ABSTRACT

Oxygenated organic molecules (OOMs) are dominated by the N-containing species in polluted urban environment. As N-containing OOMs, especially those with more than one nitrogen atoms, prevailed in the high m/z range (m/z > 350Th), unambiguous identification of N-containing OOMs is highly desirable for understanding of their formation processes, precursors and influencing factors. To achieve this, we applied an ultra-high-resolution chemical ionization-orbitrap (CI-Orbitrap) in a field campaign and found that OOMs contain one (1N-OOMs), two (2N-OOMs) and three (3N-OOMs) nitrogen atoms respectively comprised 50%, 26% and 4% of total OOMs. More interestingly, the fraction of 2N-OOMs increased with the increase of carbon number (nC) and were dominated by the ones derived from aliphatic precursors (2N-OOM_{Ali}, 64.2%), indicating the importance of multistep oxidation. Plausible precursors of 2N-OOMs were aliphatics (2N-OOM_{Ali}, 64.2%), aromatics (2N-OOM_{Aro}, 16%), and monoterpenes (2N-OOM_{MT}, 15.4%). The absolute concentrations of 2N-OOMs were greatly affected by the pollution level for the most cases. The 2N-OOM_{Ali} was the most abundant 2N-OOMs and its fraction even increased in the polluted day with enhanced proportion of the ones with nC>10. While 2N-OOM_{Ali} and 2N-OOM_{Aro} were dominated by daytime photochemical production, nighttime NO₃-initiated oxidation played a comparable role as the daytime photochemistry in the formation of 2N-OOM_{MT}. 2N-OOM_{Aro} were of highest oxygenation level, followed by 2N-OOM_{MT} and 2N-OOM_{Ali}, which were affected by photochemistry and NO_x concentrations. These results highlight the significant formation of 2N-OOMs and the influencing factors, on their formation in polluted urban environment, where various VOC precursors and atmospheric oxidants present.

37 **1. Introduction**

38 Secondary organic aerosol (SOA) accounts for a significant fraction of particulate matters (Donahue
39 et al., 2009; Ehn et al., 2014; Hallquist et al., 2009; Jimenez et al., 2009). Volatile organic compounds
40 (VOCs) and their oxidation products, *i.e.*, OVOCs, are important precursors of SOA in the atmosphere
41 (Atkinson and Arey, 2003; Bianchi et al., 2019; Ehn et al., 2014; Nie et al., 2022). The N-containing
42 oxygenated organic molecules (OOMs) have been identified as the important products upon VOC
43 oxidation. Especially at high NO_x levels, these products become more dominant while the others
44 (*i.e.*, alcohols, hydroperoxides and RO₂ cross-reaction products) are likely suppressed (Bianchi et al., 2019;
45 Zhao et al., 2018). The nitrogen atoms in OOM molecules are assumed to be mainly associated with nitrate
46 group (-ONO₂) formed from bi-molecular reaction between RO₂ radical and NO. Field measurements also
47 observed that up to 77 % of molecules in organic aerosol (OA) contain nitrate functional groups under
48 different atmospheric conditions (Ditto et al., 2020; Kenagy et al., 2021; Kiendler-Scharr et al., 2016; Lee
49 et al., 2016; Ng et al., 2017; Lin et al., 2021; Rollins et al., 2013; Xu et al., 2015; Ye et al., 2021; Yu et al.,
50 2019).

51 The N-containing OOM molecules can be classified into 1N-OOMs, 2N-OOMs, and 3N-OOMs,
52 according to the number of N atoms in the molecule. The chemical composition of N- containing OOMs
53 is determined by their precursors, formation pathways and NO_x level in the atmosphere (Bianchi et al.,
54 2019; Ehn et al., 2014; Nie et al., 2022; Pye et al., 2019; Riva, 2016; Yan et al., 2016). Recent observations
55 in megacities of China indicated that 2N-OOMs accounted for significant fractions (about 30-33%) among
56 total N-containing OOMs besides 1N-OOMs (66-70%) due to the high NO_x concentrations in polluted
57 urban environment (Nie et al., 2022; Yan et al., 2021). Some laboratory studies also proposed that the
58 potential formation pathways of 2N-OOMs, such as the multiple-step OH oxidation (Garmash et al., 2020)
59 or the NO₃-initiated oxidation followed by NO termination (Kiendler-Scharr et al., 2016; Liebmann et al.,
60 2019), suggesting the increased importance of multi-step bimolecular oxidation in the formation of 2N-
61 OOMs. On the other hand, it was also found that the formation of 2N-OOMs showed the clear preference
62 of specific precursors compared to 1N-OOMs, *i.e.*, significantly higher branch ratio of 2N-OOMs from

63 aliphatic hydrocarbons than those from aromatics (Nie et al., 2022), suggesting considerable difference
64 from 1N-OOMs in terms of formation pathway. Determining the formation pathway of N-containing
65 OOM molecules, especially those containing two to three nitrogen atoms, in real atmosphere, is
66 challenging. Identification of their chemical compositions in molecular level is the key for advancing our
67 understanding in the precursor, formation and sources of N-containing OOMs in polluted atmosphere,
68 where thousands of oxidation products exist and evolve constantly.

