16 **Abstract.** Current process-based research mainly used the box model to evaluate the photochemical
17 ozone production and destruction rates, it is not clear to which extend the photochemical reaction
18 mechanisms were understood. Here, we modified and improved a net photochemical ozone production
19 rate (NPOPR, $P(O_3)_{net}$) detection system based on current dual-channel reaction chamber technique,
20 which make the instrument applicable to different ambient environment, and its various operating
21 indicators were characterized, i.e., the airtightness, light transmittance, wall losses of the reaction and
22 reference chambers, conversion rate of O_3 to NO_2 , the air residence time, and the performance of the
23 reaction and reference chambers, etc. The limit of detection of NPOPR detection system were determined
24 as 0.07, 1.4, and 2.3 ppbv h^{-1} , at the sampling flow rates of 1.3, 3, and 5 $L\ min^{-1}$, respectively. We further
25 applied NPOPR detection system in the field observation at an urban site at Pearl River Delta (China).
26 During the observation period, the maximum value of $P(O_3)_{net}$ was 34.1 ppbv h^{-1} , which was ~ 0 ppbv
27 h^{-1} at night within the system detection error and peaks at around noon local time, the daytime (from
28 6:00–18:00) average value of $P(O_3)_{net}$ was 12.8 (± 5.5) ppbv h^{-1} . We investigated the detailed
29 photochemical O_3 formation mechanism in the reaction and reference chambers of NPOPR detection
30 system using a zero-dimensional box model. We found that the photochemical reactions in the reaction
31 chamber were very close to that in the ambient air, but it was not zero-chemistry in the reference chamber,
32 on the contrary, the reaction related to the production and destruction of RO_2 ($=HO_2+RO_2$) continues in

33 the reference chamber, which led to small amount of $P(\text{O}_3)_{\text{net}}$. Therefore, the $P(\text{O}_3)_{\text{net}}$ measured here
34 can be regarded as the lower limit of the real $P(\text{O}_3)_{\text{net}}$ in the atmosphere, however, the measured $P(\text{O}_3)_{\text{net}}$
35 were still $\sim 7.5 \text{ ppbv h}^{-1}$ to 9.3 ppbv h^{-1} higher than the modeled $P(\text{O}_3)_{\text{net}}$ value depending on different
36 modeling methods, this may be due to the inaccurate estimation of HO_2/RO_2 radicals in the modeling
37 study. Short-lived intermediates measurements coupling with direct $P(\text{O}_3)_{\text{net}}$ measurements are needed
38 in future in order to understand the O_3 photochemistry better. Our results show that the NPOPR detection
39 system can achieve high time resolution and continuous field observation, which helps us to understand
40 photochemical O_3 formation better and provides a key scientific basis for the continuous improvement
41 of air quality in China.

42

43

44 1 Introduction

45 Surface O₃ pollution has become a major challenge in air quality management in China (Shen et al.,
46 2021). Elevated surface O₃ concentrations exert severe adverse effects on public health, such as
47 respiratory diseases, and the estimated annual mortality attributable to surface O₃ exposure is over
48 150,000 deaths in China (Malley et al., 2017). O₃ pollution is also detrimental to key staple crop yields,
49 reducing the yields of wheat, soybean, and maize by up to 15 %, and is threatening global food security
50 (Avnery et al., 2011; Mills et al., 2018; Karakatsani et al., 2010; Berman et al., 2012; O'Neill et al., 2003).
51 As a greenhouse gas, O₃ also contributes significantly to climate change (Bell et al., 2004). With the
52 rapid economic development and urbanization in the Pearl River Delta (PRD) region in China, O₃
53 pollution is pretty severe, especially in summer and autumn (Zou et al., 2015; Zhang et al., 2021).

54 The variation of O₃ in the planetary boundary layer is predominantly influenced by deposition,
55 advection transport, vertical mixing, meteorological factors, and chemical reactions. Therefore, the O₃
56 budget in the boundary layer can be expressed as Eq. (1) (Sadanaga et al., 2017; Cazorla et al., 2010).

$$57 \quad \frac{\partial [O_3]}{\partial t} = \underbrace{P(O_3)}_{P(O_3)_{\text{net}}} - \underbrace{D(O_3)}_{SD} - \underbrace{\frac{v}{H} [O_3]}_{SD} + \underbrace{u_i \frac{\partial [O_3]}{\partial x_i}}_A \quad (1)$$

58

59 where [O₃] is the ambient O₃ concentration, $P(O_3)_{\text{net}}$, $P(O_3)$, and $D(O_3)$ are the net chemical production
60 rate, chemical O₃ production rate, and O₃ chemical loss rate, respectively; SD, v , H , u_i and A represent
61 surface deposition, O₃ deposition velocity, mixing layer height, velocity in three directions and advection
62 consisting of the u_i times the O₃ gradient in those three directions.

63 Tropospheric O₃ is a key component of photochemical smog, mainly formed by photochemical
64 reactions of nitrogen oxides (NO_x=NO+NO₂) and volatile organic compounds (VOCs) (Lee et al., 2010).
65 The specific process of the photochemical reaction is the photolysis of NO₂ at 424 nm to generate O(³P)
66 atoms, thereby promoting the formation of O₃. Simultaneously, there is a RO_x (RO_x =OH + HO₂ +RO₂)
67 radical cycle in the troposphere, which continuously provides HO₂ and RO₂ to oxidize NO to NO₂
68 resulting in the accumulation of O₃ (Shen et al., 2021; Sadanaga et al., 2017; Cazorla et al., 2010).

69 Typical meteorological scenarios for the occurrence of O₃ pollution episodes in polluted urban
70 centers are usually characterized by weak winds, strong solar radiation, and high temperature (T). Under
71 such conditions, local formation of O₃ plays a crucial role in the rapid increase of surface O₃ in daytime.

72 In addition, in Eq. (1), the surface deposition and advection of O_3 are proportional to ambient O_3
73 concentration $[O_3]$, which is mainly generated by local photochemistry. If $P(O_3)_{net}$ can be reduced by
74 regulatory measures, overall O_3 levels will decline proportionately over time (Cazorla et al., 2010), thus,
75 the investigation of $P(O_3)_{net}$ formation mechanism is urgently needed.

76 Current studies on $P(O_3)_{net}$ estimation mainly rely on modeling methods, the gas-phase chemical
77 mechanisms were frequently used to identify key drivers of O_3 pollution events and provide guidance for
78 making effective O_3 reduction strategies, such as the Master Chemical Mechanism (MCM), the regional
79 atmospheric chemistry mechanism (RACM), the Carbon Bond mechanisms (CBM) and the Mainz
80 Organic Mechanism (MOM) (Shen et al., 2021; Kanaya et al., 2016; Wang et al., 2014; Tadic et al.,
81 2020; Ren et al., 2013; Lu et al., 2010; Zhou et al., 2014; Mazzuca et al., 2016). However, uncertainties
82 in emission inventories, chemical mechanisms, and meteorology make it difficult to perfectly reproduce
83 real atmospheric processes, which can lead some bias in modeling the $P(O_3)_{net}$. According to the existing
84 field observations, researchers found that the concentration of HO_2 or RO_2 obtained from the model
85 simulation was inconsistent with that obtained from the direct measurement, leading to the deviation of
86 $P(O_3)_{net}$ between observation and model simulation results (Wang et al., 2014; Tadic et al., 2020; Ren et
87 al., 2013; Martinez et al., 2003). Therefore, we urgently need a method that can directly measure the
88 $P(O_3)_{net}$.

89 Recently, researchers have developed sensors that can directly measure $P(O_3)_{net}$ in the atmosphere
90 using the dual-channel chamber technique (Sadanaga et al., 2017; Cazorla et al., 2010; Baier et al., 2021;
91 Sklaveniti et al., 2018), where ambient air is introduced into two chambers of identical size, one UV
92 transparent chamber (reaction chamber) and one UV protection chamber (reference chamber). In the
93 presence of solar UV light, O_3 is produced by photochemical reactions in the reaction chamber, but not
94 in the reference chamber. The system does not directly measure O_3 concentrations, it measures the
95 combined concentration of O_3 and nitrogen dioxide (NO_2). $P(O_3)_{net}$ is determined by the difference of
96 $O_x(O_x=O_3+NO_2)$ concentration between the reaction and reference chambers. These studies have greatly
97 helped us to understand the O_3 photochemical formation mechanism, but defects still exists in current
98 studies, for example, the sensors developed by Cazorla et al. (2010) and Baier et al. (2021) both have an
99 NO_2 -to- O_3 converter unit, and uses a modified O_3 monitor (Thermo Scientific, Model 49i, USA) to
100 measure O_x , but the zero point of the O_3 monitor is easy to drift, together with the limitation of the

101 conversion efficiency of NO_2 to O_3 (~ 99.9 %) and the effects of the T and relative humidity (RH) to O_3
102 monitor, this method can introduce large measurement uncertainties. Sklaveniti et al. (2018) have shorten
103 the average residence time in the chambers to 4.5 minutes, which reduced the scattering and increased
104 the time resolution of ΔOx measurement, but large wall loss still exists in their system, which are 5 %
105 and 3 % for O_3 and NO_2 , respectively. Sadanaga et al. (2017) passed the NO standard gas into the PFA
106 tube to convert O_3 into NO_2 to detect Ox, which is easy to operate, but the LIF- NO_2 detector is less
107 portable and maintainable. Furthermore, all the current sensors have different degrees of NO_2 and O_3 that
108 can even reach 15 %, which largely affect the accuracy of the evaluation of $P(\text{O}_3)_{\text{net}}$.

