5-fold cross validation, we retrained the model, individually
196 omitting each of the inputs, to determine the percent difference between the mean RMSE of the 5 folds
197 for the model without a specific input and one including all inputs. Omitting the inputs listed in Table 1
198 lead to increases in the RMSE, suggesting that each is necessary for improved model performance. As a
199 result of this analysis, we do not use water vapor layers for pressures less than 300 hPa because these
200 decreased model performance.

201

202 Finally, we found that it was not necessary to apply satellite averaging kernels and shape factors to the
203 training dataset. Of the satellite retrievals used in this work (discussed in Sect. 2.2 and listed in Table 1),
204 only CO, HCHO, and NO₂ could require convolving the model with the averaging kernel. Shape factors
205 for the OMI NO₂ retrieval are determined from a similar setup of the GEOS model, also employing the
206 GMI chemical mechanism and MERRA2 meteorology. Applying the satellite shape factors to the
207 simulation discussed here would therefore not result in significant changes in the modeled NO₂
208 (Anderson et al., 2021). To test whether it is necessary to apply the averaging kernels for CO and HCHO,
209 we created a separate training dataset, where we convolved the daily MERRA2 GMI output with the
210 averaging kernel and a priori from the level 2 data for both species for February 2005 - 2019. All other
211 inputs were kept the same. We then retrained the model with these adjusted CO and HCHO variables.
212 When we applied the satellite data to the model for February 2017, as described in Section 4, the
213 resulting TCOH differed by less than 1% on average from the model that did not include averaging kernel
214 information. This level of uncertainty is significantly smaller than the other uncertainties discussed in
215 Section 5, so we do not include averaging kernels in our analysis.

216

217 **2.2 Description of satellite products**

218 To create the observationally-constrained OH product, we use multiple satellite retrievals, listed in Table
219 1 and briefly described here. For each satellite retrieval, we use the level 3 gridded product, with the
220 exception of SST which is level 4. Where necessary, we regridded the retrieval to a common horizontal

221 grid with a resolution of $1.0^\circ \times 1.0^\circ$ and averaged to the monthly scale. Each instrument is located
222 onboard a polar orbiting satellite that provides near global coverage daily.
223
224 We use retrievals of three species – HCHO, O₃, and NO₂ – from the Ozone Monitoring Instrument (OMI),
225 an ultraviolet-visible spectrometer located onboard the Aura satellite, which has an overpass of
226 approximately 13:30 local solar time (LST). We use the Smithsonian Astrophysical Observatory (SAO)
227 version 3 HCHO retrieval (González Abad et al., 2015). Wolfe et al. (2019) found that this retrieval
228 captured the variability of the HCHO columns in the remote atmosphere observed during the
229 Atmospheric Tomography (ATom) campaign with little bias. For total column O₃, we use the TOMS-like
230 (Total Ozone Mapping Spectrometer) retrieval version 3 (McPeters et al., 2015), which agrees with
231 ground-based and other satellite observations within approximately 1% (Labow et al., 2013). Finally, we
232 use the Goddard Space Flight Center version 4 NO₂ retrieval (Lamsal et al., 2021). While previous
233 studies have thoroughly evaluated this retrieval in more polluted atmospheres (e.g., Lamsal et al.,
234 2014;Choi et al., 2020), evaluation in the remote tropical atmosphere, as defined in this study, is limited.
235

236 For water vapor and aerosol optical depth (AOD) at 550 nm, we use retrievals from AIRS and the
237 Moderate Resolution Imaging Spectroradiometer (MODIS) instruments, respectively, both located
238 onboard the Aqua satellite with an overpass of approximately 13:30 LST. We use the total column water
239 vapor standard physical retrieval as well as the 7 water vapor layers listed in Table 1 (Susskind et al.,
240 2014). Multiple studies have evaluated the accuracy of the AIRS H₂O_(v) column and layers retrievals in
241 the remote tropical atmosphere, finding bias of 5% or less and high correlation against both remote and
242 *in situ* observations (Bedka et al., 2010;Anderson et al., 2016;Pérez-Ramírez et al., 2019). We use
243 collection 6 of the dark target MODIS AOD retrieval at 550 nm, which is highly correlated with
244 observations from the AERONET network over the ocean (Levy et al., 2013).
245

246 We also use retrievals of CO from MOPITT, which is onboard the Terra satellite with an overpass of
247 10:30 LST. We use the version 8 retrieval that includes both near and thermal infrared radiances (Deeter
248 et al., 2019). CO retrievals from MOPITT in the remote tropics generally agree with ground-based
249 remotely-sensed observations within 10% (Hedelius et al., 2019;Buchholz et al., 2017).
250

251 Finally, we use SSTs from the Multi-scale Ultra-high Resolution (MUR) analysis, which combines
252 nighttime SST observations from multiple satellite platforms, including MODIS, as well as *in situ*
253 observations and agrees with other SST analyses within 0.36° C (Chin et al., 2017).
254

255 **3 Evaluating the Suitability of the MERRA2 GMI Simulation as a Training Dataset**

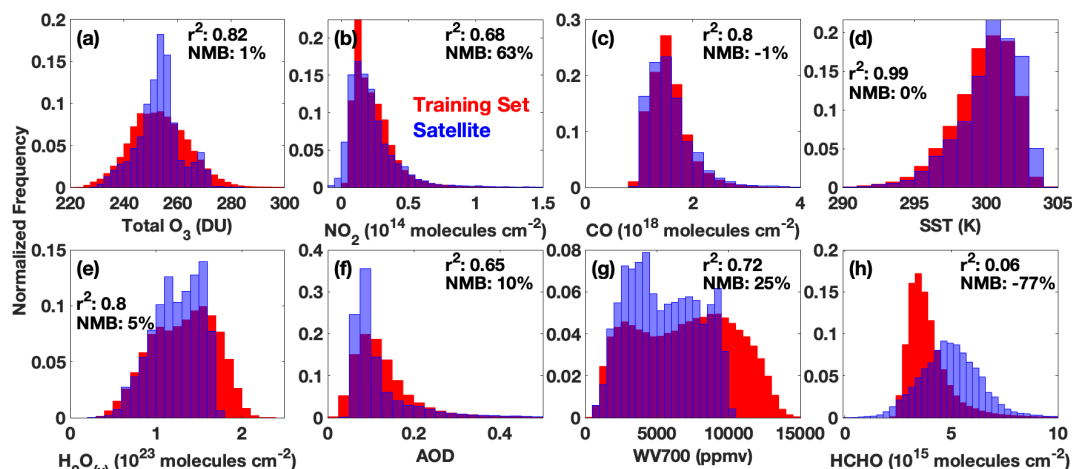

256 Before generating the GBRT model to predict TCOH, we first demonstrate that the MERRA2 GMI
257 simulation is suitable to use as a training dataset. Because of the paucity of *in situ* observations of OH
258 over most of the globe, we necessarily use output from an atmospheric chemistry model to train the
259 machine learning model. The atmospheric chemistry model output must reasonably capture the
260 distribution, magnitude, and ENSO-related variability of OH and the drivers listed in Table 1, as GBRT
261 models are unable to extrapolate beyond the photochemical environments on which they are trained
262 (Anderson et al., 2022).
263