69 Traditionally, a chemical ionization atmospheric pressure interface time-of-flight mass spectrometer
70 (CI-APi-TOF) has been used to measure the gaseous OOMs (Berndt et al., 2016; Ehn et al., 2014; Jokinen
71 et al., 2014; Rissanen et al., 2014). Using a CI-APi-TOF, increasing number of studies have been reporting
72 the formation of OOMs through the oxidation of various VOC precursors in chamber or flow tube (Berndt
73 et al., 2016, 2018; Ehn et al., 2014; Garmash et al., 2020; Jokinen et al., 2014, 2015; Rissanen et al., 2014;
74 Wang et al., 2020; Zhao et al., 2018). While 2N-OOMs in real ambient almost exclusively located in high
75 m/z (mass-to-charge) range (*i.e.*, 300 - 500 Th), a CI-APi-TOF with highest mass resolving power of
76 12,000 (m/Δm, in full width at half maximum) at m/z=200 Th and above, can hardly identify the molecular
77 compositions of 2N-OOMs unambiguously. This is because low mass resolving power imposes significant
78 uncertainties on separating overlapping peaks, which increases rapidly with increasing m/z and decreasing
79 mass resolving power. Taken the integer m/z of 342 as an example, multiple peaks overlap at this nominal
80 mass, *i.e.*, C₇H₈O₁₀N₂(NO₃)⁻ (342.0057 Th), C₈H₁₂O₉N₂(NO₃)⁻ (342.0421 Th), C₉H₁₆O₈N₂(NO₃)⁻
81 (342.0785 Th), C₁₀H₂₀O₇N₂(NO₃)⁻ (342.1149 Th). The adjacent peaks are of mass differences (Δm) of
82 0.0364 and a good peak separation of these peaks (4σ) requires mass resolving power of at least 16,000.
83 Therefore, development and application of mass spectrometry techniques with extremely high
84 performance in detection limit, time resolution, and mass resolving power, are highly desirable.

85 To achieve accurate identification of molecular formula from the extremely complex mass spectra, a
86 CI (nitrate) inlet had also been coupled to an orbitrap mass spectrometer (CI-Orbitrap) to measure the
87 OOMs in ultra-high mass resolving power (m/Δm> 100,000 at m/z=200-500 Th) (Riva et al., 2019a;
88 Zhang et al., 2022). The ultra-high mass resolving power of CI-Orbitrap will undoubtedly provide

89 significant improvements in molecular identification, separation, and quantification. Herein, we applied a
90 CI-Orbitrap in a field campaign for the measurements of OOMs, with a special focus on 2N-OOMs, in
91 molecular level in urban Shanghai. The site represents a typical eastern Chinese megacity characterized
92 by intense human activities, multiple anthropogenic emissions and high NO_x concentrations. Based on the
93 measurement results as well as our current knowledge on N-containing OOM formation, we classify the
94 observed 2N-OOMs into different precursor groups and explore the potential influencing factors on their
95 formation. Furthermore, supported by positive matrix factorization (PMF), sources and gas-phase
96 oxidation processes for 2N-OOM formation in urban Shanghai were identified.

97 **2. Ambient measurement and methodology**

98 **2.1 Measurements**

99 The field campaign was carried out from 31th October to 18th November, 2020 on the top-floor of an
100 8-story building in Shanghai Academy of Environmental Sciences (31°18' N, 121°43' E, Figure S1), which
101 sits in a densely populated region surrounded by commercial properties and residential dwellings without
102 significant industrial sources nearby. The site can represent a typical urban area of Shanghai affected by
103 severe local emissions from vehicular traffic, commercial, and residential activities. Our campaign was
104 carried out in autumn which represents a typical transition period from strong photochemistry in summer
105 to intense regional transport in winter. At times, air masses transported from the neighboring provinces or
106 even further from the northern China can also affect the air quality of the site.

107 The 2N-OOMs as well other OOMs molecules were measured in real time with a nitrate-Orbitrap.
108 The operation of nitrate-Orbitrap has been detailed in previous studies as well as in one of our companion
109 studies (Zhang et al., 2022), thus is only briefly described here. Ambient air was drawn into the ionization
110 source through a 1m stainless-steel tube (3/4 inch). The reagent ion was produced by passing nitric acid
111 in sheath flow (20L/min) into a PhotoIonizer (Model L9491, Hamamatsu, Japan) and was then introduced
112 into a co-axial laminar flow reactor, in which the reagent ions interact with the air samples. The charged
113 species were detected by an orbitrap mass analyzer with a mass resolving power of about 140,000. Mass-
114 dependent transmission calibrations was also performed using a depletion method (Heinritzi et al., 2016).