109 In this study, we modified and improved the $P(\text{O}_3)_{\text{net}}$ sensor based on the dual-channel technique
110 as described above and named it as a net photochemical ozone production rate (NPOPR) detection system.
111 The improvement and characterization of the NPOPR detection system are described in Sect. 2.
112 Furthermore, we applied the NPOPR detection system to the observation campaign conducted at
113 Shenzhen Meteorological Gradient Tower (SZMGT) in PRD region in China. A zero-dimensional box
114 model based on the Framework for 0-D Atmospheric Modeling (F0AM) v3.2 coupled with MCM v3.3.1
115 was used to simulate the photochemical reactions inside both the reaction and reference chambers in the
116 NPOPR system, which make us be able to access the ability of the current modeling method to model
117 $P(\text{O}_3)_{\text{net}}$, as described in Sect. 3. The current research can help us to study the source and formation
118 mechanism of O_3 , and provide effective theoretical support for the prevention and control of O_3 pollution.
119 Since the system can directly obtain real-time $P(\text{O}_3)_{\text{net}}$ under different environmental conditions, it can
120 meet richer and more specific research needs.

121 **2 Method and materials**

122 **2.1 Development of the NPOPR detection system**

123 The schematic and actual diagram of the NPOPR detection system are shown in Fig. 1, the integral
124 construction is similar to the $P\text{-}L(\text{Ox})$ measurement system built by Sadanaga et al. (2017) and Sklaveniti
125 et al. (2018), which mainly consists the reaction and reference chambers with the same geometry and
126 made of quartz (190.5 mm inner diameter and 700 mm length, more details can be found in Fig. S1). In
127 order to prevent photochemical reactions inside the reference chamber, a UV protection film (SH2CLAR,
128 3M, Japan) is used to cover the outer surface of it to block the sunlight with the wavelengths < 390 nm.

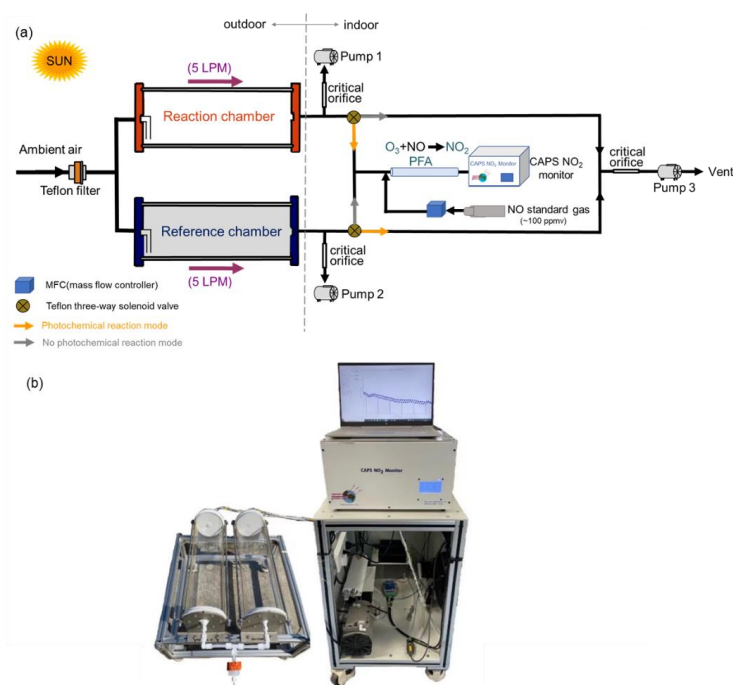

129 During the experiment, both reaction and reference chambers are located outdoors, exposing to the
130 sunlight directly to simulate the genuine ambient photochemistry reactions, ambient air are introduced
131 into the reaction and reference chambers with the same flow rate, a Teflon filter was amounted before
132 the chamber inlet to remove fine particles. A stream of the air from the two chambers is alternately
133 introduced into a NO-reaction chamber every 2 minutes to covert O_3 in the air to NO_2 in the presence of
134 a high concentrations of NO ($O_3+NO=NO_2$), and the O_x concentrations from the outlet NO-reaction
135 chamber, i.e., the total NO_2 concentration including the inherent NO_2 in the ambient and that converted
136 from O_3 is measured by a Cavity Attenuated Phase Shift (CAPS) NO_2 Monitor (Aerodyne research, Inc.,
137 Billerica MA, USA), in order to avoid other nitrogen oxides interferences to the NO_2 measurement (such
138 as alkyl nitrates, peroxyacyl nitrates, peroxyacetic acid, nitrogen pentoxide, etc.). Compared to previous
139 studies which use a dual-channel UV-absorption O_3 monitor (Cazorla et al., 2010) or the LIF- NO_2
140 monitor (Sadanaga et al., 2017) for the O_x measurements, our choice could make the NPOPR detection
141 system has more stable zero base line and more portable. Additionally, we modified the air sampling
142 system to adjust the total air flow rates freely from 1.3 to 5 L min^{-1} in the reaction and reference chambers,
143 which enable us to achieve different air residence time from 3.8 to 21 minutes, this time range covered
144 all the residence time from previous studies using different O_x measurement techniques, which ranged
145 from 4.5 to 20.5 minutes (Cazorla et al., 2010; Baier et al., 2015; Sadanaga et al., 2017; Sklaveniti et al.,
146 2018). According to the simulation results described in Sect. 3, the reaction rates of O_3 formation and
147 destruction pathways and the radicals that play critical roles in photochemical O_3 formation, such as HO_2 ,
148 RO_2 and OH , reached quasi-steady states in about 3 minutes, so it is reasonable for us to set the air flow
149 rate highest at 5 L min^{-1} , where the sampled air have already reacted for 3.8 minutes in the reaction and
150 reference chambers. On the other hand, this also demonstrated that it is reasonable to set the alternate
151 sampling time for the reaction and reference chambers at 2 minutes, where the sampled air actually have
152 already reacted for at least 3.8 minutes in the reaction and reference chambers. The switch system was
153 controlled by two Teflon three-way solenoid valves (001-0028-900, Parker, GER) located before the NO-
154 reaction chamber (see Fig. 1). To keep the flow rates in the reaction and reference chambers always the
155 same and avoid the gas flow accumulation in the chamber, a pump (pump 3) is connected to the Teflon
156 three-way solenoid valves in parallel to NO-reaction chamber to evacuate the air that is not introduced
157 into the NO-reaction chamber. To reduce NO interference, the system uses O_x to infer the amount of O_3

158 generated by photochemical reactions (Liu et al., 1977; Pan et al., 2015; Lu et al., 2010). The difference
159 of O_x concentrations in the reaction and reference chambers, denoted by ΔO_x , represents the amount of
160 O_3 generated by photochemical reaction. $P(O_3)_{net}$ was obtained by dividing ΔO_x by the average residence
161 time of air in the reaction chamber (τ):

$$162 \quad P(O_3)_{net} = P(O_x) = \frac{\Delta O_x}{\tau} = \frac{[O_x]_{reaction} - [O_x]_{reference}}{\tau} \quad (2)$$

163
164 **Figure 1: (a) Schematic and (b) actual diagram of the NPOPR detection system.**

165 The major improvements of NPOPR detection system described here compared to previous studies
166 to optimize the $P(O_3)_{net}$ measurements were as follows: (1) we improved the design of the reaction and
167 reference chambers to make sure they have good airtightness, this will increase the measurement
168 accuracy of different species inside the chambers, more details can be found in Sect. 2.2 and Sect. S1;
169 (2) added two pumps (labeled as pump 1 and pump 2 in Fig.1) directly after the reaction and reference
170 chambers to continuously draw ambient air through the two chambers (as the makeup flow) to adjust the
171 total air flow rates freely from 1.3 to 5 L min⁻¹ in the chambers, by doing this, we are able to achieve
172 different limit of detection (LOD) of NPOPR system (see Sect. 2.4), which make the instrument applicable
173 to different ambient environment, i.e., at high polluted area, we could use higher air flow rates to reduce

174 the wall loss effects of the chambers, at less polluted area, we could use lower flow rates to increase the
175 instrument LOD; (3) accordingly, we characterized the NPOPR detection system at different air flow
176 rates (including 1.3, 2, 3, 4, and 5 L min⁻¹), and tested the conversion efficiency of O₃ by NO to NO₂ in
177 the NO-reaction chamber at different NO concentrations and NO-reaction chamber lengths, all these
178 efforts enable us to understand the running parameters of NPOPR system better and do the data
179 corrections when NPOPR is operated at different air flow rates (see Sect. 2.2); (4) we tested the
180 performance of both reaction and reference chambers by combining the field measurement and the MCM
181 modelling method, which indicated that reaction pathways of *P*(O₃) and *D*(O₃) and the radicals that play
182 critical roles in photochemical O₃ formation, such as HO₂, RO₂ and OH, reached quasi-steady states
183 in about 3 minutes, thus make sure that the lowest air residence time at 3.8 min (at air flow rate of
184 5 L min⁻¹) in the reaction and reference chambers is long enough to obtain the accurate *P*(O₃)_{net}
185 values (see Sect. 3.2). By doing the above-mentioned efforts, we were able to make the NPOPR system
186 work more accurately and widely used.

