Abstract. The fourth phase of the Air Quality Model Evaluation International Initiative (AQMEII4) is conducting a diagnostic intercomparison and evaluation of deposition simulated by regional-scale air quality models over North America and Europe. In this study, we analyze annual AQMEII4 simulations performed with the Community Multiscale Air Quality Model (CMAQ) version 5.3.1 over North America. These simulations were configured with both the M3Dry and Surface Tiled Aerosol and Gas Exchange (STAGE) dry deposition schemes available in CMAQ. A comparison of observed and modeled concentrations and wet deposition fluxes shows that the AQMEII4 CMAQ simulations perform similarly to other contemporary regional-scale modeling studies. During summer, M3Dry has higher ozone (O_3) deposition velocities (V_d) and lower mixing ratios than STAGE for much of the eastern U.S. while the reverse is the case over eastern Canada and along the West Coast. In contrast, during winter STAGE has higher O_3 V_d and lower mixing ratios than M3Dry over most of the southern half of the modeling domain while the reverse is the case for much of the northern U.S. and southern Canada. Analysis of the diagnostic variables defined for the AQMEII4 project, i.e. grid-scale and land-use (LU) specific effective conductances and deposition fluxes for the major dry deposition pathways, reveals generally higher summertime stomatal and wintertime cuticular grid-scale effective conductances for M3Dry and generally higher soil grid-scale effective conductances (for both vegetated and bare soil) for STAGE in both summer and winter. On a domain-wide basis, the stomatal grid-scale effective conductances account for about half of the total O_3 V_d during daytime hours in summer for both schemes. Employing LU-specific diagnostics, results show that daytime V_d varies by a factor of 2 between LU categories. Furthermore, M3Dry vs. STAGE differences are most pronounced for the stomatal and vegetated soil pathway for the forest LU categories, with M3Dry estimating larger effective conductances for the stomatal pathway and STAGE estimating larger effective conductances for the vegetated soil pathway for these LU categories. Annual domain total O_3 deposition fluxes differ only slightly between M3Dry (74.4 Tg/year) and STAGE (76.2 Tg/yr), but pathway-specific fluxes to individual LU types can vary more substantially on both annual and seasonal scales which would affect estimates of O_3 damages to sensitive vegetation. A comparison of two simulations differing only in their LU classification scheme shows that the differences in LU cause seasonal mean O_3 mixing ratio differences on

the order of 1 ppb across large portions of the domain, with the differences generally largest during summer and in areas characterized by the largest differences in the fractional coverages of the forest, planted/cultivated, and grassland LU categories. These differences are generally smaller than the M3Dry vs. STAGE differences outside the summer season but
35 have a similar magnitude during summer. Results indicate that the deposition impacts of LU differences are caused both by differences in the fractional coverages and spatial distributions of different LU categories as well as the characterization of these categories through variables like surface roughness and vegetation fraction in look-up tables used in the land-surface model and deposition schemes. Overall, the analyses and results presented in this study illustrate how the diagnostic grid-scale and LU-specific dry deposition variables adopted for AQMEII4 can provide insights into similarities and differences between
40 the CMAQ M3Dry and STAGE dry deposition schemes that affect simulated pollutant budgets and ecosystem impacts from atmospheric pollution.

1 Introduction

Over the past four decades, grid-based chemical transport models have been used to study air pollution on urban to global scales (McRae and Seinfeld, 1983; Chang et al., 1987; Russell et al., 1988; Harley et al., 1993; Hass et al., 1993; Scheffe and
45 Morris, 1993; Kumar et al., 1994; Jacobson et al., 1996; Chang et al., 1997; Kasibhatla and Chameides, 2000; Sistla et al., 2001; Bey et al., 2001; Grell et al., 2005; Byun and Schere, 2006; Gaydos et al., 2007; Mathur et al., 2017). In these models, the removal of gases and aerosols from the atmosphere through wet and dry deposition is one of the key processes of the simulated pollutant budgets. While the representation of gas and aerosol dry deposition in many of these models is derived from the resistance framework introduced in Wesely and Hicks (1977) and Wesely (1989), its specific implementation can
50 differ between models (Hardacre et al., 2015; Galmarini et al., 2021) and its use to represent aerosol dry deposition is an area of active model development (Saylor et al., 2019; Emerson et al., 2020; Pleim et al., 2022; Alapaty et al., 2022, Cheng et al., 2022). Likewise, the calculation of wet deposition fluxes in many models follows similar approaches as those used during initial acid deposition modeling (Chang et al., 1987; Irving and Smith, 1991; Hass et al., 1993) but differences exist in how models represent microphysics, precipitation, and aerosols.

55 Intercomparisons of air quality models can play an important role in assessing how such different process representations can impact simulated pollutant concentrations, model performance, and the use of models for planning applications. One such model intercomparison activity, the Air Quality Model Evaluation International Initiative (AQMEII), was launched in 2009 (Rao et al., 2011) and since then has organized several activities focused on evaluating regional-scale air quality models used for research and regulatory applications over North America and Europe. As discussed in Galmarini et al. (2021), its fourth
60 phase (AQMEII4) employs both grid and box modeling techniques for a diagnostic intercomparison and evaluation of simulated deposition with a specific focus on dry deposition of gaseous species. The grid model component of AQMEII4 is based on eight groups performing annual simulations for two years over North America and Europe and collecting detailed

dry deposition diagnostics for a range of trace gases. The Community Multiscale Air Quality (CMAQ) model (Byun and Schere, 2006) has been a part of all AQMEII activities performed to date and its performance in previous activities has been documented in both detailed comparisons of CMAQ simulations to observations (Appel et al., 2012; Hogrefe et al., 2015; Hogrefe et al., 2018) and comparisons to other modeling systems participating in AQMEII (Solazzo et al., 2012a,b; Im et al., 2015a,b; Solazzo et al., 2017).

This present study is conducted in the context of AQMEII4 and has three main objectives. The first objective is to evaluate the CMAQ simulations contributed to AQMEII4 by comparing simulated pollutant fields and wet deposition fluxes to observations while leveraging results from a recent extensive CMAQ evaluation study (Appel et al., 2021) that used the same model version as the AQMEII4 simulations but differed in terms of several input fields and configuration options. The focus of this analysis is on quantifying the impacts of these setup differences and comparing model performance across both configurations. The second objective is to use the AQMEII4 diagnostics introduced in Galmarini et al. (2021) and Clifton et al. (in preparation) to diagnostically compare the two dry deposition schemes implemented in CMAQ and used in the AQMEII4 simulations as discussed in Section 2, i.e. the M3Dry (Pleim et al., 1984; Pleim and Ran, 2011) and Surface Tiled Aerosol and Gaseous Exchange (STAGE) (Appel et al., 2021, Galmarini et al., 2021; Bash et al., submitted) schemes. The third objective is to quantify the impacts of differences in the representation of land use (LU) in the meteorological and air quality model on concentrations and fluxes and compare them to the impacts of different dry deposition schemes.

Section 2 provides an overview of the modeling system utilized in this study, the sensitivity simulations performed and analyzed, details on the configuration of the M3Dry and STAGE dry deposition schemes for these AQMEII4 simulations, and describes the observational datasets used for model evaluation. Section 3.1 presents results from the model performance evaluation, Section 3.2 presents results of a diagnostic gas phase dry deposition comparison between M3Dry and STAGE on both the grid scale and for specific LU types, and Section 3.3 analyzes the sensitivity of estimated dry deposition to the underlying LU classification scheme. Results are summarized and discussed in Section 4.

2 Description of model simulations and observational database

2.1 Base case model configuration

The 2010 and 2016 base case CMAQ simulations analyzed in this study closely follow the configuration of the “CMAQ531_WRF411_M3Dry_BiDi” and “CMAQ531_WRF411_STAGE_BiDi” 2016 CMAQv5.3.1 simulations analyzed in Appel et al. (2021). Key aspects of that configuration as well as deviations in the current study are summarized below.