264 **3.1 Comparison of the Distribution and Magnitude of Simulated OH Drivers to Observations**

265 Simulated OH from MERRA2 GMI agrees with observations over the remote ocean within the
266 instrumental uncertainty. Anderson et al. (2021) compared MERRA2 GMI output to *in situ* observations
267 from the first two deployments of the Atmospheric Tomography mission (ATom), finding modest
268 correlation (r^2 values between 0.3 and 0.78 depending on the hemisphere and season) between

269 observations and the model. The average normalized mean bias was on the order of 20%, a slight high
270 bias but within the 2σ observational uncertainty of 35%. Agreement was highest in the remote
271 atmosphere, whereas the largest error was in regions of fresh, continental outflow off the coasts of
272 South America and New Zealand.
273

274
275 **Figure 1:** Comparison of the normalized distributions of the training dataset (red) for the February model and
276 satellite observations of the indicated species for February 2017 (blue). Purple indicates regions of overlap. We
277 use $\text{H}_2\text{O}_{(v)}$ at 700 hPa as an example for all $\text{H}_2\text{O}_{(v)}$ layers. Distributions of the other $\text{H}_2\text{O}_{(v)}$ layers are shown in Figure
278 S1. We also indicate the r^2 of the correlation between MERRA2 GMI output for February 2017 and the
279 corresponding satellite retrieval as well as the normalized mean bias of that output.

280 The simulation captures both the observed variability and the magnitude of the majority of GBRT model
281 inputs with reasonable fidelity, suggesting that the satellite retrievals highlighted in Section 2.2 are
282 suitable inputs for a machine learning model trained on MERRA2 GMI output (Fig.1). Figure 1 compares
283 the distribution of the February training dataset created from the MERRA2 GMI simulation for 2005 –
284 2019 to the satellite observations of the indicated species for February 2017, a month omitted from the
285 training dataset. Distributions of the remaining water vapor layers are shown in Figure S1. In addition,
286 correlations between observations and MERRA2 GMI output for February 2017 are shown, as an
287 example, in Figures S2 and S3. With the exception of HCHO, distributions of the species are similar
288 between the observations and MERRA2 GMI, with the training dataset encompassing the full range of
289 almost all species. A GBRT model trained on MERRA2 GMI will therefore likely not have to extrapolate
290 to photochemical environments on which it was not trained when applied to the satellite data. Further,
291 MERRA2 GMI total column O_3 , $\text{H}_2\text{O}_{(v)}$ column, AOD, CO, and SSTs are all highly correlated (r^2 of 0.65 or
292 higher) with their respective satellite observations, and biases are within 10%, on average. Anderson et
293 al. (2021) did show that MERRA2 GMI CO columns demonstrate biases of opposite sign in the Northern
294 and Southern Hemispheres, however.
295

296 Agreement between MERRA2 GMI and satellite observations for NO_2 , HCHO, and the $\text{H}_2\text{O}_{(v)}$ layers is
297 more variable than for the other species. While modeled NO_2 is moderately correlated with
298 observations ($r^2 = 0.68$) with relatively similar distributions, MERRA2 GMI has a NMB of 63%. This
299 disagreement is most pronounced at low column values, however, where observational uncertainty is
300 large. Further, Anderson et al. (2021) demonstrated distinct regions of bias in NO_2 related to biomass
301 burning and lightning emissions. Modeled HCHO, on the other hand, is not correlated with observations

302 and is biased low by -77%. Modeled water vapor layers are all modestly correlated with observations (r^2
303 of 0.64 or greater) but vary in their bias, with the 925, 850, 700, and 300 hPa layers biased within 30%
304 and the remaining layers biased up to 71%.

305
306 The satellite product is insensitive to the differences between the HCHO distribution of the satellite and
307 training dataset highlighted in Figure 1. To determine the effects of the difference in HCHO distribution,
308 we extended the training dataset to cover the full time period of the MERRA2 GMI simulation (1980 –
309 2019) and then subsampled the resultant data to match the satellite HCHO distribution. Extending the
310 training dataset to 1980 allows for the subsampled training dataset to have a similar size (~600,000
311 points) as the original training set. We then created a new machine learning model using this sub-
312 sampled dataset and calculated OH fields for Feb. 2017 using the satellite inputs from Table 1. We
313 compared this to the TCOH field calculated from a model using the original training dataset, finding
314 agreement within 5%. This uncertainty is small in comparison to that resulting from uncertainties in the
315 NO₂ and HCHO satellite retrievals discussed in Section 5.2. If the uncertainty of the satellite inputs
316 decreases, as retrievals and instruments improve, then it will become necessary to more closely align
317 the training and observed HCHO distributions.

318
319 Finally, because NO₂ and HCHO have the largest differences between satellite observations and the
320 training dataset, we trained a separate machine learning model to predict TCOH, omitting these two
321 species as inputs. When this model was evaluated using the independent MERRA2 GMI output
322 described in Section 4.1, the NRMSE was 10.1%, a more than factor of 2 degradation in performance as
323 compared to the baseline model. This suggests that omitting these species from the machine learning
324 model would result in a greater uncertainty in the final TCOH product than that which results from the
325 retrieval uncertainties and the potential discrepancies between observations and the training dataset.