115 Other ancillary measurements, including the PM_{2.5} concentrations, trace gases (SO₂, O₃ and NO_x), volatile
116 organic compounds, as well as meteorological parameters (wind direction and speed, solar radiation, etc.)
117 were detailed in Supporting Information (SI-1). An overview of the measurement data, illustrating the air
118 quality as well as the meteorological conditions during the campaign, is provided in SI-2 and Figure S2.

119 **2.2 Data analysis of nitrate CI-Orbitrap**

120 The raw mass spectra were first extracted by Orbitool (Cai et al., 2020) and the molecular information
121 was then achieved by applying a homemade toolkit based on the MATLAB software. The toolkit drew on
122 the idea from “tofTools” package which is used for analyzing the mass spectral data obtained from the
123 TOF analyzer, such as nitrate CI-API-TOF (Junninen et al., 2010). The concentrations of the detected
124 species are then determined as follows:

$$125 \quad [X] = \frac{i[X^-]}{NO_3^- \cdot (HNO_3)_{0-2}} \cdot C \quad (1)$$

126 where $i[X^-]$ is the transmission-corrected signal intensity of ion X in unit of counts per second (cps), C
127 represents the calibration factor. C is determined from the collision frequency of target species with the
128 nitrate ions (cluster) during its residence in the charger, taking into account of the losses onto the walls of
129 the reactor and the tube (Eq. 2):

$$130 \quad C = C_{H_2SO_4} = \frac{1}{k_{ion} \times RT \times f_{inlet}} \quad (2)$$

131 where k_{ion} is the ion collision frequency in the range of $(1.7 - 2.3) \times 10^{-9} \text{ cm}^3 \text{ s}^{-1}$ (Ehn et al., 2014); RT is
132 the residence time in the charger and f_{inlet} represents the fractions of target species that passed through the
133 inlet.

134 Herein, we apply the C determined for sulfuric acid (H₂SO₄) of $3.4 \times 10^9 \text{ molecules cm}^{-3} \text{ ncps}^{-1}$ to
135 semi-quantify the concentrations of OOMs, which is widely used in previous studies (Ehn et al., 2014;
136 Yan et al., 2021; Yao et al., 2018). Among the low volatility vapors, it had been demonstrated that nitrate
137 ions exhibit highest charging efficiency toward H₂SO₄ (Ehn et al., 2014; Hyttinen et al., 2015, 2018; Riva
138 et al., 2019b). The estimated concentrations of OOMs thus can be considered as the lower limits with an
139 uncertainty of $\pm 50\%$ according to error propagation (Ehn et al., 2014). Positive matrix factorization (PMF)
140 was also performed for the measured species using Source Finder (SoFi, v6.3) based on Igor and run by

141 the multilinear engine (ME-2) as detailed in SI-S3 and Figure S3-S6 (Canonaco et al., 2013).

142 **3. Results and discussion**

143 **3.1 Chemical characteristic of OOMs**

144 In total, we have identified 562 OOMs, which concentrated in the nC range of 5 to 10, taking up 84.6%
145 of total OOMs during the whole campaign (unless otherwise stated, all the reported values hereafter were
146 corresponding to the average of the whole campaign). Possible precursors of C₅₋₁₀ OOMs include isoprene
147 (C₅), benzene/alkyl benzenes (C₆₋₁₀), aliphatic VOCs (C₅₋₁₀) and monoterpene (C₁₀) according to previous
148 studies (Bianchi et al., 2019; Nie et al., 2022). C_{≤4} OOMs only took up a small fraction of 6.7% among
149 total OOMs and were likely a result of the decomposition from OOMs with large carbon numbers as
150 suggested by one of our companion studies (Zhang et al., 2022). The rest 8.7% were C_{>10} OOMs which
151 accounted for a dominating fraction (70%, Figure S7) among the extremely low-volatility organic
152 compounds (ELVOC, C* < 3 × 10⁻⁵ µg m⁻³) based on a volatility parameterization proposed by Donahue
153 and co-workers (Donahue et al., 2011, 2012; Schervish and Donahue, 2020), and potentially poses larger
154 impacts on SOA formation owing to their lower volatility.

155 We further classified the detected OOMs into four groups based on the number of N atoms they
156 possessed, including non-nitrogen (0N-) OOMs, 1N-OOMs, 2N-OOMs, and 3N-OOMs. Their average
157 fractional contributions to total OOM concentrations as well as the carbon number (nC) distributions are
158 shown in Figure 1. We found 1N-OOMs dominated the total OOM concentration with an average fraction
159 of 50%, followed by 2N-OOMs (26%), demonstrating the dominance of N-containing OOMs among total
160 OOMs. The 3N-OOMs only took up a small fraction (4%) of total OOMs and the rest 20% was 0N-OOMs.