2.1.1. Meteorological modeling

As in the Appel et al. (2021) study, meteorological fields were generated with the Weather Research and Forecast (WRF) model version 4.1.1. WRFv4.1.1 configuration options in common with Appel et al. (2021) include the Rapid Radiation

Transfer Model Global (RRTMG) for long- and short-wave radiation (Iacono et al., 2008), the Morrison microphysics scheme (Morrison et al., 2005), and the Kain-Fritsch (KF) cumulus parametrization scheme (Kain, 2004). Furthermore, both Appel et al. (2021) and this study used the Pleim-Xiu land-surface model (PX-LSM; (Pleim and Xiu, 1995; Xiu and Pleim, 2001; Pleim and Gilliam, 2009) and Asymmetric Convective Mixing 2 planetary boundary layer (PBL) model (Pleim, 2007a,b) with the Pleim surface layer scheme (Pleim, 2006). WRF data assimilation followed Appel et al. (2021) and is described in greater detail in Gilliam et al. (2021), and soil temperature and moisture nudging followed Pleim and Gilliam (2009) and Pleim and Xiu (2003). In contrast to Appel et al. (2021), the WRF simulations used in this study obtained sea surface temperature from the North America Model (NAM) reanalysis data set (Mesinger et al., 2006) instead of the Group for High Resolution Sea Surface Temperature (GHR SST), did not include lightning assimilation (Heath et al., 2016), and classified LU with the 20-category Moderate Resolution Imaging Spectroradiometer (MODIS) satellite derived LU classification scheme instead of the 40-category National Land Cover Dataset (NLCD) (Dewitz and U.S. Geological Survey, 2021; Yang et al., 2018) LU data set. In a further contrast to Appel et al. (2021), the WRF PX LSM in this study was configured to obtain Leaf Area Index (LAI) and areal fraction covered by vegetation (VEGF) from the PX LSM MODIS LU-scheme lookup table values rather than directly ingesting MODIS satellite-derived inputs interpolated from monthly data as described in Ran et al. (2016). Finally, it should be noted that after performing the two 2010 CMAQ simulations analyzed in this study, it was discovered that the WRF fields for several time periods in September, October, and November 2010 were affected by inconsistencies in the WRF input file preparation that affected simulated precipitation. These time periods were excluded from the model performance evaluation.

2.1.2 Emissions

The anthropogenic emissions for 2010 and 2016 were harmonized for all AQMEII4 modeling groups and are described in Galmarini et al. (2021). For 2016, these AQMEII4 emissions were based on an earlier version of emission inventories compared to the 2016 emissions described in Appel et al. (2021). For lightning NO emissions, the CMAQ simulations performed for this study used the GEIA monthly climatological data (Price et al., 1997) as described in Galmarini et al. (2021) for consistency with other AQMEII4 modeling groups while Appel et al. (2021) used lightning NO estimated from hourly year-specific lightning flash data from the National Lightning Detection Network (NLDN). Both this study and Appel et al. (2021) estimated biogenic VOC and soil NO emissions with the CMAQ inline Biogenic Emission Inventory System (BEIS) option with the same underlying LU dataset and emission factors.

2.1.3 Boundary conditions

Lateral chemical boundary conditions for both 2010 and 2016 for all AQMEII4 model simulations, including the CMAQ simulations analyzed in this study, were obtained from the Copernicus Atmospheric Monitoring Service (CAMS) EAC4 reanalysis product (Inness et al., 2019) as described in Galmarini et al. (2021). This differs from the 2016 CMAQ simulations

analyzed in Appel et al. (2021) which used hemispheric CMAQ (Mathur et al., 2017) simulations to generate boundary
125 conditions for the regional-scale modeling domain over North America.

2.1.4 Air quality modeling

The base version of CMAQ used in this study is 5.3.1 (U.S. Environmental Protection Agency, 2019) and matches that used
for the “CMAQ531_WRF411_M3Dry_BiDi” and “CMAQ531_WRF411_STAGE_BiDi” simulations in Appel et al. (2021).
All CMAQ simulations were performed on the same 12 km modeling domain with 35 vertical layers covering the conterminous
130 U.S, southern Canada, and northern Mexico that was used in Appel et al. (2021). Science configuration options include the
cb6r3 chemical mechanism (Luecken et al., 2019), the aero7 aerosol module (Pye et al., 2017, 2019; Qin et al., 2021; Appel
et al., 2021), and the bi-directional treatment of NH₃ fluxes, all matching the configuration options used in Appel et al. (2021).
As in Appel et al. (2021), the fertilizer and soil NH₃ information required for the bi-directional treatment of NH₃ fluxes were
generated by the Environmental Policy Integrated Climate (EPIC; Williams, 1995) model through the Java-based Fertilization
135 Emission Scenario Tool for CMAQ (FEST-C; Ran et al., 2019), though it should be noted that the 2010 EPIC fields used in
this study suffered from an EPIC configuration error that resulted in an unrealistically large allocation of annual fertilizer
application to the beginning of the year. Dry deposition was simulated with both science options available in CMAQv5.3.1,
i.e. the M3Dry and STAGE schemes. The application of both schemes to this study and modifications for the STAGE dry
deposition option relative to the CMAQv5.3.1 base version are described in Section 2.3.

140 2.2 CMAQ Sensitivity Simulations

Besides the 2010 and 2016 CMAQ M3Dry and STAGE base case simulations described in Section 2.1, additional CMAQ
sensitivity simulations were performed for 2016 to quantify the impacts of some of the differences relative to the Appel et al.
(2021) CMAQ configuration and to gain further diagnostic understanding on the choice of model inputs on modeled deposition.
Table 1 provides a listing of all base case and sensitivity simulations, their acronyms used in the following analyses and
145 discussions, and the input data sets and/or configuration options differentiating them. As discussed further in Section 2.3,
STAGE_REF_2016 is designed to quantify the impact of modifying the CMAQ STAGE code for AQMEII4 relative to the
unmodified STAGE code in CMAQv5.3.1 used by Appel et al. (2021). M3DRY_NLCD40_2016 is designed to study the
impact of using a different LU classification scheme in both WRF and CMAQ on simulated concentrations, deposition fields,
and deposition diagnostics. M3DRY_HCMAQ_2016 can be used to assess the impact of using chemical boundary conditions
150 from CAMS compared to using boundary conditions from H-CMAQ as in Appel et al. (2021). Finally, the set of
M3DRY_LTGNO_BASE_2016 and M3DRY_LTGNO_NLDN_2016 simulations can be used to study the impacts of different
lightning NO emission representations (GEIA vs. NLDN) on simulated concentration and deposition fields. It should be noted
that these two simulations used the 2021 WRFv4.1.1 fields from Appel et al. (2021) rather than those used for the base case

155 **Table 1.** Configurations of the AQMEI4 CMAQ simulations performed for this study.

simulations described in Section 2.1.1. Because these sensitivity simulations were performed for 2016, the focus of the analysis in Section 3 will be on that year.

2.3 Application of M3Dry and STAGE for AQMEI4

160 A key component of the AQMEI4 activity is to compute and analyze dry deposition pathways and component resistances on both a grid-scale and LU-specific basis (Galmarini et al., 2021). This section describes how this diagnostic information is

generated from the CMAQ simulations contributed to the AQMEII4 activity and analyzed in this study. A schematic representation of both M3Dry and STAGE and equations for their computations of the AQMEII4 dry deposition diagnostic variables can be found in Appendix B of Galmarini et al. (2021). As described in Appel et al. (2021), both M3Dry and STAGE originate from earlier versions of the M3Dry scheme which has a long history in CMAQ and other chemical transport models (Pleim et al., 1984). However, both algorithms follow different approaches in terms of their consideration of sub-grid scale variations in LU and the calculation of some component resistances.

2.3.1 M3Dry

The M3Dry dry deposition calculations performed in CMAQ are designed to maintain maximum consistency with the flux calculations performed in the WRF PX LSM. Specifically, the M3Dry calculations are performed on a grid scale basis. Sub-grid scale variations in LU are accounted for by computing relevant grid-scale parameters like roughness length (z_0), VEGF, and leaf area index (LAI) as LU-weighted averages from LU-specific lookup table values. Grid scale aerodynamic resistance (R_a), stomatal resistance (R_s), friction velocity (u_*), VEGF, and LAI computed in the WRF PX LSM are directly used in the CMAQ M3Dry deposition calculations. To compute the LU-specific and dry deposition diagnostic variables required for AQMEII4 (Galmarini et al., 2021), a post-processing tool was developed to estimate these variables by performing M3Dry calculations separately for each LU category encountered in a grid cell. While these LU-specific post-processor calculations used the same formulations and parameter values as the grid-scale deposition calculations performed in CMAQ M3Dry, the fact that WRF PX LSM uses parameter values weighted by LU fraction for the calculation of R_a , R_s , and other relevant variables means that the LU-weighted averages of the LU-specific post-processor estimates for deposition velocity (V_d) and effective conductance may slightly deviate from the grid-scale CMAQ M3Dry calculations and should therefore be viewed as an approximation. However, the LU-specific dry deposition fluxes computed by the post-processor were normalized by the grid cell values so that the LU-weighted flux sums equal the total grid cell fluxes. The CMAQ M3Dry calculations and post-processor estimates of LU-specific and aggregated diagnostic variables were performed using the native 20 category MODIS LU scheme (or 40 category NLCD LU scheme for the M3DRY_NLCD40_2016 sensitivity simulation) that was also used in the WRF simulations. Aggregation to the 16 category AQMEII4 LU scheme used in our analysis (Galmarini et al., 2021) was performed through mapping and LU-weighted averaging of equivalent categories (Table S1).