187 2.2 Characterization of the NPOPR detection system

188 We characterized the NPOPR detection system following the same procedures as the previous researchers
189 have been done, including the residence time of the air, the wall losses of NO₂ and O₃, and the
190 transmittance of the light in the reaction and reference chambers, as well as the quantitative conversion
191 efficiency of O₃ to NO₂ (α) in the NO-reaction chamber. Additionally, we have investigated the residence
192 time of the air and the wall losses of NO₂ and O₃ in the reaction and reference chambers at different flow
193 rates (including 1.3, 2, 3, 4, and 5 L min⁻¹), and the conversion efficiency of O₃ by NO to NO₂ in the NO-
194 reaction chamber at different NO concentrations and NO-reaction chamber lengths. The detailed
195 experimental performances and data analysis are shown in the supplement (Sect. S1), the corresponding
196 results are described as follows.

197 **The residence time.** We tested the residence time of air in both chambers under different air flow
198 rates, including 1.3, 2, 3, 4, and 5 L min⁻¹, the obtained related residence time in the reaction chamber
199 were 0.35, 0.16, 0.11, 0.07, and 0.06 h, respectively. By setting different air flow rates, we were able to
200 obtain different residence time thus different limit of detection of NPOPR system, which make it
201 applicable to different ambient environment. To make sure that the mean residence time of air is the same

202 in the reaction and reference chambers, we also tested the residence time of air in the reference chamber
203 in parallel, which were not much difference with that in the reaction chamber, as shown in Table S1. The
204 experimental schematic diagram is shown in Fig. S2, the related results of different air flow rates are
205 shown in Figs. S3 and Table S1.

206 **The wall losses of NO₂ and O₃.** At the air flow rates of 1.3, 2, 3, 4, and 5 L min⁻¹, the wall losses
207 of O₃ in the reaction chamber were found to be approximately 2 %, 0 %, 0 %, 0 %, and 0 %, respectively,
208 the wall losses of O₃ in the reference chamber was found to be approximately 2 %, 1 %, 1 %, 0%, and
209 0.7 %, respectively. While the wall losses of NO₂ in the reaction chamber at the air flow rates of 1.3, 2,
210 3, 4, and 5 L min⁻¹ were found to be approximately 4 %, 4 %, 2 %, 0%, and 0.3 %, respectively, the wall
211 losses of NO₂ in the reference chamber were found to be approximately 2 %, 1 %, 0 %, 0 %, and 0.6 %,
212 respectively. The experimental schematic diagram is shown in Fig. S4, the related results of different air
213 flow rates are shown in Figs. S5 and Table S2. We further compared the wall losses of O₃ and NO₂ in the
214 reaction and reference chambers at 5 L min⁻¹ with previous studies (as shown in Table S3), and found
215 they were significantly smaller, but even with the flow rate of 1.3 L min⁻¹, the wall losses were still smaller
216 than 4 % and 2 % in the reaction chamber and the reference chambers, respectively, this indicates the
217 small effects of Ox loss to $P(O_3)_{\text{net}}$ measurements in our NPOPR detection system.

218 **The transmittance of the light.** It is worth noting that there was still low transmittance of the light
219 ranged from 390 nm to 790 nm of the UV protection film, the reference chamber could not be regarded
220 as the totally dark condition, thus we tested the solar UV transmittance through the reaction and reference
221 chambers of the NPOPR detection system in the laboratory by using a sunlight simulation lamp (SERIC
222 XG-500B, Japan) to provide different intensities of illumination. The photolysis frequencies of the NO₂,
223 O₃, HONO, H₂O₂, NO₃_M (photolysis of NO₃ generates NO+O₂), NO₃_R (photolysis of NO₃ generates
224 NO₂+O), HCHO_M (photolysis of HCHO generates H₂+CO), and HCHO_R (photolysis of HCHO
225 generates H+HCO) inside and outside the reaction and reference chambers were measured using the
226 actinic flux spectrometer (PFS-100; Focused Photonics Inc, China). Table 1 presents the $J(\text{NO}_2)$, $J(\text{O}^1\text{D})$,
227 and $J(\text{HONO})$ results for outside and inside chambers, from this study and that from the literatures.
228 $J(\text{H}_2\text{O}_2)$, $J(\text{NO}_3_M)$, $J(\text{NO}_3_R)$, $J(\text{HCHO}_M)$, and $J(\text{HCHO}_R)$ are shown in Table S4. The photolysis
229 frequencies of all species inside the reaction chamber were in agree with those measured outside the
230 reaction chamber within 4 %. For the reference chamber, the transmittivity of $J(\text{O}^1\text{D})$ and $J(\text{NO}_2)$ were

231 ~ 2 % and 9 %, respectively, the transmittivity of other species (i.e., $J(\text{H}_2\text{O}_2)$, $J(\text{HCHO}_M)$ and
232 $J(\text{HCHO}_R)$, etc.) were almost 0 %. Specifically, the transmittivity of $J(\text{NO}_3_M)$ and $J(\text{NO}_3_R)$ of
233 reference chamber were more than 90 % (Table S4). The influence of the different transmittivity of
234 different species will be discussed in Sect. 3. Table S4 shows the transmittivity of $J(\text{H}_2\text{O}_2)$, $J(\text{NO}_3_M)$,
235 $J(\text{NO}_3_R)$, $J(\text{HCHO}_M)$, and $J(\text{HCHO}_R)$ in the reaction chamber were more than 90 %. The
236 transmittivity of $J(\text{H}_2\text{O}_2)$, $J(\text{HCHO}_M)$, and $J(\text{HCHO}_R)$ of reference chamber were almost 0 %, but
237 the transmittivity of $J(\text{NO}_3_M)$ and $J(\text{NO}_3_R)$ of reference chamber were more than 90 %.

238

239 **Table 1. Photolysis frequency J (s^{-1}) of different species inside and outside the reaction and reference chambers.**
240 **The shaded and clear regions correspond to the photolysis frequencies with the reference (Ultem coated) and**
241 **reaction (clear) chambers, respectively. The transmittivity column shows the transmittivity of tested chambers**
242 **measurements with the set photolysis frequencies using SERIC XG-500B sunlight (this study) and ambient**
243 **(literatures).**

	Transmittivity			
	Averaged (this study)	Cazorla <i>et al.</i> , 2010	Baier <i>et al.</i> , 2015	Sadanaga <i>et al.</i> , 2017

244

245 **The quantitative conversion efficiency of O_3 to NO_2 (α)** in the NO-reaction chamber is crucial for
246 accurate measurement of $P(\text{O}_3)_{\text{net}}$. Here we used PFA tube (outer diameter of 12.7 mm; inner diameter
247 of 9.5 mm) as the NO-reaction chamber. The experimental schematic diagram is shown in Fig. S6. A
248 known concentration of O_3 was introduced into the NO-reaction chamber, NO reacts with O_3 and produce
249 NO_2 , and the total NO_2 concentrations including that from the ambient air was measured using a CAPS-
250 NO_2 monitor ($[\text{NO}_2]_{\text{CAPS}}$). The O_3 concentration was controlled at approximately 310 ppbv according to
251 the maximum concentration range in the normal ambient atmosphere (to ensure that all ambient and
252 newly generated O_3 can react with NO and produce equivalent amount of NO_2). An O_3 generator
253 equipped with a low-pressure mercury lamp was employed to generate O_3 , and the generated O_3
254 concentration ($[\text{O}_3]_{\text{g}}$) was measured by 2B O_3 monitor as mentioned above. Here we note that the O_3

255 concentration was diluted by the added NO/N₂ gas (with the flow rate of 20 mL min⁻¹) in the NO-reaction
256 chamber (with the total flow rate of 1.11 L min⁻¹), taking 1800 ppbv NO/N₂ gas as an example, the
257 relationship between [NO₂]_{CAPS} and [O₃]_g can be described by Eq. (3):

$$258 \quad [\text{NO}_2]_{\text{CAPS}} = \frac{1.09}{1.11} [\text{O}_3]_{\text{g}} \alpha \quad (3)$$

259 In order to determine the optimal length of the NO-reaction chamber and NO concentrations, we
260 did the cross test of α under the following scenarios: the NO-reaction chamber lengths were increased
261 from 30 to 650 cm in 50 cm step, and the NO standard gas (102.1 ppmv) was diluted to 600, 900, 1200,
262 1500, 1800, 2100, and 2400 ppbv in the NO-reaction chamber, the results are shown in Fig. 2. We found
263 that at [O₃]_g was approximately 310 ppbv, with the NO concentrations \geq 1800 ppbv in the NO-reaction
264 chamber, α could reach 99 %, 99.6 %, and 99.9 % with the NO-reaction chamber length of 50, 70, and
265 100 cm, respectively, where the corresponding O₃ residence time in NO-reaction chamber were 1.95 ,
266 2.74, and 3.91 s, respectively. Considering both the optimal reaction time in the NO-reaction chamber
267 and α , we selected the NO-reaction chamber length as 100 cm with the NO concentrations of 1800 ppbv
268 for the NPOPR detection system.

269
270 **Figure 2:** The conversion efficiency of O₃ by NO to NO₂ in the NO-reaction chamber as a function of the NO-
271 chamber length, color coded with the NO concentrations.

272 *The airtightness of the reaction and reference chambers* Here we also checked the airtightness
273 of the reaction and reference chambers by passing through gases with different flow rates, and compared
274 the values of [air flow rate × pressure] between the inlet and outlet of the chambers (as indicated in Fig.
275 3). We found that the deviation of [air flow rate × pressure] at the inlet and outlet of the reaction and
276 reference chambers at different flow rates were <3 % (as shown in Table S5), indicating the good

277 airtightness of the reaction and reference chambers. This will make sure that the photochemical reactions
278 in the reaction and reference chambers are not affected by the ambient air outside the chambers.