161 More interestingly, we found 1N-OOMs prevailed among the OOMs with nC ≤ 10, yet 2N-OOMs
162 dominated the C_{>10} OOMs (41.8-84.2%), suggesting the increased importance of multi-step bimolecular
163 oxidation in the formation of 2N-OOMs with nC > 10. We also note that the fraction of 2N-OOMs increased
164 stepwise with the increase of nC (Figure 1b) while 3N-OOMs don't exhibit a similar dependence. The
165 potential reason is that, with the increase of nC, on the one hand, more active sites are potentially provided
166 to promote the occurrence of multi-step oxidation, but on the other hand, the potential larger steric effect

167 can hinder multi-step oxidation. From our observation, these two factors lead an overall positive coupling
168 for 2N-OOMs, but result in a non-monotonic trend for 3N-OOMs. Furthermore, these 2N-OOMs with
169 $nC > 10$ had an average molecular composition of $C_{12.5}H_{22.7}O_{2.1}(NO_3)_2$. Assuming the nitrogen atoms are
170 only associated with nitrate group (-ONO₂), the mean double bond equivalent value (DBE) (Nie et al.,
171 2022; Xu et al., 2021) was 1.15 on the carbon skeleton, suggesting its origination from aliphatic
172 compounds, such as alkanes, alkenes, etc. (Gong et al., 2005; Mentel et al., 2015; Wang and Hildebrandt
173 Ruiz, 2018).

174 We thus further classified the 2N-OOMs to their possible VOC precursors following a recently
175 developed workflow proposed by Nie and co-workers, which is based on the up-to-date understanding of
176 VOC oxidation and molecular characters (*i.e.*, number of different elements, DBE) as well as PMF results
177 (Nie et al., 2022), *i.e.*, aromatics (2N-OOM_{Aro}), aliphatics (2N-OOM_{Ali}), and monoterpene (2N-OOM_{MT}).
178 Note that we group isoprene 2N-OOMs (2N-OOM_{Iso}) into 2N-OOM_{Ali} as well because of the low
179 concentration of isoprene in cold season. As a result, the average fractions of 2N-OOM_{Aro}, 2N-OOM_{Ali}
180 and 2N-OOM_{MT} among total 2N-OOMs were 16.0%, 64.2% and 15.3%, respectively (Figure 2),
181 suggesting significant contribution of aliphatic compounds to 2N-OOMs formation. Taken together, the
182 increased fraction of 2N-OOMs with the increase of nC and the dominant fraction of 2N-OOM_{Ali} highlight
183 the significant contribution of high-molecular-weight aliphatic precursors (*i.e.*, intermediate volatility or
184 semi-volatile organic compounds, I/SVOCs) to high-molecular-weight 2N-OOM formation, which were
185 potentially important SOA material. We thus focus our attention on the formation of 2N-OOMs in the
186 following sections.

187 **3.2 2N-OOM formation in PM episodes**

188 To investigate the formation mechanisms and factors that may affect the 2N-OOM formation, one
189 clean day (4th-5th November) and one polluted day (7th-8th November) based on the pollution levels, *i.e.*,
190 PM_{2.5} concentrations, were selected for further analysis. Since OOM formation is directly mediated by
191 photochemistry or nighttime chemistry, the clean and polluted cases were thus split into one clean daytime
192 case (CL_{day}), one clean nighttime case (CL_{night}), one polluted daytime case (PL_{day}) and one polluted

193 nighttime case (PL_{night}). Detailed information on durations, pollution levels, meteorological conditions
194 and 2N-OOM concentrations during these four cases were summarized in Table 1.

195 During the whole campaign, the concentrations of 2N-OOMs ranged from 1.1×10^6 to 42.0×10^6
196 molecule cm^{-3} as shown in Figure 2. We found the concentrations of 2N-OOMs in the polluted cases were
197 1.7-2.7 times higher than those in clean cases. Table 1 further indicates that the absolute abundances of
198 almost 2N-OOM classes were higher during the polluted cases as compared to clean case no matter in the
199 daytime or nighttime except for the daytime 2N-OOM_{Aro}. Specifically, 2N-OOM_{Ali} occupied the largest
200 fractions, which were even higher in polluted cases (66-66%) than those in clean cases (56-61%, Figure
201 2). Especially for the 2N-OOM_{Ali} with $nC > 10$, its concentration in polluted cases increased by a factor of
202 2.3-4.8 compared to the clean cases (Figure 3). From PMF analysis, we also identified a factor
203 characterized by a series of 2N-OOM_{Ali} (*i.e.*, $C_nH_{2n-2}O_8N_2$, $n=5-11$) as the fingerprint molecules (Table
204 S1). This factor tracks the $PM_{2.5}$ concentration well especially during PM episodes (Figure S8), likely due
205 to the availability of adequate aliphatic precursors during pollution episode. Furthermore, 2N-OOM_{Ali}
206 with $nC > 10$ presented both higher concentrations and fractions during daytime than nighttime cases
207 (Figure 3), suggesting that the photochemical formation of 2N-OOM_{Ali} prevailed compared to nighttime
208 formation. To compare CL_{night} and PL_{night} , it was also found that the pollution case would lead enhanced
209 importance of nighttime formation pathways of 2N-OOM_{Ali} with $nC > 10$.