2.3.2 STAGE

The STAGE dry deposition option was first introduced in CMAQv5.3 (Appel et al., 2021). It unifies bi-directional and uni-directional deposition schemes following the resistance model frameworks of Massad et al. (2010) and Nemitz et al. (2001). In contrast to M3Dry, STAGE computes individual resistances, V_d , and deposition fluxes for each LU category present in a grid cell and then aggregates these calculations to the grid scale value for use by the CMAQ surface exchange module. Therefore, some of the deposition diagnostics required for AQMEII4 (LU-specific and grid scale V_d and fluxes) were readily

available from the standard version of STAGE in CMAQv5.3.1. Code modifications were made to output the desired component resistances and conductances that were computed but not output in the standard version of STAGE. Moreover, the STAGE code used in this study was also modified to perform all deposition calculations directly on the 16 AQMEII4 LU categories (Galmarini et al., 2021) rather than the 20 MODIS categories used in the WRF PX LSM calculations. This was accomplished by applying the same mapping used in the M3Dry post-processing and shown in Table S1 and also defining LU-specific lookup table values for required parameters like z_0 , VEGF, and LAI for each of the 16 AQMEII4 categories in the modified STAGE code. As a result of deriving grid-scale deposition-related variables from LU-specific calculations and using a more aggregated LU classification scheme with a separate set of lookup table values, some of these grid-scale variables such as R_a , R_s , u_* , VEGF, and LAI may differ from the corresponding values used in the WRF PX LSM flux calculations, creating a potential inconsistency in the treatment of surface-air exchange processes simulated in WRF PX LSM and CMAQ STAGE. It should be noted that in the most recent version of CMAQ released in October 2022 (U.S. Environmental Protection Agency, 2022), STAGE was updated to normalize LU-specific calculations for R_a , R_s , and u_* such that their aggregated grid-scale values match the grid scale values obtained from the LSM of the driving meteorological model.

2.4 Observational data

For the performance evaluation presented in Section 3.1, the base case CMAQ simulations were compared against observations obtained from the U.S. Environmental Protection Agency's Air Quality System (AQS; <https://www.epa.gov/aqs>) database and the National Atmospheric Deposition Program's National Trend Network (NADP NTN; <https://nadp.slh.wisc.edu/networks/national-trends-network/>). Specifically, model evaluation was performed for hourly nitrogen oxides (NO_x) and sulfur dioxide (SO_2), daily maximum 8-hr average O_3 (MDA8 O_3), and daily $\text{PM}_{2.5}$ sulfate (SO_4^{2-}), nitrate (NO_3^-), organic carbon (OC), elemental carbon (EC), and total $\text{PM}_{2.5}$ mass from AQS as well as weekly integrated precipitation and wet deposition of SO_4^{2-} , NO_3^- , and ammonium (NH_4^+) from NADP NTN. The number of 2016 (2010) monitors with available observations was 425 (374) for NO_x , 464 (446) for SO_2 , 1323 (1278) for MDA8 O_3 , 1926 (2006) for $\text{PM}_{2.5}$ mass, 318 (398) for $\text{PM}_{2.5}$ SO_4^{2-} , 312 (393) for $\text{PM}_{2.5}$ NO_3^- , 297 (177) for $\text{PM}_{2.5}$ OC, 297 (177) for $\text{PM}_{2.5}$ EC, and 259 (237) for precipitation and SO_4^{2-} , NO_3^- , and NH_4^+ wet deposition, though not all monitors had year-round data coverage. All model values were matched in time and space against the available 2010 and 2016 observations using the Atmospheric Model Evaluation Tool (AMET; Appel et al., 2011) version 1.4.

3 Results

220 3.1 Model performance evaluation

Comparisons of modeled and observed MDA8 O₃, SO₂, NO_x, PM_{2.5}, SO₄²⁻, NO₃⁻, OC, and EC concentrations at AQS monitors and precipitation and wet deposition of SO₄²⁻, NO₃⁻, and NH₄ at NADP monitors are presented in Figures 1 – 2, S1, and Tables 2 – 3.

Table 2a shows key model performance metrics for several gas phase and aerosol species for the M3DRY_2016 and
225 STAGE_2016 base case simulations as well as the corresponding 2016 CMAQ531_WRF411_M3Dry_BiDi and
CMAQ531_WRF411_STAGE_BiDi simulations from Appel et al. (2021). These performance metrics are the observed and
modeled mean values and standard deviations, the normalized and absolute mean bias (NMB and MB, respectively), the root
mean square error (RMSE), and the correlation coefficient. The metrics shown in this table were computed across all stations
and available observation – model pairs. Corresponding time series of monthly mean observed and modeled values and RMSE
230 are shown in the left column of Figures 1a and 2a.

For MDA8 O₃, a comparison of the AQMEI4 simulations to the Appel et al. (2021) simulations shows a positive instead of a
negative bias, a larger absolute bias, a similar or lower RMSE, and a higher correlation coefficient. The AQMEI4 simulations
are closer to the observations for February – July while the Appel et al. (2021) are closer for the remaining months. The
differences between performance statistics for the M3Dry and STAGE simulations are small but that is partially due to the
235 seasonally and spatially varying nature of differences between these schemes that will be discussed in Section 3.2. For NO_x,
the AQMEI4 simulations show slightly lower concentrations and hence a slightly more pronounced negative bias and higher
RMSE compared to the Appel et al (2021) simulations but the time series indicate that all simulations deviate substantially
from observations, especially during winter. For SO₂, model performance is similar for all four simulations. For PM_{2.5} mass,
the AQMEI4 simulations show higher concentrations especially during summer, a positive instead of a negative bias, a larger
240 absolute bias, a higher RMSE, and lower correlations than the corresponding Appel et al. (2021) simulations. M3DRY_2016
shows slightly lower concentrations, MB and RMSE than STAGE_2016. For PM_{2.5} species, the AQMEI4 simulations have a
lower absolute bias than Appel et al. (2021) for SO₄²⁻ and NO₃⁻ and higher absolute bias for OC and EC. The AQMEI4
simulations also have a higher RMSE and lower correlation for all species except NO₃⁻. A comparison of the spatial patterns
of MDA8 O₃ and PM_{2.5} biases in Figure S1 shows that the overall higher concentrations of both pollutants in the 2016
245 AQMEI4 simulations resulted in a higher positive bias in the eastern U.S. compared to Appel et al. (2021) while the general
underestimation in the western U.S. seen in the Appel et al. (2021) results was reduced for PM_{2.5} and turned into a general
overestimation for MDA8 O₃.

295 **Figure 2b:** RMSE of monthly mean observed and modeled precipitation and wet deposition at NADP sites. Appel_M3DRY and Appel_STAGE refers to the “CMAQ531_WRF411_M3Dry_BiDi” and “CMAQ531_WRF411_STAGE_BiDi” 2016 CMAQv5.3.1 simulations analyzed in Appel et al. (2021).

Table 2b and the right columns of Figures 1a and 2a show the corresponding results for the 2010 AQMEII4 simulations
300 M3DRY_2010 and STAGE_2010 but do not include a comparison against results from Appel et al. (2021) because no 2010
simulations were performed in that study. The results show that the sign of the NMB and MB for 2010 is the same as that for
the 2016 results for MDA8 O₃, NO_x, SO₂, PM_{2.5} mass, OC and EC. Bias results for SO₄²⁻ and NO₃⁻ show greater differences
between the years, suggesting that the effects of the substantial reductions in SO₂ and NO_x emissions (Foley et al., 2022)
between 2010 and 2016 on these aerosol species may not be captured perfectly. The observed decrease in concentrations
305 between 2010 and 2016 is captured by both simulations for all pollutants and is likely caused in large parts by substantial
decreases in emissions (Foley et al., 2022) although differences in meteorological conditions between these years may also
have played a role. The magnitude of the decrease is overestimated for O₃, NO_x, and PM_{2.5} mass, though it is important to note
that the monitors at which the statistics are calculated differ both between pollutants and between years. The differences in
model performance between M3DRY_2010 and STAGE_2010 are similar to those between M3DRY_2016 and STAGE_2016.