326 327 **3.2 Evaluation of the simulated ENSO-related variability of OH drivers**

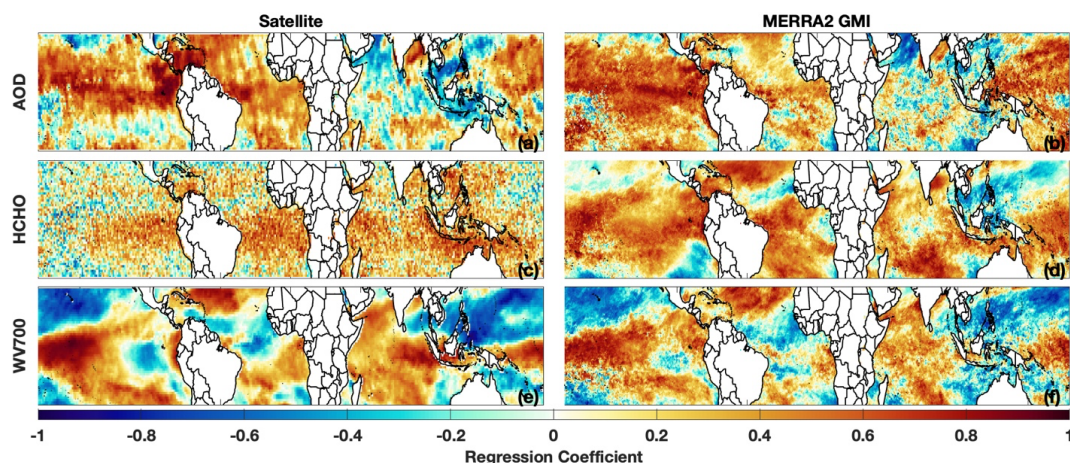

328 Because ENSO is the dominant mode of OH variability (Anderson et al., 2021; Turner et al., 2018), the
329 training dataset must also capture the ENSO-related variability of the GBRT model inputs. Anderson et
330 al. (2021) demonstrated that the correlation of columns of CO, H₂O_(v), and to a lesser extent NO₂, from
331 the MERRA2 GMI simulation with the Multivariate ENSO Index (MEI) (Wolter and Timlin, 2011) agreed
332 closely with correlations of the corresponding species for observations from MOPITT, AIRS, and OMI.
333 Unsurprisingly, based on the strong correlation and low bias of MERRA2 GMI SSTs with observations, the
334 simulation also captures the relationship between SSTs and ENSO. The simulation therefore sufficiently
335 captures the ENSO-related variability of these species to act as training data for the GBRT model. We
336 now evaluate this relationship for the remaining GBRT model inputs.

337
338 The MERRA2 GMI-simulated ENSO-related variability of AOD and the various water vapor layers also
339 agrees well with observations. Figures 2 and S4 show the correlation of AOD, HCHO, and the various
340 H₂O_(v) layers with the MEI for the satellite retrievals and MERRA2 GMI. MERRA2 GMI captures the
341 general distribution and magnitude of correlation between AOD and ENSO, despite the low optical
342 depths over much of the domain. There are some regional differences, however, particularly in the
343 eastern Southern Hemispheric Pacific. For the H₂O_(v) layers, the simulation underestimates the
344 magnitude of the correlation in some areas, but in general, there is excellent agreement for all layers
345 throughout the troposphere. This suggests that, despite the high bias discussed above, including the
346 H₂O_(v) layers could provide important, vertically-resolved information to the machine learning model.

347
348 Modeled accuracy of the HCHO-ENSO relationship is more difficult to assess. While both the OMI
349 retrieval and MERRA2 GMI demonstrate broad regions of anti-correlation between HCHO and ENSO, the

350 correlations with OMI HCHO are weaker and noisier than for the other satellite retrievals. Over much of
351 the domain, HCHO abundance is low, often at or below the retrieval detection limit, suggesting that the
352 HCHO retrieval might not be of sufficient quality to capture ENSO-related variability. We investigate the
353 impacts of the HCHO observational uncertainty in Section 5.
354

355 **Figure 2:** Distribution of the regression coefficient of a linear least squares fit of the indicated variable against the
356 MEI for the respective satellite retrieval (a, c, and e) and MERRA2 GMI (b,d, and f) for February. Regressions of
357 AOD are for 2010 to 2019, the years for which we have a one-degree, gridded satellite product, while HCHO and
358 water vapor 700 hPa are for 2005 to 2019. Satellite data are on a $1^\circ \times 1^\circ$ grid while model output is at the native
359 model resolution.
360

361 Finally, because we use total column O_3 as an input to the GBRT model, we do not evaluate the
362 relationship between ENSO and O_3 , as the stratosphere dominates the O_3 column and the ENSO-related
363 variability is mostly confined to the troposphere. Oman et al. (2013) found that a GEOS CCM simulation
364 and a combination of O_3 retrievals from the Microwave Limb Sounder (MLS) and the Tropospheric
365 Emission Spectrometer (TES) exhibited similar ENSO-related variability in the middle and upper
366 troposphere, demonstrating that simulations in the GEOS framework can capture this relationship. If a
367 TES-like satellite retrieval were currently available, it could be a valuable contributor to the GBRT model
368 described here, as it would provide vertically-resolved information about one of the primary drivers of
369 OH production.
370

371 **4 Tropical tropospheric column OH constrained with observations of its drivers**

372 We now demonstrate the ability of the GBRT model to determine TCOH. First, we show that the GBRT
373 model can reproduce MERRA2 GMI modeled TCOH from a year independent of the training dataset, a
374 so-called “hold out set” (Sect. 4.1). We then input satellite data from one month from each season into
375 the GBRT model to evaluate the realism of the calculated TCOH fields (Sect 4.2).
376

377 **4.1 Evaluation with an independent year from MERRA2 GMI**

378 The machine learning model is able to capture both the magnitude and the variability of TCOH across
379 each season when applied to MERRA2 GMI output from 2017, a year independent of the training
380 dataset. For August 2017 (Fig. 3b), the predicted TCOH is highly correlated with MERRA2 GMI (r^2 of
381 0.98). TCOH from the machine learning model agrees with the CTM simulation within 4.8% on average.
382 The overall normalized mean bias (NMB) is negligible (-0.1%), although there are some regions of

383 coherent bias (Fig. 3a). Results are similar for February, May, and October 2017 (Fig. S5). The
384 normalized root mean square error for each of these months is comparable to that found for a GBRT
385 parameterization of OH created with a similar methodology that included 27 inputs (Anderson et al.,
386 2022). This suggests that limiting inputs to model variables observable from space does not degrade the
387 ability of the machine learning model to predict TCOH. The low bias and high correlation between the
388 GBRT and MERRA2 GMI TCOH for all four months examined here also suggests that any potential
389 overfitting by the GBRT model is minimal.