279
280 **Figure 3: The relationship of the values of [air flow rate × pressure] between the inlet and outlet of the**
281 **chambers (psia: Pounds Per Square Inch Absolute).**

282 *The flow states in the reaction and reference chambers* We calculated the Reynolds number to
283 check the gas flow state in the reaction and reference chambers. The Reynolds number (expressed as Eq.
284 (4)) is a dimensionless number that can be used as the basis for judging the flow characteristics of the
285 fluid:

$$286 \text{Re} = \rho v d / \mu \quad (4)$$

287 where v , ρ and μ are the flow velocity, density and viscosity coefficient of the fluid, respectively. In this
288 study, the fluid is air, d is the equivalent diameter of the reaction and reference chambers. The calculated
289 Reynolds number in the two chambers under the flow rates at 1.3, 2, 3, 4, and 5 L min⁻¹ are 9.39, 14.58,
290 21.75, 29.05, and 36.34, respectively, indicating laminar flows in both chambers at different flow rates.

291 2.3 Calibration and measurement error of CAPS-NO₂ monitor

292 The Ox in NPOPR detection system was measured by the CAPS-NO₂ monitor. Detailed descriptions of
293 this technique can be found elsewhere (Kebabian et al., 2008, 2005). We calibrated the CAPS-NO₂
294 monitor as follows: a. injected ~ 10–100 ppbv of NO₂ for 30 minutes to passivate the surfaces of the
295 monitor and then injecting ultrapure air for ~ 10 minutes to ensure the zero point did not drift, according
296 to the ultrapure air condition, the LOD of CAPS was 0.88 and 0.02 ppbv (3 σ) at an integration time of
297 35 and 100 s, respectively; b. injected a wide range of NO₂ concentration (from 0–160 ppbv) prepared

298 from a NO₂ standard gas (with the original concentration of 2.08 ppmv) mixed with ultrapure air into the
299 CAPS-NO₂ monitor, repeated the experiments for three times at each NO₂ concentration, the final results
300 are shown in Fig. 4.

301 In order to get accurate measurement error of CAPS-NO₂ monitor ($(O_{XCAPS})_{error}$), we fitted the
302 calibration results with a 68.3 % confidence level, and the blue line in Fig. 4 represents the maximum
303 fluctuation range under this confidence level, $(O_{XCAPS})_{error}$ was then calculated from the fluctuation
304 range of the 68.3 % confidence interval of the calibration curve, the relationship between the
305 $(O_{XCAPS})_{error}$ and the measured Ox value ($[Ox]_{measured}$) can be expressed as a power function curve, as
306 shown in Eq. (5):

$$307 \quad (O_{XCAPS})_{error} = 9.72 \times [Ox]_{measured}^{-1.0024} \quad (5)$$

308 Subsequent $P(O_3)_{net}$ error estimation according to the instrument measurement error of CAPS-NO₂
309 monitor and the O₃ light-enhanced ingestion in the reaction and reference chambers are described in the
310 supplement (Sect. S2).

311
312 **Figure 4:** Calibration results of CAPS-NO₂ monitor with different concentrations of NO₂, the y-axis
313 represented the NO₂ concentration measured by CAPS-NO₂ monitor, the x-axis represents the prepared NO₂
314 concentrations from the diluted NO₂ standard gas.

315 2.4 The LOD of the NPOPR detection system

316 To test the LOD of the NPOPR detection system, the ultrapure air were introduced into the NPOPR
317 detection system in sequence to adjust the system for ~ 2 hours, followed by the ultrapure air or ambient
318 air when the time resolution of the CAPS NO₂ monitor was 1 s and the integration time period was 100

319 s (the measurement duration for the reaction and reference chambers are both 2 minutes), the LOD of the
320 NPOPR detection system was obtained at time resolutions of 4 minutes by propagating the errors of the
321 O_x measured by CAPS- NO_2 monitor when ultrapure air or ambient air was introduced into the NPOPR
322 detection system, combined with the related $\langle \tau \rangle$ under different flow rates, i.e., $\langle \tau \rangle$ was 0.063 h at the flow
323 rate of 5 L min^{-1} , the detailed calculation method is shown in Eq. (6):

$$324 \text{ LOD} = \frac{3 \times \sqrt{([O_x]_{\text{rea_STD}})^2 + ([O_x]_{\text{ref_STD}})^2}}{\tau} \quad (6)$$

325 where $[O_x]_{\text{rea_STD}}$ and $[O_x]_{\text{ref_STD}}$ represent the standard deviation of O_x in the reaction and reference
326 chambers measured by CAPS- NO_2 monitor with the integration time period of 100 s, respectively. When
327 injecting ultrapure air, the LOD increases as the flow rate decreases, the LOD of the NPOPR detection
328 system was about 0.07, 1.4, and 2.3 ppbv h^{-1} at air flow rate of 1.3, 3, and 5 L min^{-1} , respectively, the
329 results are summarized in Table S6.

330 However, considering the background O_x concentration (measured by CAPS NO_2 monitor of the
331 air in the reference chamber) changes when measuring the ambient air, and the measured O_x errors in
332 the reaction and reference chambers change with the O_x concentration (as shown in Sect. 2.3), the LOD
333 must also be a function of the intrinsic ambient and photochemically formed O_3 and NO_2 concentrations
334 (i.e. the O_x concentration measured by the CAPS NO_2 monitor). It's worth noting that the measured O_x
335 errors may be also influenced by the light-enhanced ingestion of O_3 in the reaction and reference
336 chambers under the ambient conditions when the light intensity (especially J_{O1D}) and O_3 concentration
337 are high, as tested and shown in the supplement (Sect. S2), but this effect is included in the measured O_x
338 errors. Therefore, when injecting the ambient air into the NPOPR system, the LOD can be calculated as
339 Eq. (7):

$$340 \text{ LOD} = \frac{3 \times \sqrt{(\text{O}_{X_Y})_{\text{rea_error}}^2 + ((9.72 \times [O_x]_{\text{measured}})^{-1.0024})_{\text{ref_error}}^2 + (\text{O}_{X_Y})_{\text{ref_error}}^2 + ((9.72 \times [O_x]_{\text{measured}})^{-1.0024})_{\text{ref_STD}}^2}}{\tau} \quad (7)$$

341 where $(\text{O}_{X_Y})_{\text{rea_error}}$ and $(\text{O}_{X_Y})_{\text{ref_error}}$ represent the measurement error caused by the light-enhanced
342 ingestion of O_3 in the reaction and reference chambers, respectively; and $(9.72 \times$
343 $[O_x]_{\text{measured}})^{-1.0024})_{\text{rea_STD}}$ and $(9.72 \times [O_x]_{\text{measured}})^{-1.0024})_{\text{ref_STD}}$ represent the standard deviation
344 of O_x in the reaction and reference chambers caused by CAPS- NO_2 monitor with the integration time
345 period of 100 s, respectively. More details about the $(\text{O}_{X_Y})_{\text{rea_error}}$ and $(\text{O}_{X_Y})_{\text{ref_error}}$ estimation method
346 can be found in the supplement (Sect. S2).

347 In conclusion, the LOD of the NPOPR detection system is determined by the measurement error of
348 O_x and the residence time. As the measurement error of the CAPS- NO_2 monitor decreases with the
349 increases of the O_x concentrations (as shown in Sect. 2.3), the higher limit values of the LOD could be
350 obtained when injecting the ultrapure air into the NPOPR detection system, which were approximately
351 0.07, 1.4, and 2.3 ppbv h^{-1} at air flow rate of 1.3, 3, and 5 $L\ min^{-1}$, respectively. During the field
352 observations, the LOD values are highly depend on the ambient conditions, especially the light intensity
353 and the O_x concentrations, higher O_3 concentrations and lower light intensity will likely resulted in lower
354 values of LOD.

355 2.5 Laboratory tests of NPOPR detection system

356 We conducted an experiment in the laboratory to test the performance of the NPOPR detection system at
357 Jinan University Panyu Campus (23.0° N, 113.4° E) on 26 March 2021. 5 $L\ min^{-1}$ ambient air was
358 simultaneously injected into the reaction and reference chambers of the NPOPR detection system in
359 parallel, and the sunlight simulation lamp as mentioned above was used to simulate the sunlight radiation.
360 Light intensities of the sunlight simulation lamp were decreased from 26000 cd to 0 cd in step of 3700
361 cd. $P(O_3)_{net}$ was 28.6 ppbv h^{-1} at the light intensity of 26000 cd and gradually approaching 0 ppbv h^{-1} at
362 0 cd (as shown in Fig. 5), indicating that the $P(O_3)_{net}$ changing due to the different sunlight radiation
363 could be well captured by the NPOPR detection system.