310 Tables 3a-3b and Figures 1b and 2b show model performance results for weekly precipitation and wet deposition at NADP
NTN monitors in 2016 and 2010. 2016 Precipitation has a smaller dry bias than Appel et al. (2021) but also lower correlation
coefficients and higher RMSE. This suggests that the benefit of using lightning assimilation in the WRF meteorological model
predominantly is an improved representation of the temporal and spatial variability in precipitation (Heath et al., 2016). The
statistics for the AQMEII4 SO₄²⁻ and NO₃⁻, and NH₄⁺ deposition fluxes also show lower correlations and higher RMSE
315 compared to the Appel et al. (2021) simulations. Consistent with the negative precipitation bias, simulated wet deposition flux
biases also are negative for all pollutants, though the difference between the AQMEII4 and Appel et al. (2021) simulations
varies between SO₄²⁻ and NO₃⁻, likely also influenced by other differences in model setup, particularly boundary conditions
and lightning NO emissions. Overall, these results confirm that model performance for precipitation is a key driver for wet
deposition model performance. However, despite the noticeable degradation in precipitation model performance relative to the
320 WRF simulations described in Appel et al. (2021) that used lightning assimilation, the NMB results presented here fall within
the range of retrospective long-term simulations over North America (Zhang et al., 2019). The results for 2010 are similar as
those for 2016, again with negative biases for all variables. A comparison between 2010 and 2016 shows that the model
captured the sign of the observed changes for precipitation and wet deposition fluxes, with wetter conditions in 2016 but mostly
similar or slightly lower wet deposition fluxes, likely due to significant reductions in NO_x and SO₂ emissions.

325 To quantify the impacts of several differences in model inputs compared to Appel et al. (2021) on these evaluation results,
Figures S2 – S5 present maps of annual mean differences between the M3DRY_2016 base case and several of the sensitivity
simulations listed in Table 1. Figure S2 shows the results of a comparison of M3DRY_2016 against
M3DRY_LTNGNO_BASE_2016. The only difference between these two CMAQ simulations is the input meteorology, with
M3DRY_LTNGNO_BASE_2016 using the WRFv4.1.1 fields from Appel et al. summarized in Section 2.1.1. For the
330 meteorological variables, the M3DRY_2016 simulations show a tendency for generally lower temperatures and higher
precipitation while wind speed and solar radiation show both positive and negative differences. Concentrations over land either

showed small changes or decreases. Therefore, the overall higher ozone (O_3) and $PM_{2.5}$ concentrations in M3DRY_2016 compared to Appel et al. (2021) cannot be explained by the differences in meteorological fields. Figure S3 shows the difference in annual mean concentrations between the M3DRY_2016 and M3DRY_HCMAQ_2016 simulations that differ only in their boundary conditions. Results show substantially higher MDA8 O_3 concentrations when using CAMS rather than H-CMAQ to generate lateral boundary conditions, with annual mean differences ranging from more than 10 ppb near the boundaries to 3-5 ppb for most of the eastern U.S. The CAMS-derived boundary conditions used in the current study also yield higher annual average $PM_{2.5}$ concentrations, with most of the increase caused by organic aerosols and crustal components associated with long-range transport of dust. Figure S4 shows the difference in annual mean concentrations between the M3DRY_2010 and M3DRY_APPEL_EMIS_2016 simulations that differ in their anthropogenic and wildland fire emission inputs. Use of the AQMEII4 emissions resulted in localized higher concentrations of total $PM_{2.5}$ compared to using the Appel et al. (2016) emissions, with partially compensating effects for different $PM_{2.5}$ components. Figure S5 shows the percentage difference in May - September mean surface O_3 and NO_2 concentrations, total dry and wet N deposition, and column NO_2 between M3DRY_LTNGNO_BASE_2016 and M3DRY_LTNGNO_NLDN_2016 to quantify the impact of using lightning NO emissions based on GEIA climatology in AQMEII4 rather than NLDN lightning flash data in Appel et al. (2021). The results indicate that this choice of input data has only a relatively minor impact on the surface concentrations considered in the model performance analysis but has a significant impact on modeled NO_2 columns which in turn impacts total nitrogen deposition, mostly through wet deposition. The noticeable impact of different datasets to represent lightning NO emissions on wet deposition of nitrogen is consistent with a recent study by Kang et al. (2022). The analysis of these sensitivity simulations indicates that the choice of lateral boundary conditions was the largest driver of differences in mean model concentrations and biases compared to the corresponding CMAQv5.3.1 simulations analyzed in Appel et al. (2021). Overall, the results presented in this section demonstrate that the AQMEII4 CMAQ simulations perform similarly to other comparable regional-scale modeling studies (Emery et al., 2017; Kelly et al., 2019; Simon et al. 2012; Appel et al., 2021). The overall sensitivity to M3Dry vs. STAGE is smaller than the sensitivity to model input data sets and boundary conditions that represent the large-scale chemical environment. However, the following sections demonstrate how the choice of deposition scheme is an important consideration depending on the ecological region and the season that the model is applied.

3.2 Diagnostic gas phase dry deposition comparison M3Dry vs. STAGE

The following sections use the diagnostic variables generated for AQMEII4 to gain insights into the processes causing differences between the M3Dry and STAGE CMAQ simulations. This analysis starts with a comparison of grid-scale quantities, then proceeds to comparisons performed for the specific LU types defined for AQMEII4 (Galmarini et al., 2021), and finally compares and discusses different approaches for handling sub-grid LU variations and LU aggregation in M3Dry and STAGE. All analyses in these sections focus on the CMAQ AQMEII4 simulations performed for 2016.

3.2.1 Grid Scale Dry Deposition Diagnostics and Fluxes

Figure 3 shows differences in seasonal mean O_3 V_d and mixing ratios M3DRY_2016 minus STAGE_2016. It can be seen that
365 the spatial patterns of differences in V_d and O_3 mixing ratios are closely linked, with areas of positive (negative) V_d differences
between M3Dry and STAGE generally corresponding to areas of negative (positive) mixing ratio differences. During summer,
M3Dry has higher V_d and lower mixing ratios than STAGE for much of the eastern U.S. while the reverse is the case over
eastern Canada and along the West Coast. In contrast, during winter STAGE has higher V_d and lower mixing ratios than
370 M3Dry over most of the southern half of the modeling domain while the reverse is the case for much of the northern U.S. and
southern Canada. The differences in seasonal mean mixing ratios reach 2-3 ppb in a number of locations, indicating that the
effects of different dry deposition schemes can be more pronounced locally than in the spatially aggregated metrics presented
in Section 3.1

To diagnose reasons for the differences in V_d between M3Dry and STAGE, we apply the concept of effective conductances
(Paulot et al., 2018; Clifton et al., 2020b) as adapted for AQMEII4 (Galmarini et al., 2021). Given that the sum of the effective
375 conductances equals V_d , this allows an attribution of V_d to distinct pathways controlled by different processes. The four
pathways defined in Galmarini et al. (2021) and based on the original Wesely (1989) scheme are stomatal, cuticular, lower
canopy, and soil. Neither M3Dry nor STAGE include a deposition pathway to the lower canopy (see Figures B2 and B3 in
Galmarini et al., 2021) but both distinguish between deposition to bare vs. vegetated soil with the latter including an additional
in-canopy convective resistance term. Therefore, we analyzed effective conductances for the stomatal, cuticular, vegetated
380 soil, and bare soil pathways. We also note that the effective conductances analyzed here represent grid-scale values calculated
from LU-weighted averages of the corresponding LU-specific diagnostic variables requested for AQMEII4.

Seasonal average effective conductance maps for each pathway for M3Dry and STAGE as well as their differences are shown
in Figure 4a for summer and in Figure 4b for winter. Average diurnal cycles for summer and winter computed over all non-
water grid cells are shown in Figure 5a (absolute effective conductances) and Figure 5b (percentage contribution to V_d). Figures
385 4a-b show that the absolute and relative magnitude of the different pathways varies both spatially and seasonally for both
M3Dry and STAGE, with a generally greater importance of the stomatal and cuticular pathways in the more vegetated eastern
and northern portions of the modeling domain especially during summer and a greater importance of the deposition to soil,
especially bare soil, in the southwestern portion of the modeling domain and during winter. The comparison between M3Dry
and STAGE shows generally higher summertime stomatal and wintertime cuticular effective conductances for M3Dry and
generally higher soil effective conductances (both vegetated and bare) for STAGE in both summer and winter. The diurnal
390 cycles in Figures 5a-b confirm the seasonal variations and differences between M3Dry and STAGE shown in Figures 4a-b and
also illustrate the strong diurnal variation of several pathways, especially the stomatal pathway. In a relative sense, the stomatal
effective conductance accounts for about half of the total V_d during daytime hours in summer, though these diurnal cycles

395 represent an average over the entire domain so the contribution would be expected to be higher over the eastern portion of the modeling domain and lower over the southwestern portion of the modeling domain.