390
391 **Figure 3:** Percent difference between TCOH predicted by the machine learning model and that from MERRA2 GMI
392 for August 2017, a month and year omitted from the training dataset (a). A regression of the machine learning TCOH
393 against MERRA2 GMI for the same month (b). The r^2 of a linear, least squares regression, along with the normalized
394 mean bias (NMB) and normalized root mean square error (NRMSE), are also indicated.

395 4.2 TCOH from satellite observations of its drivers

396 We now apply satellite data from the four months corresponding to the ATom campaign (Aug. 2016,
397 Feb. 2017, Oct. 2017, and May 2018) to the GBRT model to determine TCOH fields across the tropics.
398 More details about ATom as well as evaluation of the GBRT model with ATom observations are in
399 Section 5. We use the satellite observations listed in Table 1, all of which have been averaged to the
400 monthly scale and to a $1^\circ \times 1^\circ$ horizontal resolution. We include only grid boxes with observations for
401 all GBRT model inputs and where those observations are within the range of the corresponding inputs
402 from the training dataset. Because the satellite inputs for most species exclude grid boxes with a cloud
403 fraction greater than approximately 30%, the product presented here represents predominantly clear
404 sky conditions.

405
406 The GBRT model and multi-satellite inputs yield TCOH fields that are geophysically credible based on our
407 current understanding of OH photochemistry. Although the domain-wide average changes little with
408 season, with a minimum of 5.84×10^{12} molecules/cm² in May 2018 and a maximum of 6.35×10^{12}
409 molecules/cm² in August 2016, the spatial distribution varies widely among the four months (Fig. 4). In
410 both Feb. 2017 and Aug. 2016, TCOH minimizes in the winter hemisphere, consistent with lower OH
411 production due to low insolation. The reverse is true for the summer hemisphere. In addition, TCOH
412 maximizes in regions with strong continental outflow and along coastlines, regions likely to be impacted
413 by anthropogenic and biomass burning emissions of OH drivers.

414
415 In general, TCOH from the multi-satellite product differs in both magnitude and distribution from the
416 MERRA2 GMI simulation. For example, for Feb. 2017, mean MERRA2 GMI TCOH is 6.96×10^{12}
417 molecules/cm², 12% higher than the satellite product (Fig. S6). This is consistent with the comparison to
418 *in situ* observations discussed in Section 3.1 where MERRA2 GMI overestimates ATom observations by
419 ~20% and underestimates CH₄ lifetime, suggesting that the satellite product is again of reasonable
420 magnitude. While understanding the satellite/model differences is beyond the scope of this work, we
421 consider the variety in TCOH spatial distributions generated by the GBRT model to be promising. The
422 difference between the satellite-constrained product and MERRA2 GMI lends some confidence that the
423 GBRT model is not overfit or “tied” to geographic determiners in the training dataset, but rather, is

424 sensitive to variations in the chemical and dynamical drivers of OH. These results all suggest that the
425 methodology presented here can produce a reasonable satellite TCOH product in the tropics, with
426 values and distributions independent of the chemistry model used to create the GBRT model.
427

428
429 **Figure 4:** TCOH calculated with the machine learning model using satellite inputs for the months of each ATom
430 deployment: Feb. 2017 (a), May 2018 (b), Aug. 2016 (c), and Oct. 2017 (d). The mean, domain-wide TCOH value in
431 molecules/cm² for each month is also indicated.

432 5 Understanding and mitigating potential challenges in using this methodology to constrain TCOH

433 In this section, we outline possible limitations of the machine learning methodology and the current
434 observational network of the GBRT model inputs and provide potential means to mitigate these
435 limitations where necessary. In section 5.1, we discuss the current lack of sufficient in situ observations
436 to thoroughly evaluate the methodology, highlighting this point by validating the GBRT model with data
437 from the ATom campaign. In section 5.2, we investigate the impacts of random retrieval errors in
438 satellite retrievals on the TCOH product, while in section 5.3, we evaluate the impacts on TCOH when
439 using different satellite retrievals as inputs.

440

441 5.1 Insufficient in situ observations for thorough independent evaluation

442 While we demonstrated in Section 4.1 that TCOH calculated with the GBRT model agrees closely with a
443 hold-out set from MERRA2 GMI, it is also important to demonstrate that the GBRT model can replicate
444 observed TCOH from the actual atmosphere. Because the satellite TCOH product shown in Figure 4 is
445 monthly and at a 1° × 1° resolution, however, there are no observations with which to evaluate the
446 product. We can test the ability of the GBRT model to reproduce observed TCOH from field campaigns,
447 however, assuming there are concomitant observations of the input species listed in Table 1. The
448 additional need for tropospheric column values of many of these species severely limits the datasets
449 available for validation. To our knowledge, the ATom campaign is the only source of the required inputs
450 with enough observations to attempt a limited validation.

451

452 During ATom (Thompson et al., 2022), scientists measured a suite of air quality and climate relevant
453 trace gases and aerosols throughout the atmosphere above the remote Pacific and Atlantic. ATom took
454 place in four parts: ATom 1 (July – August 2016), ATom 2 (January – February 2017), ATom 3 (September
455 – October 2017), and ATom 4 (April – May 2018). During each deployment, flights consisted of a series
456 of ascents and descents across all tropical latitudes over the Pacific and Atlantic Oceans. This allows for
457 the calculation of tropospheric column content of the observed species and evaluation of the machine
458 learning model across most latitudes of our study domain and across all seasons.

459

460 To evaluate the GBRT model performance, we calculated TCOH using the GBRT model and observations
461 from the ATom deployments as inputs. We then compared the values to the observed OH columns. To

462 calculate the column values from the observations, we averaged data into 25 hPa pressure bins for each
463 ATom profile. We filled in missing data using a log-linear interpolation and then integrated the column.
464 Our analysis here includes only profiles with observations of all necessary species, that spanned at least
465 700 hPa, and where less than 25% of the pressure bin values were interpolated. We also omitted any
466 profiles that had pressure bins with negative OH values. In addition, we restrict our analysis to latitudes
467 within 25° of the equator and profiles conducted between 12:00 and 15:00 LST. Values for total column
468 O₃, AOD, and SSTs, for which there were no observations during ATom, were taken from the MERRA2
469 GMI simulation from the grid box closest to the center of the respective profile. The spatial distribution
470 of the valid ATom columns and the corresponding columns calculated with the GBRT model are shown
471 in Figure S7.
472

473
474 **Figure 5:** Regression of TCOH observed from the ATom deployments against that predicted from the GBRT model.
475 Error bars represent the 2 σ observational uncertainty as reported in Brune et al. (2020) and the GBRT uncertainty
476 described in Section 5.2. The r^2 of a linear least squares fit and the mean bias is also shown.