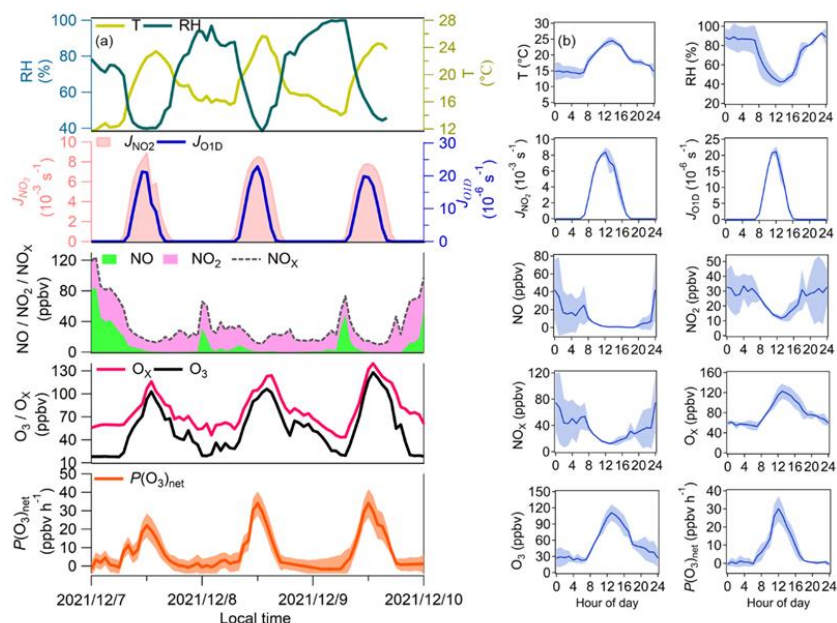

364
365 **Figure 5: (a) Measured O_x concentration in the reaction and reference chambers and (b) the related $P(O_3)_{net}$**
366 **as a function of the light intensity during the experiment.**

367 **3 Atmospheric study and discussion**

368 **3.1 Field observation**

369 The self-built NPOPR detection system was employed in the field campaign conducted at SZMGT, which
370 is located in Shenzhen, China (as shown in the Supplement Sect. S3: Fig. S8), from 7 to 9 December
371 2021. During the campaign, in order to achieve the lowest O₃ and NO₂ wall loss, we used 5 L min⁻¹ air
372 flow rate in the reaction and reference chambers (with the residence time of ~ 4 minutes). Photolysis
373 frequencies of different species were measured using the actinic flux spectrometer as mentioned above.
374 O₃ and NO_x (NO+NO₂) concentrations were measured using a 2B O₃ monitor and a chemiluminescence
375 NO_x monitor (Model 42i, Thermo Fisher Scientific, USA), respectively. *T* and RH were measured by a
376 portable weather station (Met Pak, Gill Instruments Ltd, UK). The VOCs were measured by a high-
377 resolution proton transfer reaction time-of-flight mass spectrometry (PTR-ToF-MS, Ionicon
378 Analytik, Austria) (Wang et al., 2020a; Wu et al., 2020) and an off-line GC-MS-FID technique
379 (Wuhan Tianhong, Co. Ltd, China) (Yuan et al., 2012) (Table S8). Additionally, a self-built
380 formaldehyde analyzer was used to detect formaldehyde (HCHO) (Zhu et al., 2020). Figure 6 presents
381 the temporal and diurnal variations of $P(\text{O}_3)_{\text{net}}$, O_x, O₃, NO, NO₂, NO_x, *T*, RH, $J(\text{O}^1\text{D})$, and $J(\text{NO}_2)$
382 concentrations at SZMGT during the campaign.

383

384 **Figure 6: (a) Time series and (b) diurnal of $P(O_3)_{net}$, $J(NO_2)$, $J(O^1D)$, T, RH, O_x , NO_2 and NO measured at**
 385 **SZMGT from 7 to 9 December 2021. The shaded areas represent the error of each measured species, where**
 386 **the error of $P(O_3)_{net}$ was calculated according to the method described in the supplement (Sect. S2) (the**
 387 **estimation of the $P(O_3)_{net}$ error).**

388 During the measurement period, the $P(O_3)_{net}$ ranged from ~ 0 to 34.1 ± 7.8 ppbv h^{-1} , with the daytime
 389 (from 6:00–18:00) average value of $12.8 (\pm 5.5)$ ppbv h^{-1} , the maximum $P(O_3)_{net}$ at SZMGT was lower
 390 than that measured at the urban area of Houston in US ($40\text{--}50$ ppbv h^{-1} and 100 ppbv h^{-1} in autumn
 391 and springtime, separately) (Baier et al., 2015; Ren et al., 2013), close to that measured at the Indiana in
 392 US (~ 30 ppbv h^{-1} in springtime) (Sklaveniti et al., 2018), and much higher than that measured at the
 393 Wakayama Forest Research Station, a remote areas of Japan (10.5 ppbv h^{-1} in summertime) (Sadanaga
 394 et al., 2017) and the urban area of Pennsylvania in US (~ 8 ppbv h^{-1} in summertime) (Cazorla et al., 2010).
 395 The result indicates the rationality of the measured $P(O_3)_{net}$ in this study. From previous studies, the O_3
 396 pollution in the PRD area was more severe in summer and autumn than in winter and spring (Zhang et
 397 al., 2021). In this study, the $P(O_3)_{net}$ was measured in wintertime, which was already high, so we believe
 398 that the O_3 pollution of PRD is severe and urgently needs to be controlled. More measurements of $P(O_3)_{net}$
 399 worldwide are listed in Table S7, we found that $P(O_3)_{net}$ is much higher in urban areas than that in remote
 400 areas using both modelling or direct measurement methods.

401 According to the diurnal variation of all the measured pollutants indicators, $P(O_3)_{net}$ started to
402 increase at around 7:00 am at local time, this may be due to two reasons: (1) the rise of the O_3 precursors
403 (i.e., VOCs) due to high-altitude atmospheric residual layer transported down to the near-surface at this
404 time; (2) the increase of solar radiation intensity after 7:00 am, which increased the oxidation capacity
405 of the pollutants. These two factors jointly enhanced the photochemical oxidation reaction of VOCs and
406 gradually increased $P(O_3)_{net}$. $P(O_3)_{net}$ was then reached a peak at around 12:00 at noon time, which was
407 consistent with $J(NO_2)$, but this peak time was earlier than that of O_3 , which peaks at around 14:00, this
408 may be due to the photochemical reactions dominate O_3 concentration changes between 12:00 and 14:00.
409 After 14:00, the O_3 concentration started to decrease, this may be due to other processes dominated O_3
410 concentration changes at this time, such as O_3 reacted with other pollutants, or the surface deposition and
411 the outflow of O_3 by physical transport. In conclusion, changes of O_3 concentrations were influenced by
412 both photochemical production and physical transport.

413 3.2 Model simulation of $P(O_3)_{net}$ in the reaction and reference chambers

414 Based on the field observation data, we modeled the ozone production rate $P(O_3)$ and ozone destruction
415 rate $D(O_3)$ during the 4-minute photochemical reaction in the reaction and reference chambers at 12:00
416 on 7 December 2021, using a zero-dimensional box model based on the Framework for 0-D Atmospheric
417 Modeling (F0AM) v3.2 (Wolfe et al., 2016) coupled with MCM v3.3.1, which contains a total of 143
418 VOCs, more than 6700 species, involving more than 17000 reactions (Jenkin et al., 2015). $P(O_3)_{net}$ can
419 be expressed by the difference between $P(O_3)$ and $D(O_3)$, $P(O_3)$ and $D(O_3)$ can be expressed as Eq. (8)–
420 (9).

$$421 P(O_3) = k_{HO_2+NO}[HO_2][NO] + \sum_i k_{RO_{2,i}+NO}[RO_{2,i}][NO]\varphi_i \quad (8)$$

$$422 D(O_3) = k_{O(^1D)+H_2O}[O(^1D)][H_2O] + k_{OH+O_3}[OH][O_3] + k_{HO_2+O_3}[HO_2][O_3]$$

$$423 + \sum_i (k_{O_3+Alkene_i}[O_3][Alkene_i] + k_{OH+NO_2}[OH][NO_2] + k_{RO_2+NO_2}[RO_2][NO_2]) \quad (9)$$

424 where k_{M+N} represents the bimolecular reaction rate constant of M and N, and φ_i is the yield of NO_2 from
425 the reaction $RO_{2,i} + NO$. The relevant reaction rates of $P(O_3)$ and $D(O_3)$ and the VOCs concentrations
426 during 7–9 December 2021 in SZMGT used in the model are listed in Tables 2 and S8.