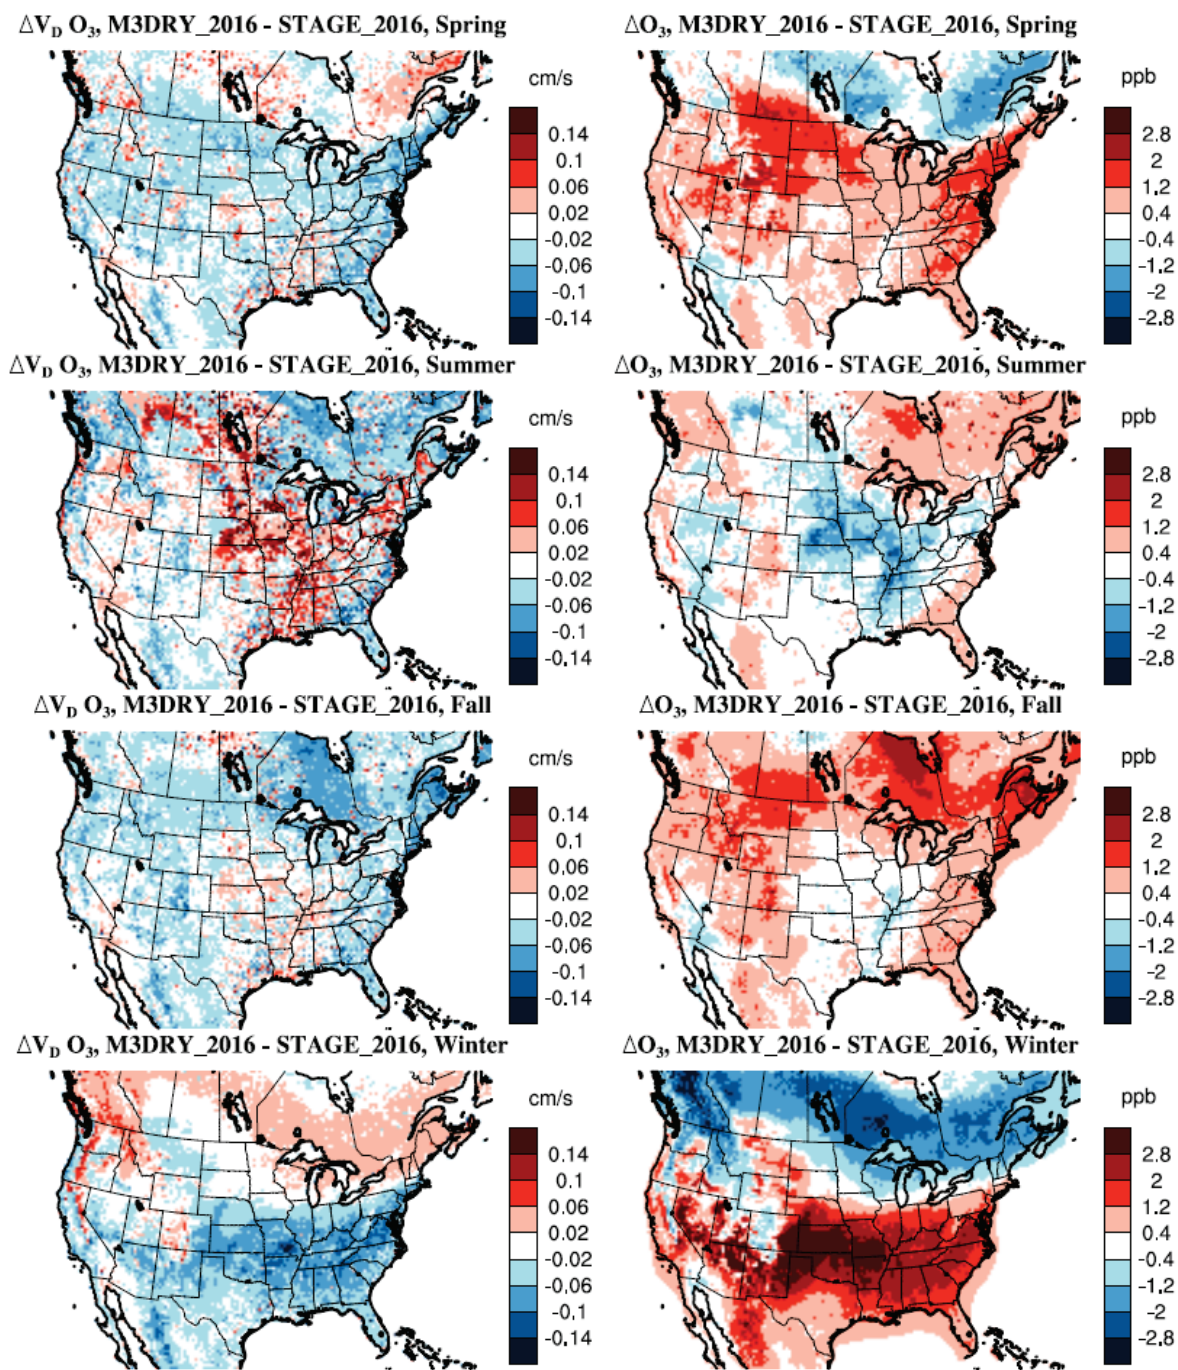

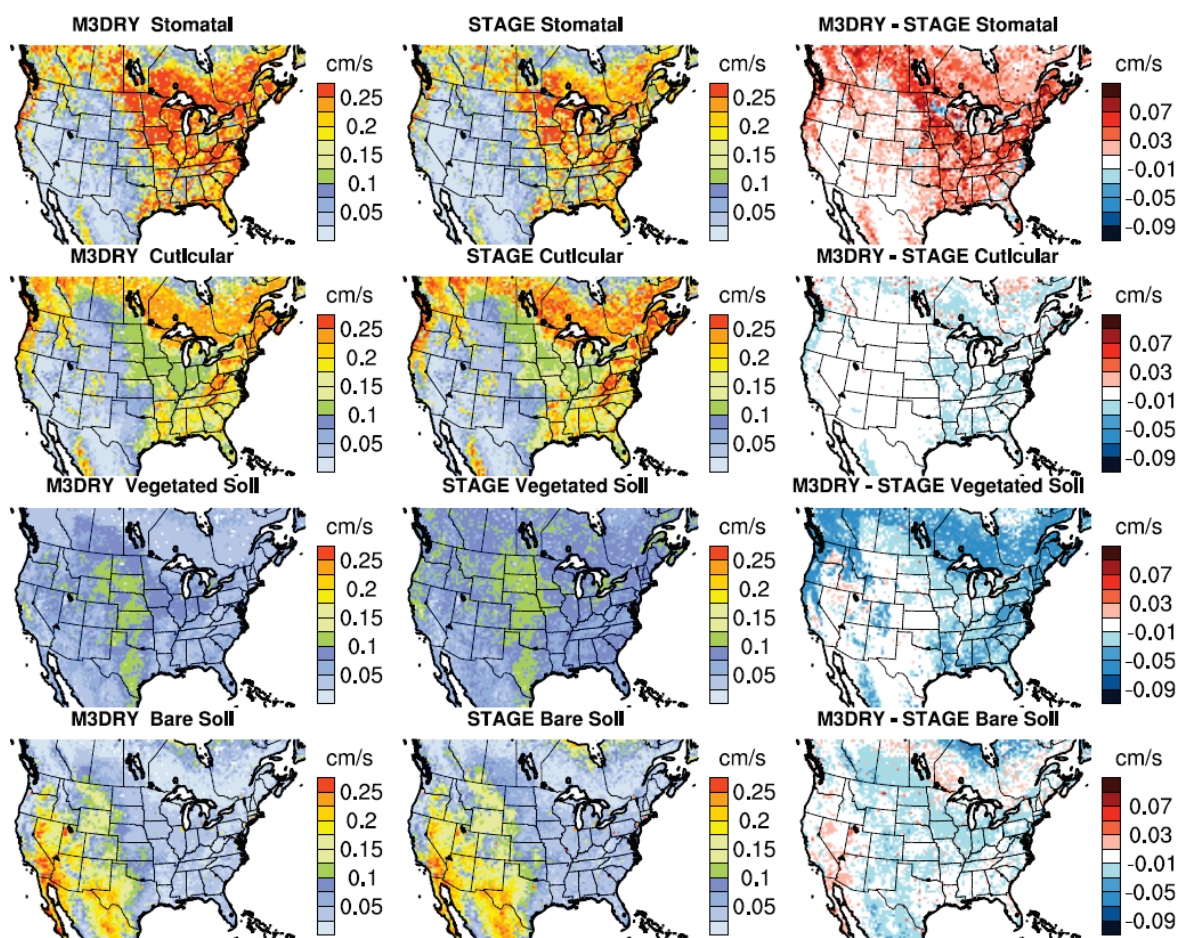

Figure 3: Differences in seasonal mean O₃ deposition velocities and mixing ratios M3DRY_2016 minus STAGE_2016.