477 The GBRT model captures the variability of the observed TCOH although there is a consistent high bias.
478 When applied to all ATom deployments, predicted TCOH is correlated with the observations with an r^2
479 of 0.61 and a mean bias of 2.67×10^{12} molecules/cm² (Fig.5). Despite the high bias, many of the data
480 points agree within the combined modeled and observational uncertainty. The r^2 value is heavily driven
481 by one outlier from the ATom 2 campaign (open circle), which, when removed, increases the r^2 to 0.78.
482 Likewise, there is variability in the correlation among the deployments, ranging from 0.94 for ATom 1
483 and 3 to 0.57 for ATom 2. The level of agreement between observed and predicted OH, particularly for
484 ATom1 and 3, is comparable or better than that of other methods to infer OH from space. For example,
485 Pimlott et al. (2022) found an r of 0.78 ($r^2 = 0.61$) when estimating ATom OH using a steady state
486 approach, with r values ranging from 0.51 to 0.85 (r^2 of 0.26 to 0.72) for the different deployments. The
487 level of agreement we show here therefore demonstrates the validity of the machine learning method
488 to capture the variability of OH.

489
490 The source of the constant high bias, equal almost to a factor of 2 overestimate at the lowest column
491 values, is unclear, although there are multiple potential error sources. For example, a typical profile
492 taken during ATom spanned 300 – 400 km in latitude, disconnecting the top and bottom of the profile in
493 space. This is in contrast to the data used to train the model, which were vertical columns over one
494 location. This could lead to a degradation in model performance when applied to ATom, since the
495 columns are not directly analogous to the training dataset. These effects are likely limited because
496 ATom observations are in the remote atmosphere, where the spatial distribution of relevant species is

497 likely to be more homogeneous than over land. Likewise, in most cases, ATom columns do not span the
498 entire troposphere. While this is unlikely to consistently result in large errors, if a large fraction of the
499 tropospheric column of one input was outside the range of the ATom profile, this would likely cause
500 large errors in calculated TCOH.

501
502 Further, there is a known interference with the ATom NO₂ observations. Because of thermal
503 degradation of NO₂ reservoir species, such as organic nitrates and peroxyacetyl nitrate, in the
504 instrument inlet, NO₂ observations are likely biased high (Shah et al., 2022;Thompson et al.,
505 2022;Silvern et al., 2018). Recalculating the TCOH from ATom with NO₂ from a box model constrained
506 with NO observations with a setup similar to that described in Nicely et al. (2016) yields a similar
507 correlation (Fig. S8) as that shown in Figure 5 but with a lower slope, leading to underestimates at
508 higher column values. The uncertainty in observed NO₂ could explain some of the scatter seen in Figure
509 5. For more certain evaluation with observations, greater certainty in the in situ NO₂ observations is
510 needed. Although the in situ observations are insufficient to evaluate the absolute accuracy of the
511 product, the results presented here demonstrate that a machine learning model trained on data from a
512 CTM simulation can capture TCOH variability in the actual atmosphere.

514 **5.2 Impacts of uncertainties in the satellite retrievals on TCOH**

515 In the remote atmosphere where HCHO and NO₂ abundances are low, retrieval uncertainty of an
516 individual pixel for both species can be on the order of 100% and is often reflective of the *a priori*
517 (González Abad et al., 2015;Lamsal et al., 2021). Given the importance of these species to the GBRT
518 model as well as to OH chemistry, it is necessary to determine how the propagation of the retrieval
519 uncertainties from these and other model inputs impacts the predicted TCOH.

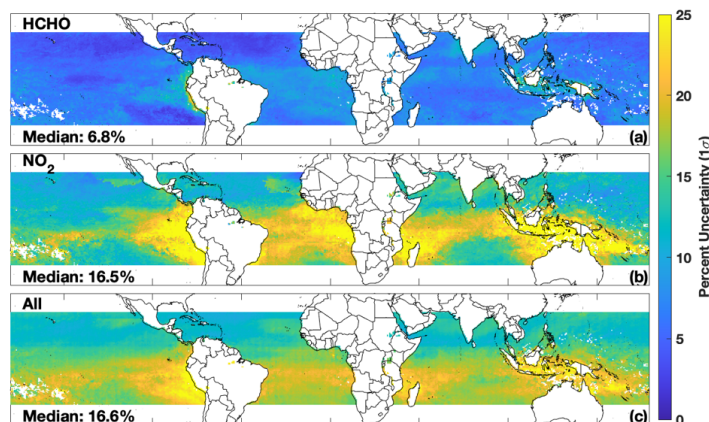

520
521 We determined the total uncertainty in TCOH from all inputs as well as the resultant uncertainty from
522 each individual input for Feb. 2017. First, we estimated an average retrieval uncertainty for each input
523 based on reported values in the retrieval files or from the literature (Table S1). We note that for NO₂
524 and HCHO we use a fit uncertainty for a single retrieval. Because we are using monthly-averaged data at
525 1° × 1° horizontal resolution, this likely significantly overestimates the actual uncertainty in these
526 retrievals as the random error from individual pixels will tend to cancel when averaged over such large
527 and spatial temporal scales. Our results are therefore an upper bound on the estimated TCOH
528 uncertainty.

529
530 Next, for each grid box and model input, we created a Gaussian distribution of 2000 values with the
531 modeled value for Feb. 2017 as the mean and the estimated uncertainty as the standard deviation. For
532 each input, we then ran the GBRT model 2000 times to create a distribution of predicted TCOH values
533 for each grid box. The normalized uncertainty in TCOH attributable to a given input is the ratio of the
534 standard deviation of the resultant distribution divided by the mean value. We repeated this process
535 individually for all inputs. In addition, to estimate a total uncertainty in TCOH, we varied all inputs
536 simultaneously with the same Gaussian distributions described above.