427 **Table 2. O_3 production and destruction reactions and the relevant reaction rates used in the model.**

Reactions	Rate coefficient / unit	Number
-----------	-------------------------	--------

O ₃ production pathways - $P(O_3)$		
RO ₂ + NO→RO + NO ₂	$2.7 \times 10^{-12} \times \exp(360/T)$ / molecules ⁻¹ cm ³ s ⁻¹	(R1)
HO ₂ + NO→OH + NO ₂	$3.45 \times 10^{-12} \times \exp(270/T)$ / molecules ⁻¹ cm ³ s ⁻¹	(R2)
O ₃ loss pathways - $D(O_3)$		
O ₃ + hv → O ¹ D + O ₂	Measured JO^1D / s ⁻¹	(R3)
O ₃ + C ₂ H ₄ → HCHO + CH ₂ OOA	$9.1 \times 10^{-15} \times \exp(-2580/T)$ / molecules ⁻¹ cm ³ s ⁻¹	(R4)
O ₃ + C ₃ H ₆ → CH ₂ OOB + CH ₃ CHO	$2.75 \times 10^{-15} \times \exp(-1880/T)$ / molecules ⁻¹ cm ³ s ⁻¹	(R5)
O ₃ + C ₃ H ₆ → CH ₃ CHOOA + HCHO	$2.75 \times 10^{-15} \times \exp(-1880/T)$ / molecules ⁻¹ cm ³ s ⁻¹	(R6)
O ₃ + C ₅ H ₈ → CH ₂ OOE + MACR	$3.09 \times 10^{-15} \times \exp(-1995/T)$ / molecules ⁻¹ cm ³ s ⁻¹	(R7)
O ₃ + C ₅ H ₈ → CH ₂ OOE + MVK	$2.06 \times 10^{-15} \times \exp(-1995/T)$ / molecules ⁻¹ cm ³ s ⁻¹	(R8)
O ₃ + C ₅ H ₈ → HCHO + MACROOA	$3.09 \times 10^{-15} \times \exp(-1995/T)$ / molecules ⁻¹ cm ³ s ⁻¹	(R9)
O ₃ + C ₅ H ₈ → HCHO + MVKOOA	$2.06 \times 10^{-15} \times \exp(-1995/T)$ / molecules ⁻¹ cm ³ s ⁻¹	(R10)
O ₃ + HO ₂ → OH	$2.03 \times 10^{-16} \times (T/300)^{4.57} \times \exp(693/T)$ / molecules ⁻¹ cm ³ s ⁻¹	(R11)
RO ₂ + NO ₂ → peroxy nitrates	$(3.28 \times 10^{-28} \times 7.24 \times 10^{18} \times P/T \times (T/300)^{-6.87} \times 1.125 \times 10^{-11} \times (T/300)^{-1.105} \times 10^{(\log_{10}(0.30))} / (1 + (\log_{10}(2.93 \times 10^{-17} \times 7.24 \times 10^{18} \times P/T \times (T/300)^{-5.765}) / 0.75 - 1.27 \times \log_{10}(0.30))^2) / (2.926 \times 10^{-17} \times 7.24 \times 10^{18} \times P/T \times (T/300)^{-5.765})$ / molecules ⁻¹ cm ³ s ⁻¹	(R12)
NO ₂ + OH → HNO ₃	$3.2 \times 10^{-30} \times 7.24 \times 10^{18} \times P/T \times (T/300)^{-4.5} \times 3 \times 10^{-11} \times 10^{(\log_{10}(0.41))} / (1 + (\log_{10}(3.2 \times 10^{-30} \times 7.24 \times 10^{18} \times P/T \times (T/300)^{-4.5} / 3 \times 10^{-11})) / (0.75 - 1.27 \times (\log_{10}(0.41))^2) / (3.2 \times 10^{-30} \times 7.24 \times 10^{18} \times P/T \times (T/300)^{-4.5} + 3 \times 10^{-11})$ / molecules ⁻¹ cm ³ s ⁻¹	(R13)
O ₃ + OH → HO ₂	$1.70 \times 10^{-12} \times \exp(-940/T)$ / molecules ⁻¹ cm ³ s ⁻¹	(R14)

428 *The rate coefficient obtained from the MCM v3.3.1 model.

429 In total three stages simulations were carried out to obtain the 4-minute photochemical reactions
 430 in the reaction and reference chambers, all these three stages model were operated in a time-dependent
 431 mode with a 1 s resolution. In the 1st stage, in order to establish a real atmospheric environment system,
 432 all the observation items on 7 November 2021, 6:00–11:30 was used to constrain the model to obtain the
 433 concentration of the unmeasured species in the genuine atmosphere. Including oxygenated volatile
 434 organic compounds (in total 16 species), non-methane hydrocarbons (in total 47 species), O₃, NO, NO₂,
 435 J value, T, RH, and pressure (P). Since O₃-NO-NO₂ was not in a steady state when all species were
 436 constrained, we conducted a 2nd stage simulation during 11:30–12:00. In this stage, we used the output
 437 concentration of the unmeasured species from the simulation in the last 1 s of the 1st stage simulation as
 438 the input, which were not constrained after giving initial values. For the measured species, O₃, NO, and

439 NO₂ were no longer constrained after giving initial values, while all other items (including NO_x, VOCs,
440 J value, RH, T , P , etc.) were still constrained in a time-dependent mode with a 1 s resolution after giving
441 initial values. In the 3rd stage, we modelled the 4-minute photochemical reactions in the reaction and
442 reference chambers. We used the output concentration of the unmeasured species (i.e., OH, HO₂, RO₂,
443 SO₂, HONO, etc.) from the simulation in the last 1 s of the 2nd stage simulation and all the measured item
444 (i.e., O₃, NO, NO₂, VOCs, J value, RH, T , P , etc.) as the model input, which were not constrained after
445 giving initial values. Figure 7 is an explicit explanation of the 3rd stage simulation.

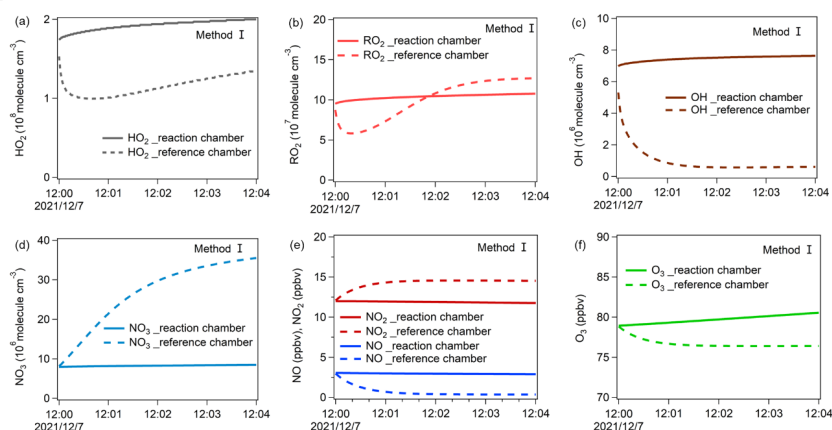

446
447 **Figure 7: Explicit explanation of the 3rd stage model simulation (input meteorological conditions: P : 1015.3**
448 **hPa, T : 295.6 K, RH: 39.7 %).**
449

450 Specifically, as the photolysis frequencies play critical roles in the simulation of $P(\text{O}_3)_{\text{net}}$, the J
451 values obtained from two methods (labeled as method I and method II) were used in the 3rd stage 4-
452 minute simulation. J values used in method I were obtained from the measured values (including $J(\text{NO}_2)$,
453 $J(\text{O}^1\text{D})$, $J(\text{HONO})$, $J(\text{H}_2\text{O}_2)$, $J(\text{NO}_3\text{-M})$, $J(\text{NO}_3\text{-R})$, $J(\text{HCHO-M})$, and $J(\text{HCHO-R})$) and the simulated values
454 using the Tropospheric Ultraviolet and Visible (TUV) radiation model (version 5.3) (including $J(\text{HNO}_3)$,
455 $J(\text{CH}_3\text{CHO})$, $J(\text{MACR})$, $J(\text{MEK})$, $J(\text{HOCH}_2\text{CHO})$, $J(\text{C}_2\text{H}_5\text{CHO})$, $J(\text{C}_3\text{H}_7\text{CHO})$, and $J(\text{C}_4\text{H}_9\text{CHO})$, etc.), while J
456 values in method II were all obtained from the simulated values using TUV model, detailed information
457 of these two methods are introduced in the Supplement (Sect. S4) (Tables S9 and S10). The variation of
458 the radicals (i.e., HO₂, OH, RO₂, and NO₃) and NO, NO₂, and O₃ concentrations obtained from method
459 I and method II during the 3rd stage 4-minute model simulation are shown in Fig. 8 and Fig. S9,
460 respectively. The production and destruction reactions of RO_x (=OH+HO₂+RO₂) in the reaction and
461 reference chambers obtained from method I and II are shown in Fig. 9 and Fig. S10, respectively, and
462 the final modeling results are put in Fig. 10 and Fig. S11, respectively.