400 **Figure 4a.** Grid-scale O_3 summer mean effective conductance maps for the stomatal, cuticular, vegetated soil, and bare soil pathways for M3DRY_2016, STAGE_2016, and M3DRY_2016 minus STAGE_2016.

Comparing the effective conductance difference maps in the right columns of Figures 4a-b to the summer and winter V_d difference maps in Figure 3 shows that the higher summer M3Dry V_d over the eastern U.S. are largely due to a larger stomatal
 405 conductance. While the M3Dry stomatal conductance is also moderately larger than for STAGE over eastern Canada, this is counteracted by a substantially larger STAGE soil effective conductance, leading to a net negative difference between M3Dry and STAGE V_d values over that region. Similarly, the split between larger winter STAGE V_d over the southern portion of the domain and larger M3Dry V_d over much of the Canadian portion of the modeling domain is the result of substantially larger
 410 STAGE soil effective conductances with only small differences in stomatal and cuticular effective conductances over the southern portion of the domain and substantially larger cuticular effective conductances in M3Dry with only small differences in soil effective conductances over the Canadian portion of the modeling domain.

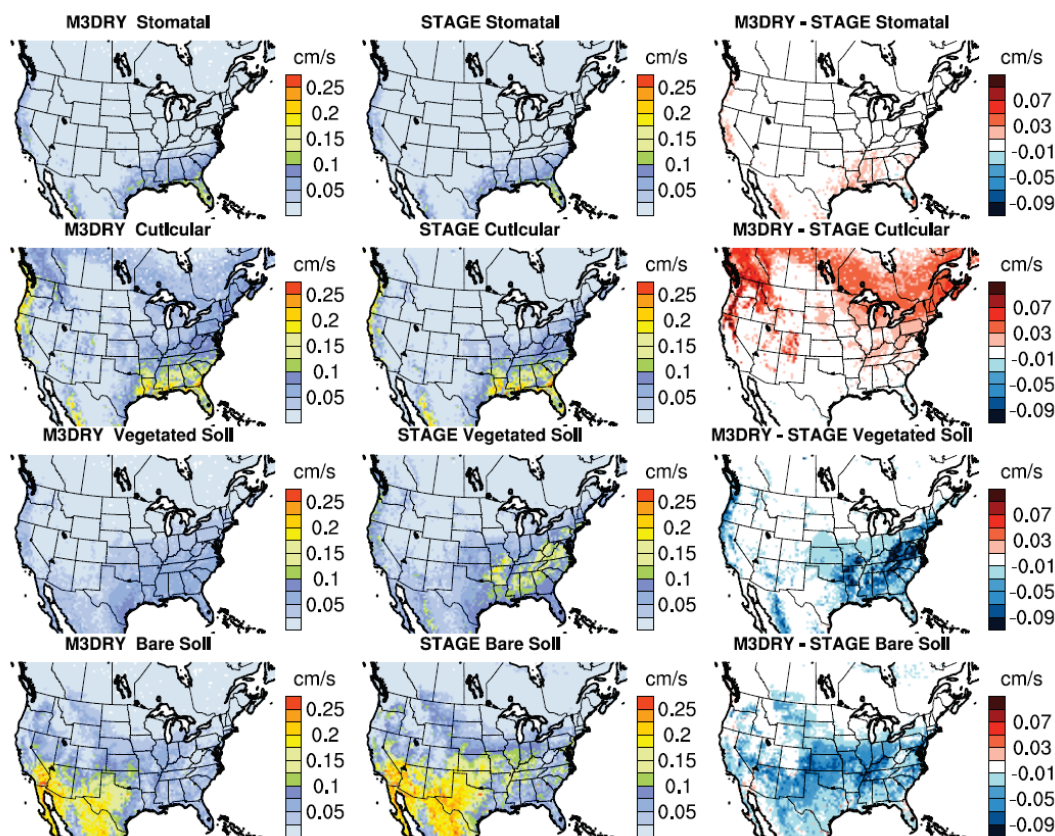

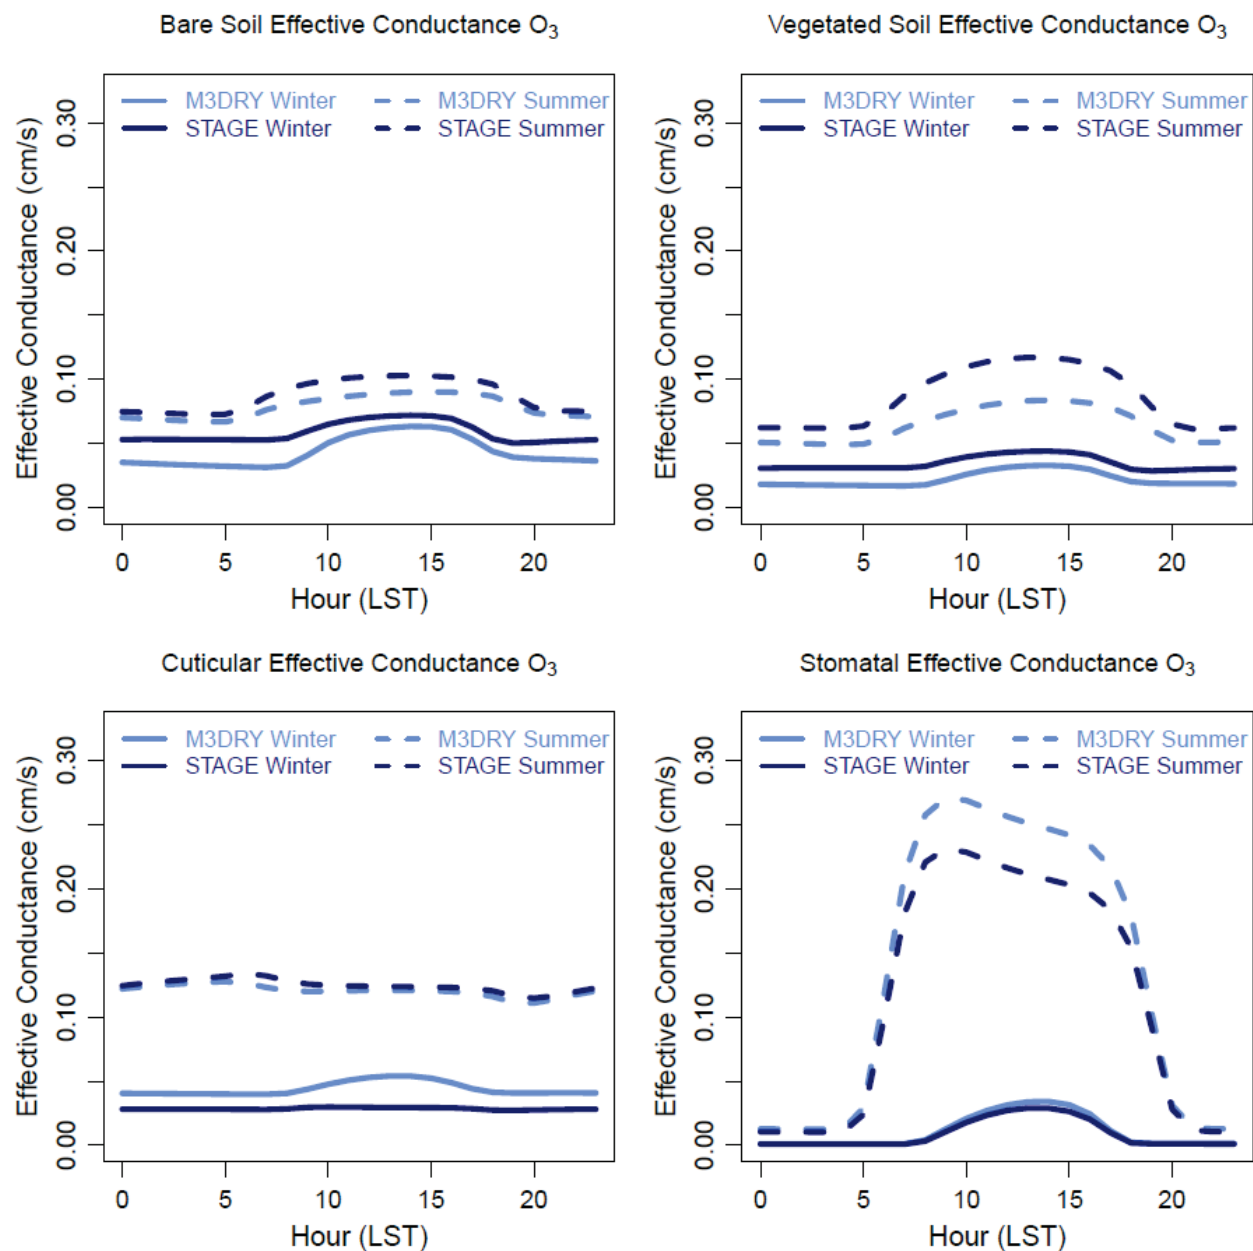

Figure 4b. As in Figure 4a but for winter mean effective conductances.