537
538 Uncertainty from the NO₂ retrieval, and to a lesser extent HCHO, dominates the total uncertainty in the
539 TCOH product but is of a magnitude comparable to that of in situ OH observations. Median TCOH 1σ
540 uncertainty resulting from NO₂ is 16.5%, with maxima in the remote atmosphere in regions where NO₂
541 columns are low. Median uncertainty in TCOH resulting from HCHO is 7%, averaged over the study
542 domain, despite the large uncertainty in the HCHO retrieval itself. In contrast to NO₂, uncertainties
543 maximize in regions with higher HCHO columns (Fig. 6), although this is likely an overestimate as the
544 retrieval uncertainty for these columns is lower than in the more remote atmosphere. In comparison,

545 median TCOH uncertainties resulting from other inputs are 2.9% or less (Figs. S9 and S10). Total TCOH
546 uncertainty is 16.6% and is dominated by the NO₂ uncertainty.
547

548 **Figure 6:** Normalized 1σ uncertainty in the satellite TCOH product due to uncertainties in the HCHO (a) and NO₂
549 (b) retrievals. The combined uncertainty from all input species is shown in panel c.
550

551 These results demonstrate that the satellite retrieval inputs to the machine learning model are of
552 sufficient quality to produce a meaningful TCOH data product when averaged over large spatial and
553 temporal scales. The 2σ uncertainty in TCOH resulting from the uncertainties in these retrievals is on
554 the order of that reported for in situ OH observations (Brune et al., 2020). As discussed earlier, this is
555 also likely an upper bound on the uncertainty from random retrieval errors, and uncertainties could be
556 reduced through further averaging, although at the expense of reduced spatial and temporal resolution.
557 Improving the satellite retrievals of NO₂ and HCHO in the remote atmosphere, using retrievals with less
558 noise over the remote atmosphere such as HCHO from the Ozone Mapping and Profiler Suite (OMPS)
559 (González Abad et al., 2016), or incorporating data from satellites with higher resolution, such as
560 TROPOMI (Tropospheric Monitoring Instrument), could also reduce the uncertainty in their retrievals
561 and thus in TCOH. As discussed in the next section, however, systematic biases between satellite
562 retrievals can also lead to uncertainties in the TCOH.
563

564 5.3 Sensitivity of TCOH to different satellite retrievals of GBRT inputs

565 The satellite retrievals listed in Table 1 provide the benefit of a long record, with data from most
566 retrievals available from at least 2005 to the present. Such a rich dataset would allow for long-term
567 trend analysis of TCOH. These instruments are near the end of their life cycle, however, so it is
568 instructive to see how retrievals from newer satellites impact the predicted TCOH from the GBRT model.
569 In addition, although these newer satellites, such as TROPOMI, have a significantly shorter observational
570 record than those in Table 1, TROPOMI also has finer spatial resolution and the added advantage of
571 providing retrievals for CO, NO₂, O₃, HCHO, and H₂O_(v). Using retrievals of multiple species from the
572 same instrument could negate errors resulting from differences in viewing geometry as well as from
573 overpass time. Here, we investigate the effects of applying retrievals from TROPOMI to the machine
574 learning model and compare them to the results from the product described in Section 4, highlighting
575 potential impacts resulting from instrumental differences as well as those resulting from differences in
576 retrieval algorithms. The results emphasize the need for thorough retrieval validation in the remote
577 atmosphere, particularly of NO₂.
578

579 5.3.1 Description of TROPOMI

580 TROPOMI, a successor instrument to OMI, is a spectrometer covering portions of the ultraviolet, visible,
581 and infrared spectrum (Veefkind et al., 2012). It is located onboard the Sentinel 5 Precursor satellite,
582 which is polar orbiting and has a local overpass time of approximately 13:30. Horizontal resolution for
583 the month examined here (May 2018) is $7 \text{ km} \times 3.5 \text{ km}$ at nadir. We have gridded the Level 2 product
584 for each species to a $1^\circ \times 1^\circ$ resolution and averaged the data to the monthly scale, applying the
585 recommended quality flags and filtering for cloud fraction greater than 30%.

586
587 We use two different retrievals of TROPOMI NO_2 for this analysis. First, we use the KNMI (Royal
588 Netherlands Meteorological Institute) NO_2 retrieval (van Geffen et al., 2020), which is based on the
589 DOMINO (Dutch OMI NO_2 product) retrieval developed for the OMI instrument. Wang et al. (2020)
590 found that this retrieval was biased high when compared to ship-based observations from a MAX-DOAS
591 instrument over the remote oceans. In addition, we use the MINDS (Multi-Decadal Nitrogen Dioxide
592 and Derived Products from Satellites) retrieval, which uses the same algorithm as for the OMI product
593 described in Section 2 (Lamsal et al., 2022). This retrieval has not been evaluated in the remote tropics.

594
595 We also use TROPOMI retrievals of HCHO, $\text{H}_2\text{O}_{(\text{v})}$, total column O_3 , and CO. The HCHO retrieval (De
596 Smedt et al., 2018) was found to have a 30% low bias with respect to an OMI retrieval using the same
597 algorithm due to differences in cloud processing (De Smedt et al., 2021). While evaluation in the remote
598 tropics is limited, the TROPOMI retrieval does overestimate HCHO in polluted regions (De Smedt et al.,
599 2021) when compared to ground-based observations. The TROPOMI $\text{H}_2\text{O}_{(\text{v})}$ (Chan et al., 2022) retrieval
600 has a slight dry bias with comparison to other satellite products, while the total column O_3 retrieval
601 (Garane et al., 2019) agrees within 0 – 1.5% with ground-based observations. Finally, the CO retrieval
602 (Borsdorff et al., 2019) agrees with MOPITT over the oceans within 3% on average (Martínez-Alonso et
603 al., 2020). TROPOMI does not have an equivalent retrieval of the AIRS $\text{H}_2\text{O}_{(\text{v})}$ layers.