210 We note that the fraction of 2N-OOM_{Ali} increased during CL_{night} primarily due to the more evident
211 decrease of 2N-OOM_{Aro} (Table 1), whose formation is dominated by photochemistry. On the other hand,
212 the decrease of 2N-OOM_{Aro} concentrations at PL_{night} was not as obvious as those on CL_{night} . Due to the
213 significant increase of 2N-OOM_{Ali} concentration, the fraction of 2N-OOM_{Aro} decreased in pollution cases,
214 but their absolute concentrations only had few changes in the daytime. 2N-OOM_{MT} showed significant
215 higher concentrations but similar fractions in polluted cases. On the other hand, equivalent or even slightly
216 higher concentrations during nighttime than those in daytime suggest the comparable importance of
217 nighttime chemistry in 2N-OOM_{MT} formation in contrast to 2N-OOM_{Ali} and 2N-OOM_{Aro}, which will be
218 discussed in later sections.

219 To summarize, the absolute concentrations of 2N-OOM were greatly affected by the pollution level
220 for the most cases. Both the concentrations and fractions of 2N-OOM_{Ali} were significantly promoted by
221 pollution condition, whereas the 2N-OOM_{Aro} were predominantly affected by photochemical production,
222 whose formation was less sensitive to pollution levels compared to 2N-OOM_{Ali} in the daytime. In contrast,
223 the absolute concentrations of 2N-OOM_{MT} were also significantly influenced by pollution levels but seem
224 not solely/almost depend on daytime/nighttime formation pathway. In addition, we note that both daytime
225 photochemistry and nighttime chemistry had profound effects on 2N-OOMs formation under different
226 pollution levels, presumably depending on availability of the precursors as well as the oxidants. We thus
227 focus our attention on the formation of 2N-OOMs during daytime versus nighttime in the following
228 sections.

229 **3.3 Daytime vs. nighttime formation of 2N-OOMs**

230 We thus investigate the effects of photochemistry and nighttime chemistry on the formation of
231 individual 2N-OOMs. While the former is dominated by OH radical oxidation, the latter involves NO₃
232 radical oxidation as well as reactions with ozone or other oxidants, *e.g.*, halogen. Herein, we use solar
233 radiation as a proxy of photochemical reactivity, and the concentrations of NO₃ radical were estimated
234 assuming that NO₃, NO₂ and N₂O₅ were under fast equilibration in troposphere (Brown and Stutz, 2012).
235 The correlation coefficients (Spearman type) between individual 2N-OOM molecules and solar radiation
236 ($R_{2N-OOMs-solar}$) or NO₃ radical ($R_{2N-OOMs-NO_3}$) derived from different precursors during the whole campaign
237 were shown in Figure 4a. It should be noted that the concentrations of 2N-OOMs and NO₃ radicals were
238 scaled with the boundary layer height before calculating the correlation coefficients here and below for
239 correcting the effects of meteorological dilution.

240 Both 2N-OOM_{Aro} and 2N-OOM_{Ali} showed stronger correlations with solar radiation over NO₃
241 radicals, indicating their association with daytime photochemistry since benzene/alkyl benzenes and
242 aliphatic VOCs rapidly react with OH radicals compared to other oxidants, such as NO₃ radicals. This is
243 also supported by the observation that both 2N-OOM_{Aro} and 2N-OOM_{Ali} peaked during noontime (12:00-
244 14:00) as shown in Figure 4b. Similarly, the PMF analysis also distinguished two daytime factors. The

245 daytime factor-1 peaked at around 12:00-14:00 (Table S1) and highly correlated with solar radiation
246 ($R=0.57$). The fingerprint-molecules of daytime factor-1 are $C_nH_{2n-4}O_{10}N_2$ ($n=8-10$) with average DBE
247 values of 2 on the carbon skeleton, suggesting the dominance of 2N-OOMs likely formed from aromatic
248 precursors. Since each step of OH oxidation of aromatics followed by RO_2+NO_x termination would
249 increase the nH by one, this factor is likely dominated by 2N-OOMs formed from two steps of OH-
250 initiated oxidation from alkylbenzenes given the carbon numbers ranged from 8 to 10.

251 The key fingerprint molecule of daytime factor-2 is $C_nH_{2n}O_8N_2$ ($n=4-5$) (accounting for 30.8% in the
252 factor profile), followed by $C_nH_{2n-2}O_8N_2$ ($n=5-6$) (accounting for 9.7% in the factor profile), which is
253 likely a result of the decomposition from 2N-OOM_{Ali} with large carbon numbers, according to their DBE
254 values of 0-1 on the carbon skeleton. This aliphatic factor presented even higher correlation with solar
255 radiation ($R=0.65$), peaking at around 12:00-14:00. Strong daytime peaks together with the good
256 correlations with irradiation suggest the dominance of photochemical oxidation in the formation of 2N-
257 OOM_{Ali}. For 2N-OOM_{Ali}, although it showed strong daytime peak, weak nighttime peak was still observed.
258 This indicates that although daytime formation of 2N-OOM_{Ali} prevails, their nighttime formation still
259 existed. For example, we have obtained a nighttime factor from PMF analysis (nighttime factor-2), whose
260 fingerprint molecules are $C_5H_8O_9N_2$ and $C_nH_{2n}O_7N_2$ ($n=5-8$). $C_5H_8O_9N_2$ was likely originated from
261 isoprene and $C_nH_{2n}O_7N_2$ were likely from anthropogenic aliphatic precursors.