415 In addition to the effective conductances, AQMEII4 also requests participating models to save and submit key component resistances common to all schemes (see Galmarini et al., 2021 Table 4 for a listing of all requested component resistances and Tables B2 and B3 for their definition in the M3Dry and STAGE deposition diagrams in Figures B2 and B3). Like for the effective conductances, these diagnostic variables are calculated for each LU category and grid scale values are calculated as LU-weighted averages from LU-specific values. Figure 6 shows average summer and winter diurnal cycles of six inverse component resistances averaged over all non-water grid cells for both M3Dry and STAGE. These component resistances are the stomatal (R_s), cuticular (R_{cut}), in-canopy convective (R_{dc}), quasi-laminar sublayer (R_b for M3Dry and $R_{can,qlsb}$ and $R_{gnd,qlsb}$ for STAGE), and aerodynamic (R_a) resistances and they are plotted as inverse resistances for easier comparison to V_d and effective conductances. As seen in Galmarini et al. (2021) Figures B2 and B3, R_s , R_{cut} , and R_{dc} are pathway specific and parallel to each other, while they are also serial with R_a and the quasi-laminar sublayer resistance. In M3Dry, the quasi-laminar sublayer resistance is pathway independent while in STAGE it differs between the canopy (cuticular and stomatal) and ground (vegetated and bare soil) pathways. Note that the y-axis range differs across different resistances to better highlight seasonal variations and differences between M3Dry and STAGE for a given resistance.

420

425

430 **Figure 5a:** Summer and winter domain average diurnal cycles of grid-scale O_3 effective conductances for the stomatal, cuticular, vegetated soil, and bare soil pathways for M3DRY_2016 and STAGE_2016.

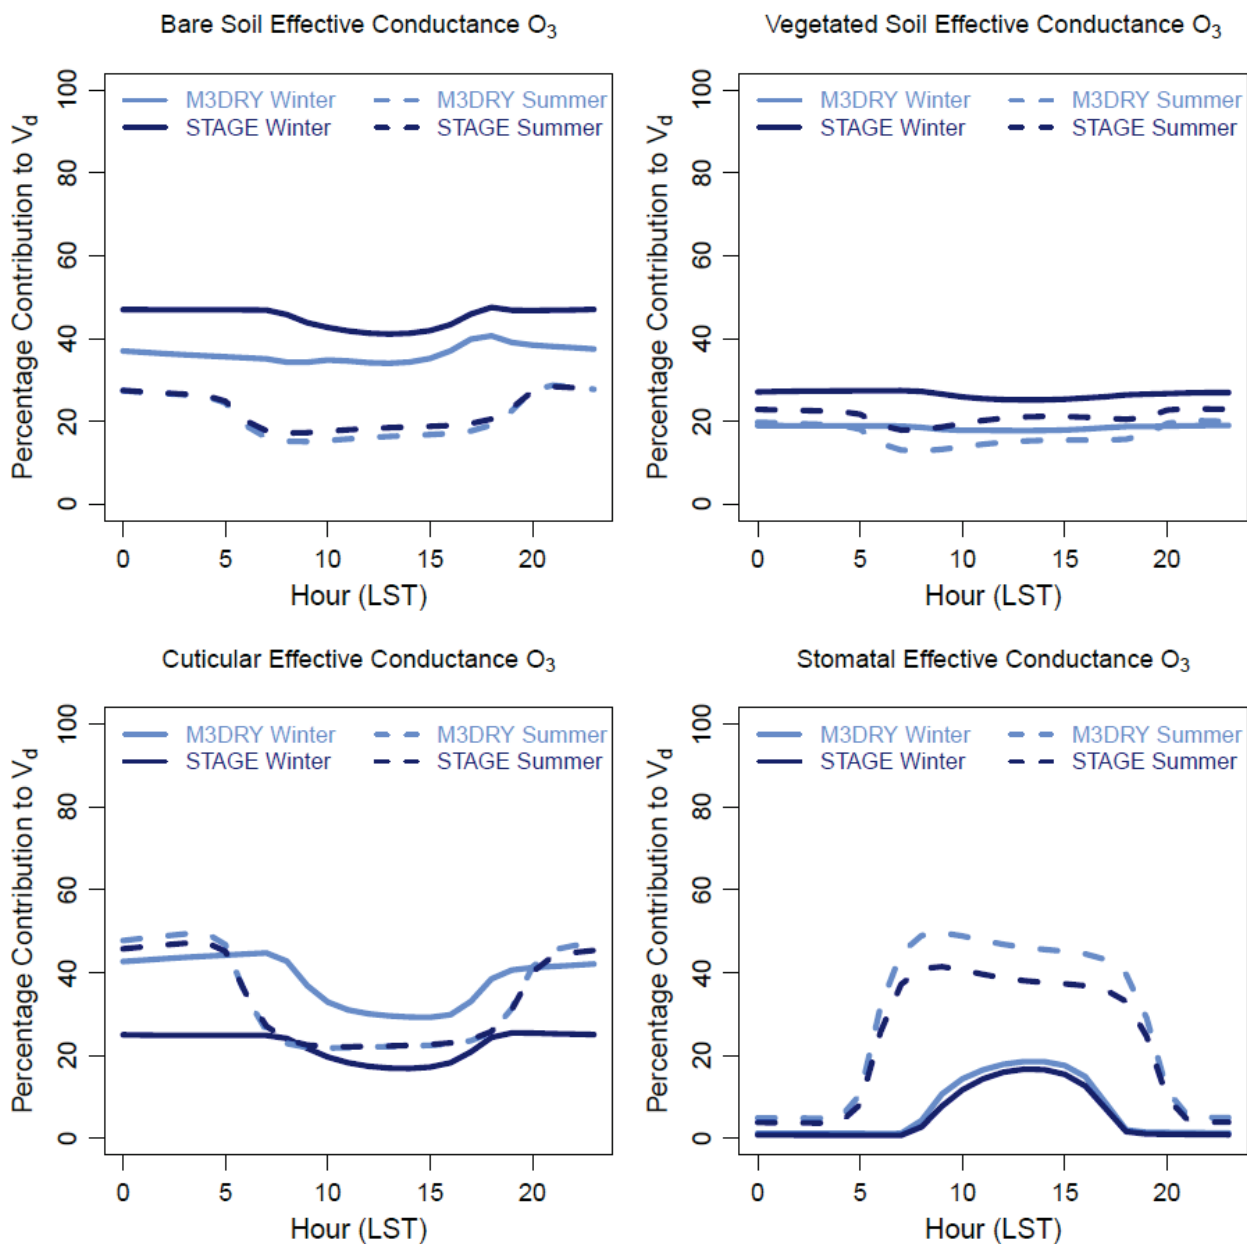

Figure 5b: As in Figure 5a, but showing the percentage contribution of the effective conductance for each pathway to the total deposition velocity.