605 5.3.2 TROPOMI data applied to the GBRT model

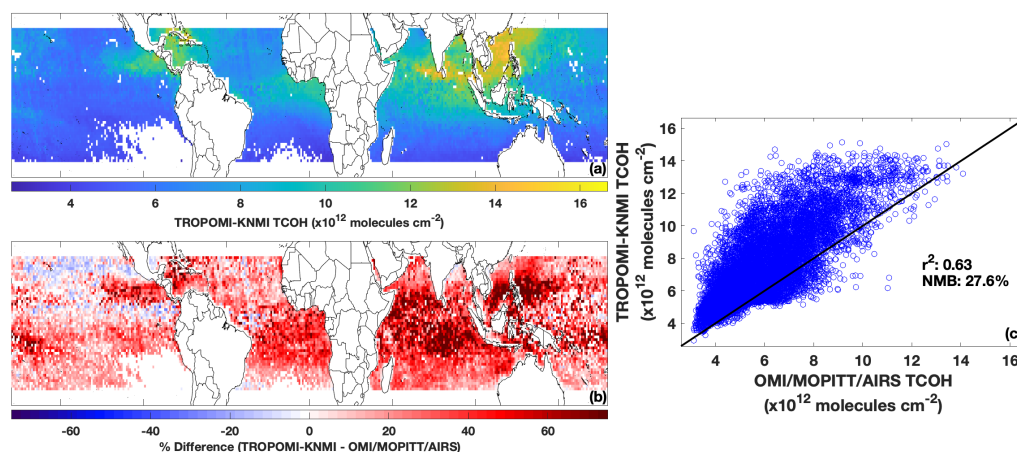

606 First, we calculate TCOH for May 2018 using inputs from TROPOMI. We trained a separate machine
607 learning model using all inputs from Table 1 except the water vapor layers, for which there are no
608 TROPOMI retrievals. Removal of the layers from the machine learning model does not significantly
609 degrade performance. For example, for May 2017, removing the $\text{H}_2\text{O}_{(\text{v})}$ layers from the model, increases
610 the NRMSE from 5.34% to 5.73% when applying the GBRT model to the hold out set. For this new
611 model, we then calculate TCOH using TROPOMI data, including the KNMI NO_2 retrieval. For SSTs and
612 AOD, we use the MUR and MODIS products respectively. While TROPOMI does have an aerosol
613 product, the UV aerosol index, the corresponding output from the MERRA2 GMI simulation is
614 unavailable. We refer to this as the TROPOMI-KNMI product. We have also calculated TCOH using the
615 satellite retrievals in Table 1, except for the water vapor layers, using this GBRT model, and refer to that
616 as the OMI/MOPITT/AIRS product.

617
618 TCOH from the TROPOMI-KNMI product are biased high with respect to those from the
619 OMI/MOPITT/AIRS product. Figure 7 shows TCOH calculated from the TROPOMI-KNMI product as well
620 as the percent difference between the two products. While there is modest correlation between the
621 two ($r^2 = 0.63$), the TROPOMI product is 27.6% higher than the multi-satellite product, with
622 overestimates across almost the entire domain. Differences between the products are most
623 pronounced in the Indian Ocean and off the coasts of Indonesia and the Philippines.

624
625 In general, observations from TROPOMI agree with those from the satellites in Table 1, with the
626 exception of NO_2 and HCHO. Ozone, $\text{H}_2\text{O}_{(\text{v})}$, and CO from TROPOMI are highly correlated (r^2 of 0.85 or

627 higher) with their respective retrievals from the OMI/MOPITT/AIRS product, with a modest high bias
628 (less than 10%) in each case (Fig. S11). Note that we do not seek to identify the more accurate retrievals
629 here; we are reporting the bias with respect to the satellite products listed in Table 1 because those
630 retrievals underlie the TCOH product. TROPOMI NO₂ and HCHO, on the other hand, are systematically
631 biased with respect to their respective OMI products, with a distinct high bias in KNMI-NO₂ (145%) and
632 low bias in HCHO (20%). The higher TCOH from the TROPOMI product is consistent with the increase in
633 NO₂, which would lead to higher secondary production of OH. Further, while TROPOMI KNMI-NO₂ is
634 modestly correlated with OMI NO₂ ($r^2 = 0.61$), TROPOMI and OMI HCHO are not correlated ($r^2 = 0.23$),
635 highlighting the difficulty of the HCHO retrieval.
636

637
638 **Figure 7:** TCOH for May 2018 determined using TROPOMI inputs, including the KNMI NO₂ retrieval (a). The
639 difference between the TROPOMI and multi-satellite product is shown in (b). Panel (c) shows the regression of
640 TCOH calculated from TROPOMI against that calculated from retrievals from MOPITT, OMI, and AIRS.

641 NO₂ drives the differences between the two TCOH products. To determine the impacts of the different
642 TROPOMI inputs on the TCOH product, we individually swapped each TROPOMI input into the
643 OMI/MOPITT/AIRS product, replacing the corresponding input from Table 1. We then determined the
644 difference in TCOH from the OMI/MOPITT/AIRS product that does not include TROPOMI. While this
645 method will not yield the exact contribution from a particular retrieval because of the non-linear nature
646 of OH chemistry, it does yield information about the relative importance of each species. Swapping in
647 TROPOMI CO, H₂O_(v), and O₃ changed TCOH by less than 2%, while using TROPOMI HCHO increased
648 TCOH by 3%. In contrast, TROPOMI NO₂ increased TCOH by 29%, showing that the high bias in the
649 TROPOMI TCOH product is dominated by differences in NO₂.

650
651 The increased TCOH in the TROPOMI product likely results from a combination of differences in the NO₂
652 retrieval algorithm as well as instrumental differences. Comparison of the KNMI and MINDS retrievals
653 illustrate this point. When compared to OMI, the MINDS NO₂ retrieval has a NMB of 58% for May 2018,
654 as compared to a NMB of 145% for the KNMI retrieval. The closer agreement is unsurprising since the
655 MINDS NO₂ uses the same retrieval algorithm as for OMI. Substituting the MINDS NO₂ as an input to the
656 TROPOMI product (TROPOMI-MINDS product) reduces the bias with respect to the OMI/MOPITT/AIRS
657 product to 18% (Fig. S12). While this is an improvement in agreement, the differences in TCOH as well
658 as the lack of change in r^2 value still suggest that differences between OMI and TROPOMI unrelated to
659 the retrieval algorithm account for some of the discrepancy.

660

661 The results here demonstrate the sensitivity of the methodology to any systematic bias in the input
662 retrievals. As with the random error analysis, the level of uncertainty introduced by these biases is low
663 enough to allow for a meaningful OH product. Despite these differences, the methodology to determine
664 TCOH using machine learning that we have presented here still captures the variability in TCOH,
665 consistent with the ATom evaluation outlined in Section 5.1. To reduce the uncertainty of TCOH, better
666 evaluation of NO₂ in the remote atmosphere is needed to determine which retrievals, if any, are
667 accurate.