463 From Fig. 8, in the reaction chamber, HO₂, OH, RO₂, and NO₃ concentrations first slightly

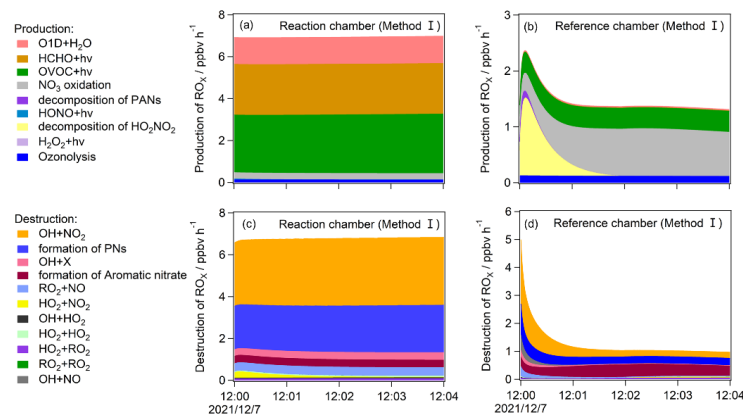

464 increased and then became stable, their final concentrations were 2.00×10^8 , 7.64×10^6 , 1.08×10^8 , and
465 8.47×10^6 molecules cm^{-3} , respectively. In the reference chamber, HO_2 and RO_2 concentrations dropped
466 during the 1st half minute and roses afterwards, the final HO_2 concentration (1.35×10^8 molecules cm^{-3})
467 was lower than that in the reaction chamber, while the RO_2 concentration exceed that in the reaction
468 chamber at the end of the 2nd minute and gradually became stable at 1.27×10^8 molecules cm^{-3} ; the OH
469 concentration dropped significantly at the 1st minute and then became stable at around 6.16×10^5
470 molecules cm^{-3} ; the NO_3 concentration rose significantly during the 4-minute simulation and became
471 3.55×10^7 molecules cm^{-3} at the end, which was much higher than that in the reaction chamber. The
472 decrease of HO_2 and RO_2 concentrations in the 1st half minute in the reference chambers may be due to
473 the NO titration effects, as high NO concentration existed at the 1st half minute, the increase of HO_2 and
474 RO_2 concentrations afterwards were largely attributable to the VOCs+ NO_3 oxidation reaction, and
475 partially due to the decomposition of PANs and HO_2NO_2 , as well as the OVOC photolysis (see Fig. 9b),
476 all of above mentioned reactions could contribute to the HO_2 and RO_2 concentration increase. The NO_3
477 sources in the reference chamber including the $\text{NO}_2 + \text{O}_3$ reaction and the N_2O_5 decomposition, the NO_3
478 consumption including its reaction with VOCs and NO, therefore, the NO_3 concentration increase in the
479 reference was jointly influenced by NO, NO_2 , O_3 , and VOCs. However, the effects of the increase of NO_2
480 concentration in the reference chamber will be neutralized by the decrease of O_3 concentration, therefore,
481 the much higher NO_3 concentration in the reference chamber compared to that in the reaction chamber
482 may be mainly due to the much less consumption of NO_3 by $\text{NO}_3 + \text{NO}$ reaction, more details about the
483 production and destruction rates of ROx are shown in Fig. 9.

492

493 Figures 10a–d show the modeled $P(O_3)_{net}$ and the source and sink of various species during the 3rd
494 stage 4-minute simulation. Figure 10a shows the steady state of $P(O_3)_{net}$ and the various species in the
495 ambient atmosphere achieved in the last 1 s of the 2nd stage simulation; Figures 10b and c show the
496 modeled $P(O_3)_{net}$ and the O₃ chemical budgets in the reaction and reference chambers during the model
497 simulation period; Figure 10d summarized the modeled $P(O_3)_{net}$ in the ambient atmosphere, and that in
498 the reaction and reference chambers, in order to compare the modeled results with our measurement
499 results, we calculated the integral mean of the modeled $P(O_3)_{net}$ in the reaction and reference chambers
500 and appended the related measured $P(O_3)_{net}$ value during this 4-minute simulation time onto Fig. 10d.
501 Further, the reaction weights of different production and destruction reactions process of O₃ are shown
502 in Figs. 10e–h.

503

504 **Figure 10:** (a)–(c) show the modeled $P(O_3)_{net}$ and the O_3 chemical budgets in (a) the ambient atmosphere when
 505 inject into the reaction and reference chambers, (b–c) the reaction and reference chambers during the 4-
 506 minute model simulation, (d) shows variable $P(O_3)_{net}$, where $P(O_3)_{net_modeled_ambient}$ represent the
 507 modeled $P(O_3)_{net}$ from the last 1 s of the 2nd stage simulation, $P(O_3)_{net_modeled_reaction\ chamber}$ and
 508 $P(O_3)_{net_modeled_reference\ chamber}$ represent the $P(O_3)_{net}$ changing trend during the 4-minute
 509 photochemical reactions in the reaction and reference chambers, respectively, $P(O_3)_{net_modeled_chamber}$ =
 510 $P(O_3)_{net_modeled_reaction\ chamber}-P(O_3)_{net_modeled_reference\ chamber}$, $P(O_3)_{net_modeled_integral\ mean}$
 511 represent the integral mean of the $P(O_3)_{net_modeled_chamber}$, and $P(O_3)_{net_measured_NPOPR}$ represent the
 512 measured $P(O_3)_{net}$ by NPOPR detection system. (e)–(h) show the reaction weights of each production and
 513 destruction reactions process of O_3 in the reaction and reference chambers in method I.

514

515 Figure 10a-h show the contribution of different reaction pathways to $P(O_3)$ and $D(O_3)$. The $P(O_3)$
 516 and $D(O_3)$ were almost the same within the 4-minute reaction in the reaction chamber (all species reached
 517 a steady state condition), while the $P(O_3)$ and $D(O_3)$ in the reference chamber decreased significantly
 518 within the 1st minute, and kept stable in the following minutes. In the reaction chamber, the HO₂+NO
 519 reaction contributed most to $P(O_3)$, accounting for 62.6 % of the total $P(O_3)$, with the integral mean
 520 value of 17.5 ppbv h⁻¹ in the reaction chamber. The second important pathway of $P(O_3)$ was RO₂+NO
 521 (occupied 37.4 % of the total $P(O_3)$). The reaction of RO₂+NO contained more than around 1200 types
 522 of RO₂ radicals, and the pathway of CH₃O₂+NO contributed 7.5 % of the total $P(O_3)$. The most important
 523 contributor of $D(O_3)$ was OH+NO₂ (48.9 %), followed by RO₂+NO₂ (33.3 %), O₃ photolysis (13.0 %),
 524 O₃+OH (2.3 %), O₃+HO₂ (1.7 %), C₅H₈+O₃ (0.4 %), C₃H₆+O₃ (0.3 %), and C₂H₄+O₃ (0.2 %). In the
 525 reference chamber, the integral mean value of HO₂+NO reaction was 2.3 ppbv h⁻¹, which had the largest

526 contribution to $P(\text{O}_3)$ (accounting for 55.0 %). The second largest contributor of $P(\text{O}_3)$ was RO_2+NO
527 (occupied 44.9 % of the total $P(\text{O}_3)$), in which the pathway of $\text{CH}_3\text{O}_2+\text{NO}$ contributed 6.6 % of the total
528 $P(\text{O}_3)$. The most important contributor of $D(\text{O}_3)$ was RO_2+NO_2 (50.8 %), followed by $\text{OH}+\text{NO}_2$ (37.0 %),
529 O_3+HO_2 (4.9 %), $\text{C}_3\text{H}_8+\text{O}_3$ (2.3 %), $\text{C}_3\text{H}_6+\text{O}_3$ (1.5 %), O_3+OH (1.4 %), O_3 photolysis (1.2 %), and
530 $\text{C}_2\text{H}_4+\text{O}_3$ (0.9 %). For all $P(\text{O}_3)$ reactions, the weight of RO_2+NO reaction in the reference chamber was
531 7.5 % higher than that in the reaction chamber, however, for all $D(\text{O}_3)$ reactions, the weight of RO_2+NO_2
532 reaction in the reference chamber was 17.5 % higher than that in the reaction chamber, which will
533 somehow mitigate the high $P(\text{O}_3)$ caused by RO_2+NO in the reference chamber. Further, the weight of
534 $\text{OH}+\text{NO}_2$ reaction in the reference chamber was 11.9 % lower than that in the reaction chamber, which
535 may be the main reason that led to NO_2 concentration in the reference chamber was much higher than
536 that in the reaction chamber. It is worth noting that the different reaction pathways of $P(\text{O}_3)$ and $D(\text{O}_3)$
537 had stabilized at around 1.5 minute for both method I and II (as shown in Figs. 10 and S11), and the
538 radicals that play critical roles in photochemical O_3 formation, such as HO_2 , RO_2 and OH , reached
539 quasi-steady states in about 3 minutes (as shown in Figs. 8 and S9). As the lowest experimental
540 residence time in the reaction and reference chambers was 3.8 min at the air flow rate of 5 L min^{-1} , the
541 photochemical reaction time at different air flow rates in the NPOPR system is sufficient enough
542 for investigating the $P(\text{O}_3)_{\text{net}}$, and it is reasonable for us to set the alternate ambient air sampling time
543 for the reaction and reference chambers at 2 minutes, where the ambient air actually has already reacted
544 for at least 3.8 minutes in the chambers.

545 The $P(\text{O}_3)_{\text{net}}$ measured by the NPOPR detection system at 12:04 was 26.0 ppbv h^{-1} , which was 7.5
546 ppbv h^{-1} higher than the modeled $P(\text{O}_3)_{\text{net}}$ value (18.5 ppbv h^{-1} , calculated from the integral mean of the
547 3rd stage 4-minute modeled $P(\text{O}_3)_{\text{net}}$ in Fig. 10d). Here we would like to note that, in order for a better
548 comparison between the measured and modeled $P(\text{O}_3)_{\text{net}}$ values, the measured $P(\text{O}_3)_{\text{net}}$ used here was
549 obtained from 4-minute time resolution, which is 1.4 ppbv h^{-1} higher than the measured $P(\text{O}_3)_{\text{net}}$ value
550 used in Fig. 6 (1-hour time resolution). The ratio of measured and modeled $P(\text{O}_3)_{\text{net}}$ values is 1.4, which
551 is consistent with the measured-to-modeled ratio of the cumulative $P(\text{O}_3)_{\text{net}}$ (1.3 and 1.4) obtained from
552 previous studies (Cazorla et al., 2012; Ren et al., 2013), where $P(\text{O}_3)_{\text{net}}$ values were also measured
553 directly in the atmosphere and were independent of the OH and HO_2 measurements. The reason for the
554 difference between measured and modeled $P(\text{O}_3)_{\text{net}}$ here may be due to the inaccurate estimation of

555 HO₂/RO₂ radicals, for example, Ren et al. (2013) found that the $P(O_3)$ calculated from the modeled HO₂
556 was lower than that calculated from the measured HO₂. The unknown HO₂ source should be identified
557 for a more accurate estimation of $P(O_3)_{net}$ in future study.