262 Nighttime chemistry plays a more important role in the formation of 2N-OOM_{MT}. This is further
263 supported by the slightly stronger correlation between 2N-OOM_{MT} and NO_3 radicals than solar radiation.
264 For some specific 2N-OOM_{MT} species, the formation is likely a result of NO_3 radical initiated oxidation.
265 As shown in Figure 5, we have identified a series of 2N-OOM_{MT} molecules with molecular composition
266 of $C_{10}H_{16}O_{7,9,11}N_2$, which showed strong positive correlations with NO_3 radical. The occurrence
267 of propagation reaction from RO_2 to RO was critical to the formation of odd oxygen as proposed in
268 previous chamber studies (Boyd et al., 2015; Claflin and Ziemann, 2018). Furthermore, under the
269 nighttime conditions observed in urban Shanghai (Table 1), it is estimated that monoterpenes primarily
270 react with NO_3 , and the fate of nighttime RO₂s is dominated by NO, which is clear different from rural

environment where NO levels likely drop to near zero after sunset (Romer et al., 2016) and RO₂s are likely terminated by NO₃-RO₂ cross-reactions (Bates et al., 2022). Therefore, formation of C₁₀H₁₆O_{7,9,11}N₂ likely started with the reaction of monoterpene with NO₃ radicals forming a NO₃-C₁₀H₁₆ alkyl radical, followed by the formation of organic peroxy radical (RO₂) upon addition of O₂. The RO₂ is then converted to an alkoxy radical (RO) upon reaction with NO. The autoxidation process would then start and stepwise introduce O₂ into the molecule, forming a series of more oxygenated RO₂ radicals, *i.e.*, NO₃-C₁₀H₁₆(O)(OO)_n. The NO termination reaction of these RO₂ radicals would finally result in ONs with chemical composition of NO₃-C₁₀H₁₆(O)(OO)_nO(NO)O (n=0, 1, 2).

On the other hand, the reaction rate between monoterpenes (*i.e.*, alpha-pinene, beta-pinene and limonene) and NO₃ are about 60,000-140,000 times faster than that between monoterpenes and O₃ at 293K (MCMv3.1), but the averaged nighttime concentrations of O₃ (22.8 ppb) was only about 18,000 times higher than that of NO₃ (1.3 ppt). Therefore, NO₃-initiated oxidation process posed significant impacts on 2N-OOM_{MT} formation during nighttime. The 2N-OOM_{MT} resulted from NO₃ oxidation is also resolved as a nighttime factor (nighttime factor-1) from PMF analysis, which tracked the NO₃ concentrations well (Figure S9, *R*=0.46) and peaked at around 19:00-23:00. Fingerprint molecule of nighttime factor-1 was mainly including C₁₀H₁₆O₉N₂ and C₁₀H₁₆O₈N₂, which is generated from NO₃-initiated oxidation followed by NO termination and this process will not change the nH of the parent monoterpene molecule.

3.4 Oxygenation level of 2N-OOMs

We then calculated the average effective oxygen number ($nO_{eff} = nO - 2nN$) of 2N-OOMs, which is used to indicate the oxidation state of carbon by excluding the oxygen atoms bonded with nitrogen atoms. Note that calculation of nO_{eff} assumes that the nitrogen atoms are only associated with nitrate group (-ONO₂), which is reasonable after excluding nitrophenol peaks. The average nO_{eff} of 2N-OOMs from different precursors in CL_{day}, CL_{night}, PL_{day} and PL_{night} were shown in Figure 6 and summarized in Table S2. 2N-OOM_{Aro} had the highest nO_{eff} (4.8-5.6), followed by 2N-OOM_{MT} (4.5-4.9) and 2N-OOM_{Ali} were of lowest nO_{eff} (3.9-4.0). Difference in the oxygenation level of different types of OOMs can be attributed to the difference in oxidation mechanisms of the initiation reactions. For example, the OH-initiated

297 oxidation of alkanes, aromatics and monoterpene/alkenes would form a $C_xH_yO_2$ radical, $C_xH_yO_5$ radical
298 and $C_xH_yO_3$ radical, respectively, incorporating different number of oxygen atoms into the original
299 precursor molecules at the first step of oxidation (MCMv3.1). On the other hand, during the multiple-step
300 oxidation in daytime, aromatics could still provide more C=C bonds than other precursors after the initial
301 step which is plausibly capable to further react with OH, O_3 and others oxidants.