668

669 **6 Discussion and recommendations for future observations**

670 The method of estimating clear-sky TCOH presented here has the potential to increase our
671 understanding of the atmospheric oxidation capacity. Because of the long record of observations from
672 MOPITT, OMI, AIRS, and MODIS, we can calculate tropical TCOH from 2005 to the present, and since the
673 methodology is not constrained to a particular satellite, newer satellite missions could extend the
674 dataset beyond the end of these instruments' lifetimes. In addition, this methodology will provide sub-
675 hemispheric information on OH variability, supplementing information available from MCF inversions.

676

677 The methodology could be expanded to the extra-tropics and over land, allowing for global constraints
678 on OH. This will likely require additional satellite retrievals, like that of isoprene (Wells et al., 2020), in
679 regions with more complex VOC chemistry than in the remote atmosphere. Expanding this product
680 beyond the tropics could increase understanding of global CH₄, CO, and VOC trends and variability and
681 allow for a wider range of satellite retrievals as inputs. For example, geostationary air quality satellites
682 such as TEMPO (Tropospheric Emissions: Monitoring of Pollution), scheduled to be launched in 2023,
683 will provide retrievals of most of the necessary inputs to the machine learning model, allowing for the
684 understanding of diurnal variability in TCOH and potentially in the diurnal variability of ozone production
685 (Zhu et al., 2022b).

686

687 A similar methodology could likely be used to determine OH at different layers of the atmosphere.
688 Because CH₄ loss is not evenly distributed throughout the tropospheric column, vertically resolved OH
689 would better help inform this process. While column inputs, such as those discussed here, could be
690 used, the inclusion of vertically resolved satellite retrievals, such as the AIRS H₂O_(v) layers, would provide
691 additional information. Tropospheric O₃ at different atmospheric layers, such as that previously
692 provided by the TES satellite, could also be invaluable here, as O₃ is a large driver of primary OH
693 production.

694

695 Satellite-derived OH would also provide a much-needed, observational constraint on OH variability in
696 global chemistry models. Because the methodology can capture variability in TCOH of both
697 observations and 3-dimensional model output, TCOH trends from a satellite-constrained product could
698 be used to evaluate modeled trends and as well as the spatial variability resulting from events like ENSO.
699 While the satellite-derived OH could not explicitly indicate the cause of differences, the spatial
700 distribution of the differences as well as differences in observed and modeled machine learning model
701 inputs could indicate potential dynamical or emission sources of error in the 3D model.

702

703 Further, the combination of the satellite-derived OH and the machine learning model could help identify
704 the impacts of any diagnosed errors in emissions inventories as well as the impacts of unexpected
705 events, such as COVID-19-related shutdowns, on TCOH. For example, if there are significant
706 discrepancies between observed and modeled NO₂ in a specific region of the atmosphere, the satellite
707 NO₂ could be scaled to more closely match the 3D model values and then be input into the machine

708 learning model. The difference in TCOH would then indicate the relative impact of the model error,
709 serving as a computationally efficient way to identify the impacts of these errors on the atmospheric
710 oxidation capacity. A similar methodology could be used for unexpected events that significantly impact
711 emissions of OH drivers, allowing for quick determination of their potential impacts on the atmospheric
712 oxidation capacity before emissions inventories could be revised.

713

714 While we have shown that the methodology captures the variability of OH, it is unclear whether a bias in
715 magnitude when compared to observations of OH results from GBRT model deficiencies or structural
716 differences between the *in situ* observations and the training dataset. Additional field campaigns with
717 observations of OH and the GBRT model inputs would allow for a more thorough evaluation of both the
718 OH product and the methodology itself. Such a field campaign would need to provide complete
719 tropospheric columns of all species and cover less horizontal distance than the ATom profiles (e.g. from
720 spiral flight patterns). In situ observations of NO₂ without significant interference from NO_x reservoir
721 species are also needed to reduce uncertainty. Alternatively, NO₂ and other species could be measured
722 through aircraft-based remote sensing. Finally, repeated sampling over the same locations for multiple
723 days within a defined area would allow for meaningful statistical analysis while also allowing for the
724 comparison of TCOH columns calculated from satellite observations.

725

726 Finally, accuracy of the TCOH product is dependent on the accuracy of the satellite retrievals input into
727 the machine learning model, with the NO₂ retrieval having the largest effect. To reduce the uncertainty
728 of the TCOH product, more information about the accuracy of individual NO₂ retrievals is required.
729 Currently, there is little validation of OMI and TROPOMI NO₂ retrievals in the remote, tropical
730 atmosphere, so it is difficult to assess, which retrievals, if any, are correct. Even retrievals of TROPOMI
731 and OMI made with the same algorithm show differences, suggesting that instrumental differences
732 could also affect the results. Future satellite missions should focus on trying to reduce the uncertainty
733 in NO₂ retrievals, both through improvements in instrument design and algorithm development.

734

735 **7 Data Availability**

736 Output from the MERRA2 GMI simulation are publicly available at [https://acd-
737 ext.gsfc.nasa.gov/Projects/GEOSCCM/MERRA2GMI/](https://acd-ext.gsfc.nasa.gov/Projects/GEOSCCM/MERRA2GMI/) (NASA Goddard Space Flight Center, 2022). All
738 satellite products, except for TROPOMI water vapor, are available at [https://disc.gsfc.nasa.gov \(GES
739 DISC, 2022\)](https://disc.gsfc.nasa.gov/GESDISC). Data from the ATom campaign are located at <https://daac.ornl.gov> (Wofsy et al., 2021).

740

741 **8 Author contributions**

742 DCA wrote the manuscript, performed the data analysis, and created the GBRT model. DCA, BND, JMN,
743 and MBFC developed the idea for the methodology. SAS performed three-dimensional modeling for the
744 work. JMN provided advice on machine learning. JL helped perform data analysis. All authors helped
745 develop ideas for the analysis and contributed to the manuscript.

746

747 **9 Competing Interests**

748 BND is a member of the editorial board of Atmospheric Chemistry and Physics. The peer-review process
749 was guided by an independent editor, and the authors also have no other competing interests to
750 declare.

751

752 **10 Financial support**

753 This research has been supported by the National Aeronautics and Space Administration (NASA)
754 Atmospheric Composition Campaign Data Analysis and Modeling (ACCDAM) program (grant no.
755 80NSSC21K1440).

756

757 **11 Acknowledgements**

758 The authors wish to thank Lok Chan and Diego Loyola for use of the TROPOMI water vapor product.

759