558 Additionally, the modeled $P(O_3)_{net}$ using the J values obtained from method II was 9.3 ppbv h⁻¹
559 lower than the measured $P(O_3)_{net}$, this discrepancy was slightly larger than that using method I, as shown
560 in the supplement (Sect. S4) (Fig. S11), the differences of the measured and modeled $P(O_3)_{net}$ by method
561 I and method II were 28.8 % and 35.8 %, respectively, this difference was mainly due to the transmittance
562 of $J(NO_2)$ in method II (30 %) was much higher than that in method I (9 %), NO₂ photolysis products
563 NO, it involved in the main reaction of O₃ production of HO₂+NO and RO₂+NO, so the modeled $P(O_3)_{net}$
564 in the reference chamber was slightly overestimated in method II, thus leading to an underestimation of
565 final $P(O_3)_{net}$.

566 In conclusion, modeling tests demonstrated that the radicals and gas species in the reaction
567 chamber of NPOPR detection system were similar to that in the genuine ambient air, while these radicals
568 were also present unexpectedly existed in the reference chamber. This was mainly due to the UV
569 protection film used by the reference chamber does not completely filtered out the sunlight, which led to
570 the low transmittance of the light ranged from 390 nm to 790 nm. The bias of the $P(O_3)_{net}$ caused by this
571 interference modeled in method I and method II were 13.9 % and 22.3 %, respectively, this make us
572 ensure that the measured $P(O_3)_{net}$ by NPOPR detection system should be regarded as the lower limit
573 values of real $P(O_3)_{net}$ in the atmosphere. We recommend the J values obtained from method I should be
574 used in the model simulation, which can better explain the photochemical formation of O₃ in the actual
575 atmosphere, but if the direct J value measurement cannot be achieved during the field observation
576 campaign, the J values obtained from method II was also acceptable in modeling study.

577

578 **4 Conclusions**

579 We modified and improved a net photochemical ozone production rate (NPOPR) detection system based
580 on a dual-channel reaction chamber technique, which can work more accurately and widely used
581 compared to previous studies. The main improvements of NPOPR detection system compared to
582 previous studies were as follows: (1) improved the design of the reaction and reference chambers to make

583 sure they have good airtightness; (2) changed the air sampling structure to enable the total air flow rates
584 change freely from 1.3 to 5 L min⁻¹ in the reaction and reference chambers, which can make the NPOPR
585 system achieve different LOD and applicable to different ambient environment; (3) characterized the
586 NPOPR detection system at different air flow rates to optimize the $P(\text{O}_3)_{\text{net}}$ measurements, the limit of
587 detection (LOD) of the NPOPR detection system are 0.07, 1.4, and 2.3 ppbv h⁻¹ at air flow rates of 1.3,
588 3, and 5 L min⁻¹, respectively; (4) tested the performance of both reaction and reference chambers by
589 combining the field measurement and the MCM modelling method.

590 The NPOPR detection system was employed in the field observation at the Shenzhen
591 Meteorological Gradient Tower (SZMGT), which is located in PRD, China. During the measurement
592 period, the $P(\text{O}_3)_{\text{net}}$ was around zero during nighttime and ranged from ~ 0 to 34.1±7.8 ppbv h⁻¹ during
593 daytime (from 6:00–18:00), with the average value of 12.8 (±5.5) ppbv h⁻¹. Besides, $P(\text{O}_3)_{\text{net}}$ start to
594 increase at around 7:00 am at local time, this may be due to the rise of the O₃ precursors (i.e., VOCs)
595 transported down from the high-altitude atmospheric residual layer to the near-surface and the increase
596 of solar radiation intensity increased the atmospheric oxidation capacity. $P(\text{O}_3)_{\text{net}}$ was then reaches a peak
597 at around 12:00 at noon time, by coupling with diurnal O₃ concentration trends, we confirmed that the
598 ground-level O₃ concentrations were influenced by both photochemical production and physical
599 transport.

600 In order to clarify the detailed photochemical reaction processes in the reaction and reference
601 chambers of NPOPR system, we modeled the $P(\text{O}_3)_{\text{net}}$ on 7 December 2021, 12:00-12:04 in the reaction
602 and reference chambers using MCM v3.3.1. As the photolysis frequencies of different species (J values)
603 play critical roles in the formation of $P(\text{O}_3)_{\text{net}}$, the J values obtained from two methods were used in the
604 4-minute chamber photochemical reaction (labeled as method I and method II), in method I, eight main
605 J values (e.g., $J(\text{NO}_2)$, $J(\text{O}^1\text{D})$, $J(\text{HONO})$, etc.) were measured directly, and other J values were obtained
606 from the simulated values using the Tropospheric Ultraviolet and Visible (TUV) radiation model, while
607 in method II, J values were all obtained from the simulated values using TUV model (as described in
608 Sect. 3.2). Modeling tests demonstrated that the concentration of different radicals and gas species (i.e.,
609 OH, HO₂, RO₂, NO₃, NO, NO₂, and O₃) in the reaction chamber were similar with those in the real
610 ambient environment, while due to the UV protection film used by the reference chamber does not
611 completely filtered out the sunlight, there was low transmittance of the light ranged from 390 nm to 790

612 nm. In the reaction chamber, the contribution of different reactions to $P(O_3)$ and $D(O_3)$ modeled by
613 method I and II were quite similar, where the HO_2+NO reaction contributed most to $P(O_3)$ (~ 62.6 %),
614 followed by the RO_2+NO reaction (~ 37.4 %). The $OH+NO_2$ reaction contributed most to $D(O_3)$, which
615 accounted for ~ 48.9 %, followed by the RO_2+NO_2 reaction O_3 photolysis, which accounted for ~ 33.3 %
616 and 13.0 %, respectively. In the reference chamber, the contribution of different reactions to $P(O_3)$ and
617 $D(O_3)$ modeled by method I and II were different, where the HO_2+NO reaction contributed ~ 55.0 % and
618 ~ 58.2 % to the total $P(O_3)$, respectively, and RO_2+NO contributed ~ 44.9 % and 41.8 % to the total
619 $P(O_3)$, respectively. The most important contributor of $D(O_3)$ modeled by method I was RO_2+NO_2
620 (50.8 %), followed by $OH+NO_2$ (37.0 %), while the most important contributor of $D(O_3)$ modeled by
621 method II was $OH+NO_2$ (46.8 %), followed by RO_2+NO_2 (44.1 %). For all $P(O_3)$ reactions, the weight
622 of RO_2+NO reaction in the reference chamber was 7.5 % and 4.3 % higher than that in the reaction
623 chamber in method I and II, respectively, however, for all $D(O_3)$ reactions, the weight of RO_2+NO_2
624 reaction in the reference chamber was 17.5 % and 10.9 % higher than that in the reaction chamber in
625 method I and II, respectively, which will somehow mitigate the high $P(O_3)$ caused by RO_2+NO in the
626 reference chamber. The different reaction pathways of $P(O_3)$ and $D(O_3)$ had stabilized at around 1.5
627 minute, and the radicals that play critical roles in photochemical O_3 formation, such as HO_2 , RO_2
628 and OH , reached quasi-steady states in about 3 minutes, the long enough ambient air residence time
629 in the reaction and reference chambers (≥ 3.8 min) make the photochemical reaction time at different
630 air flow rates in the NPOPR system sufficient enough for investigating the $P(O_3)_{net}$, and it is
631 reasonable for us to set the alternate ambient air sampling time for the reaction and reference chambers
632 at 2 minutes, where the ambient air actually has already reacted for at least 3.8 minutes in the chambers.

633 The bias of the modeled $P(O_3)_{net}$ caused by the interference of the reactions in the reference
634 chamber in method I and method II were 13.9 % and 22.3 %, respectively, thus the measured $P(O_3)_{net}$ by
635 NPOPR detection system should be regarded as the lower limit values of real $P(O_3)_{net}$ in the atmosphere.
636 Still, the measured $P(O_3)_{net}$ were 7.5 and 9.3 ppbv h^{-1} higher than the modeled $P(O_3)_{net}$ obtained from
637 method I and II, respectively, which may be due to the inaccurate modelling of HO_2/RO_2 radicals. Short-
638 lived intermediates measurements coupling with direct $P(O_3)_{net}$ measurements are needed in future study
639 in order to understand the photochemical production and destruction mechanisms of O_3 better. We
640 recommend the J values obtained from method I should be used in the model simulation, which can

641 better explain the photochemical formation of O₃ in the actual atmospheric environment, but if the direct
642 *J* value measurement cannot be achieved during the observation campaign, the *J* values obtained from
643 method II was also acceptable in modeling study.

644 The self-built NPOPR detection system in this study filled the blank of the observation method in
645 China. The research results not only help us to understand tropospheric O₃ budget, but also provide an
646 important data basis for formulating correct O₃ pollution prevention measures and control strategies.

647

648 *Data availability.* The observational data used in this study are available from corresponding authors
649 upon request (junzhou@jnu.edu.cn).

650 *Author contributions.* JZ, BY, and MS designed the experiment, YXH and JZ developed and assembled
651 the NPOPR detection system, YXH, JZ, JPZ, BY, YW, YFW, SCY, YWP, JPQ, XJH, XS and YBC
652 collected and analyzed the data. YXH and JZ wrote the manuscript, all authors revised the manuscript.

653 *Competing interests.* The authors declare that they have no known competing interests.