302 Furthermore, we also found that regardless of the pollution level, the nO_{eff} was considerably higher
303 in daytime cases than that in nighttime cases particularly for 2N-OOM_{Aro} and 2N-OOM_{MT}, suggesting a
304 profound effects of photochemistry on the formation of highly oxygenated 2N-OOMs. This is likely
305 because of the high NO_x concentrations during the nighttime (Table 1), which could efficiently suppress
306 the RO_2 radicals from autoxidation reactions forming overall less oxygenated OOM molecules. The effect
307 of NO_x on oxygenation levels would be discussed in a subsequent paragraph. The average nO_{eff} of 2N-
308 OOM_{Ali} in four sub-periods were similar without significant daytime and nighttime difference, ranging
309 from 3.9-4.0. This could be partly explained by the fact that reactions with oxidants such as OH and
310 halogen radicals will similarly result in the addition of oxygen atoms by two for alkanes during the first
311 step of oxidation. Thus, the oxygenation levels of 2N-OOM_{Ali} were supposed to be insensitive to the
312 oxidants in daytime or nighttime.

313 It is known that NO is also critical in determining the fate of RO_2 radical during the oxidation,
314 forming RO radicals or organonitrates. Formation of RO radicals and organonitrates will have opposite
315 effects on the oxidation state of the termination products since the former will significantly increase the
316 oxygenation state of carbon through initiating propagation reactions before termination. We thus explore
317 the effects of NO as well as the total NO_x concentrations on the average oxygenation levels of 2N-OOMs
318 from different precursors during the whole campaign (Figure 7). Consistent with previous studies in
319 polluted urban environment (Qiao et al., 2021; Yan et al., 2021), the detected 2N-OOMs were also of low
320 oxygenation with nO_{eff} of 3.9-5.4 (25-75% percentile) compared to those measured in forest or in
321 laboratory studies (Berndt et al., 2016; Ehn et al., 2014; Jokinen et al., 2014; Rissanen et al., 2014; Yan et
322 al., 2016). nO_{eff} of 2N-OOM_{Aro} and 2N-OOM_{MT} increased with the decrease of NO/NO_x concentrations.

323 This is likely due to the prevailing of NO termination reactions because the maximum autoxidation rate
324 constant of alkylbenzenes with long-chain substituents (e.g., isopropyl-benzene, ethyl-benzene) and
325 monoterpane are comparable to the bimolecular reaction rate between RO_2 and NO (Bianchi et al., 2019).
326 The oxygenation levels of $2\text{N-OOM}_{\text{Ali}}$ appears to be insensitive to the pollution levels and NO/NO_x
327 concentrations, which should be further investigated in future studies.

328 **4 Conclusion**

329 We report the unambiguous identification of 2N-OOMs as well as other OOMs using an ultra-high-
330 resolution orbitrap coupled with a nitrate inlet. We found that OOMs distributed in a wide range of carbon
331 numbers ($n\text{C} = 4 - 16$), among which the 2N-OOMs occupied a considerable fraction (26%) of the total
332 observed OOMs. During the whole campaign, the 2N-OOM concentrations ranged from 1.1×10^6 to
333 42.0×10^6 molecule cm^{-3} and concentrated in the $n\text{C}$ range of 5 to 10 with high molecular weight ($\text{m/z} >$
334 350 Th), suggesting their low volatilities and thus potentially high contribution to local SOA formation.

335 Aliphatic, aromatics, and monoterpenes were plausible precursors of 2N-OOMs with a fraction of
336 64.2%, 16% and 15.4%, respectively. The absolute concentrations of 2N-OOMs were greatly affected by
337 the pollution level for the most cases. The $2\text{N-OOM}_{\text{Ali}}$ was found to be the most abundant 2N-OOMs and
338 its fraction even increased in the polluted day with enhanced proportion of ones with $n\text{C} > 10$, probably
339 due to the high concentrations of aliphatic precursors accompanied with PM episodes. Significant
340 contribution of long-chain aliphatic compounds ($n\text{C} > 10$) to 2N-OOM formation is also supported by the
341 observation that 2N-OOM fraction increased with the increase of $n\text{C}$ and they are of low DBE values,
342 likely through multistep bimolecular oxidation. $2\text{N-OOM}_{\text{Ali}}$ and $2\text{N-OOM}_{\text{Aro}}$ mainly peaked in daytime
343 and showed stronger correlations with solar radiation over NO_3 radicals, indicating their association with
344 daytime photochemistry since benzene/alkyl benzenes and aliphatic hydrocarbons rapidly react with OH
345 radicals compared with other oxidants, such as NO_3 radicals. In contrast, $2\text{N-OOM}_{\text{MT}}$ prevailed both in
346 daytime and nighttime, some specific $2\text{N-OOM}_{\text{MT}}$ species showed strong positive correlations with NO_3
347 radical and were likely a result of NO_3 radical initiated oxidation, suggesting the comparable importance
348 of nighttime NO_3 chemistry in $2\text{N-OOM}_{\text{MT}}$ formation. In terms of oxygenation levels, we found that 2N-

349 OOM_{Aro} had highest averaged nO_{eff} followed by 2N-OOM_{MT}. Daytime photochemistry and low NO_x
350 concentrations had profound effects on the formation of more oxygenated 2N-OOMs. 2N-OOM_{Ali} had the
351 lowest nO_{eff} and had negligible changes under different pollution levels. These results demonstrate the
352 preference of 2N-OOM formation and the influencing factors in a Chinese megacity involving various
353 VOC precursors (biogenic VOCs such as monoterpane and anthropogenic VOCs such as aromatics,
354 aliphatic hydrocarbons) and various atmospheric oxidants (such as OH radical and NO₃ radicals), and
355 highlight the influence of PM episode.

Table 1 Summary of the four cases including the meteorological conditions and concentrations of trace gases and 2N-OOMs

Case	Time	$\overline{PM_{2.5}}$ ($\mu\text{g m}^{-3}$)	\overline{Solar} (W m^{-2})	\bar{T} (°C)	\overline{RH} (%)	$\overline{[O_3]}$ (ppb)	$\overline{[NO]}$ (ppb)	$\overline{[NO_2]}$ (ppt)	$\overline{[NO_3]}$ ($\times 10^6 \text{ cm}^{-3}$)	$\overline{[NO_{Ar}o]}$ ($\times 10^6 \text{ cm}^{-3}$)	$\overline{[2N - OOM_{Ar}]}$ ($\times 10^6 \text{ cm}^{-3}$)	$\overline{[2N - OOM_{Total}]}$ ($\times 10^6 \text{ cm}^{-3}$)
CL _{day}	Nov. 4 th 12:00 - 14:00	7.5	635.6	18.9	35.2	41.9	3.2	8.2	0.1	6.3	11.7	2.3
CL _{night}	Nov. 4 th 23:00 - Nov. 5 th 01:00	9.5	2.4	13.0	64.1	8.0	2.9	40.5	0.2	1.3	6.0	2.3
PL _{day}	Nov. 7 th 12:00 - 14:00	44.0	384.5	23.9	30.5	73.9	2.2	20.6	0.3	6.4	23.8	4.3
PL _{night}	Nov. 7 th 23:00 - Nov. 8 th 01:00	60.5	2.5	17.8	44.9	27.2	2.1	38.7	6.2	3.1	17.4	5.3

Figure Captions

Figure 1. (a) Average mass spectrum of the detected OOMs during the whole campaign. The pie chart shows the fractions of OOMs with different number of nitrogen and carbon atoms; (b) The fractions of 0N-OOMs, 1N-OOMs, 2N-OOMs and 3N-OOMs among total OOMs as a function of carbon number (nC).

Figure 2. The timeseries of 2N-OOMs originated from different precursors. Four sub-periods were selected to further investigate the fractional distribution of different type of OOM molecules as shown in the pie chart, including a clean daytime case (12:00 to 14:00 on November 4th, $PM_{2.5}=7.5 \mu\text{g m}^{-3}$, CL_{day}), a clean nighttime case (23:00 on November 4th to 01:00 on November 5th, $PM_{2.5}=9.5 \mu\text{g m}^{-3}$, CL_{night}), a daytime case in a PM episode (12:00 to 14:00 on November 7th, $PM_{2.5}=44.0 \mu\text{g m}^{-3}$, PL_{day}) and a nighttime case in a PM episode (23:00 on November 7th to 01:00 on November 8th, $PM_{2.5}=60.5 \mu\text{g m}^{-3}$, PL_{night}). The sizes of pie charts are scaled to the total concentrations of 2N-OOMs.

Figure 3. The fractions of 2N-OOM_{Ali} with different carbon numbers in the four cases.

Figure 4. (a) Statistical distribution of the correlation coefficients (Spearman type) between 2N-OOMs and solar radiation ($R_{2N\text{-}OOMs\text{-}solar}$) in red and the correlation coefficients between 2N-OOMs and $[\text{NO}_3]$ ($R_{2N\text{-}OOMs\text{-}NO_3}$) in blue for 2N-OOMs from different precursors. The horizontal lines are the median values, boxes denote the 25th- and 75th- percentile values, and whiskers represent the 10th- and 90th- percentile values. (b) The diel patterns of 2N-OOMs from different precursors.

Figure 5. Scatter plot of $R_{2N\text{-}OOMs\text{-}NO_3}$ against $R_{2N\text{-}OOMs\text{-}solar}$ for specific 2N-OOM species.

Figure 6. The nO_{eff} of 2N-OOMs derived from different precursors in the four cases, the error bars represent the standard deviations.

Figure 7. Effective oxygen number (nO_{eff}) of 2N-OOMs as a function of (a) NO concentration and (b) NO_x concentration. The colored squares represent the real measurements. The filled markers indicate the median values in the range as horizontal error bars show, the vertical error bars denote the 25th- and 75th- percentile values.