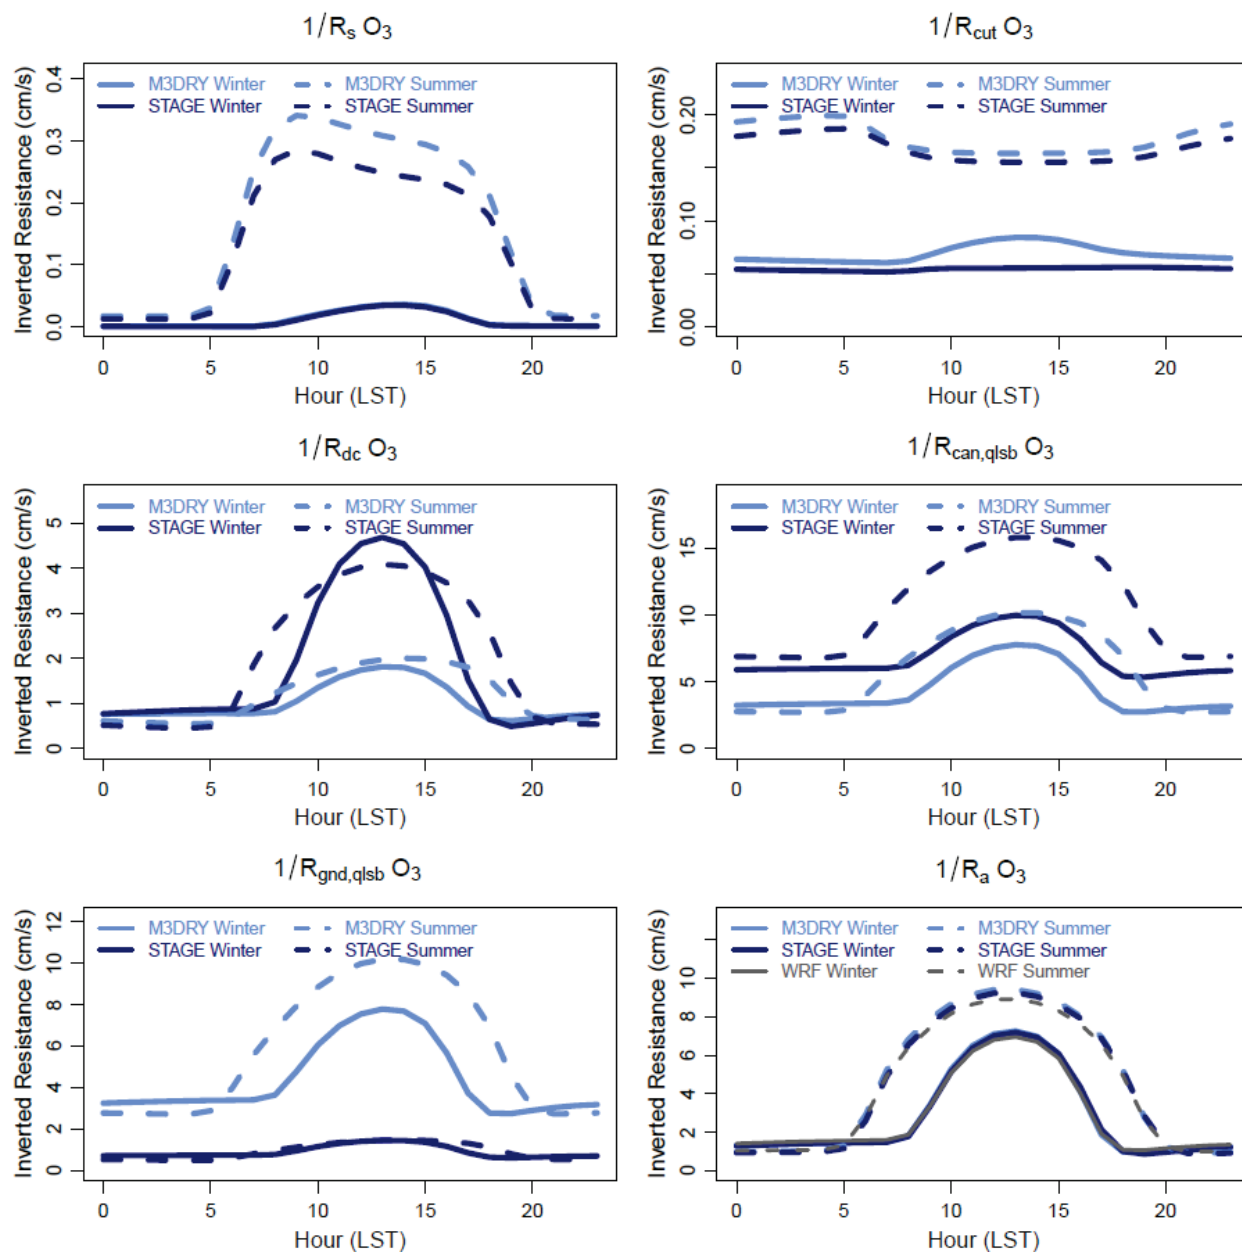

Figure 6: Summer and winter domain average diurnal cycles of grid-scale O₃ component resistances for M3DRY_2016 and STAGE_2016. Note the different y-axis ranges for different inverted resistances. The panel showing results for the inverted aerodynamic resistance 1/R_a also includes the values computed in the WRF PX LSM.

Consistent with the effective conductances shown above, values for summertime $1/R_s$ and wintertime $1/R_{cut}$ differ between M3Dry and STAGE, with the higher values of these inverted resistances in M3Dry causing higher effective conductances for these pathways. Inverted R_{dc} is substantially higher in STAGE than M3Dry. While soil resistance was not requested and saved as a separate term in AQMEII4 as its definition differs across schemes, the higher inverted STAGE R_{dc} values likely had an effect on the higher STAGE effective conductance values for the vegetated soil pathway. For the quasi-laminar sublayer resistances, inverted $R_{can,qlsb}$ for STAGE is higher than the pathway-independent inverted R_b for M3Dry which in turn is higher than the inverted $R_{gnd,qlsb}$ for STAGE. However, these resistances are typically small compared to the other resistances (i.e. their inverted values are larger) so that they generally only have a small impact on effective conductances and overall V_d . The inverted aerodynamic resistance R_a is very similar between M3Dry and STAGE for both summer and winter. As discussed in Section 2.3.1, all LU-specific diagnostic deposition variables for M3Dry are estimated through a post-processor while the M3Dry deposition calculations within CMAQ used grid-scale R_a calculated by the WRF PX LSM to maintain maximum consistency between the representation of land-surface exchange processes in WRF and CMAQ. Therefore, the panel for inverted R_a also shows the WRF-based grid-scale value used in the M3Dry CMAQ deposition calculations. This value is very similar to the post-processor based estimate for M3Dry. The different approaches taken by M3Dry and STAGE to handle sub-grid variability in LU and their impacts on deposition calculations is discussed further in Section 3.2.3.

While this section so far has focused on applying the AQMEII4 diagnostics to analyze M3Dry vs. STAGE differences in O_3 deposition, these diagnostics are also being calculated for SO_2 , NO_2 , NO , HNO_3 , NH_3 , PAN , HNO_4 , N_2O_5 , organic nitrates, H_2O_2 , and $HCHO$ (Galmarini et al., 2021). Moreover, the effective conductances and total V_d can also be used to calculate *effective fluxes*, i.e., apportion total dry deposition fluxes to specific pathways (Galmarini et al., 2021). Figure 7a shows annual domain-average (excl. water cells) V_d for M3Dry and STAGE for O_3 , H_2O_2 , $HCHO$, SO_2 , and oxidized nitrogen species as sum of the effective conductances for the four pathways while Figure 7b shows the corresponding annual total domain-wide (excl. water cells) dry deposition fluxes as sum of the effective fluxes. The V_d and deposition flux results for O_3 reflect the larger contributions from the vegetated and bare soil pathways for STAGE and the larger contributions for the stomatal and cuticular pathways for M3Dry. Annual domain total O_3 deposition fluxes differ only slightly between M3Dry and STAGE due to the seasonal and spatial variation of the V_d differences shown in Figure 3. In contrast to O_3 , most other pollutants show larger effective conductances and effective fluxes for the bare soil and sum of bare and vegetated soil pathways for M3Dry than STAGE. The cuticular effective flux is larger for M3Dry than STAGE for $HCHO$, SO_2 , HNO_4 , and organic nitrates, smaller for M3Dry than STAGE for H_2O_2 and HNO_3 , and similar between M3Dry and STAGE for other species. Stomatal effective fluxes are small for all species except O_3 , $HCHO$, and NO_2 for both M3Dry and STAGE. Total dry deposition fluxes differ the most between M3Dry and STAGE for $HCHO$ and organic nitrate, though again it should be noted that these fluxes represent annual domain totals and larger differences likely exist at sub-seasonal scales for different regions.

475 **Figure 7a.** Grid-scale annual average domain-wide (excl. water cells) effective conductances for O₃, H₂O₂, HCHO, SO₂, and oxidized nitrogen species.

Figure 7b. Grid-scale annual total domain-wide (excl. water cells) pathway-specific dry deposition fluxes (“effective fluxes”) for O₃, H₂O₂, HCHO, SO₂, and oxidized nitrogen species. Ozone dry deposition values are divided by a factor 10 to use the same y-axis as for the other pollutants.

480

3.2.2 LU-Specific Dry Deposition Diagnostics and Fluxes

In this section, we utilize the LU-specific dry deposition diagnostics generated during AQMEII4 to provide further insights into the grid-scale comparisons presented above. These LU-specific diagnostics were generated for the 16 common LU types defined in Galmarini et al. (2021). Figure S6 depicts spatial maps of the fractional coverage for each of these 16 categories, aggregated through post-processing from the native 20 MODIS LU categories used in the M3DRY_2016 simulations (see

485

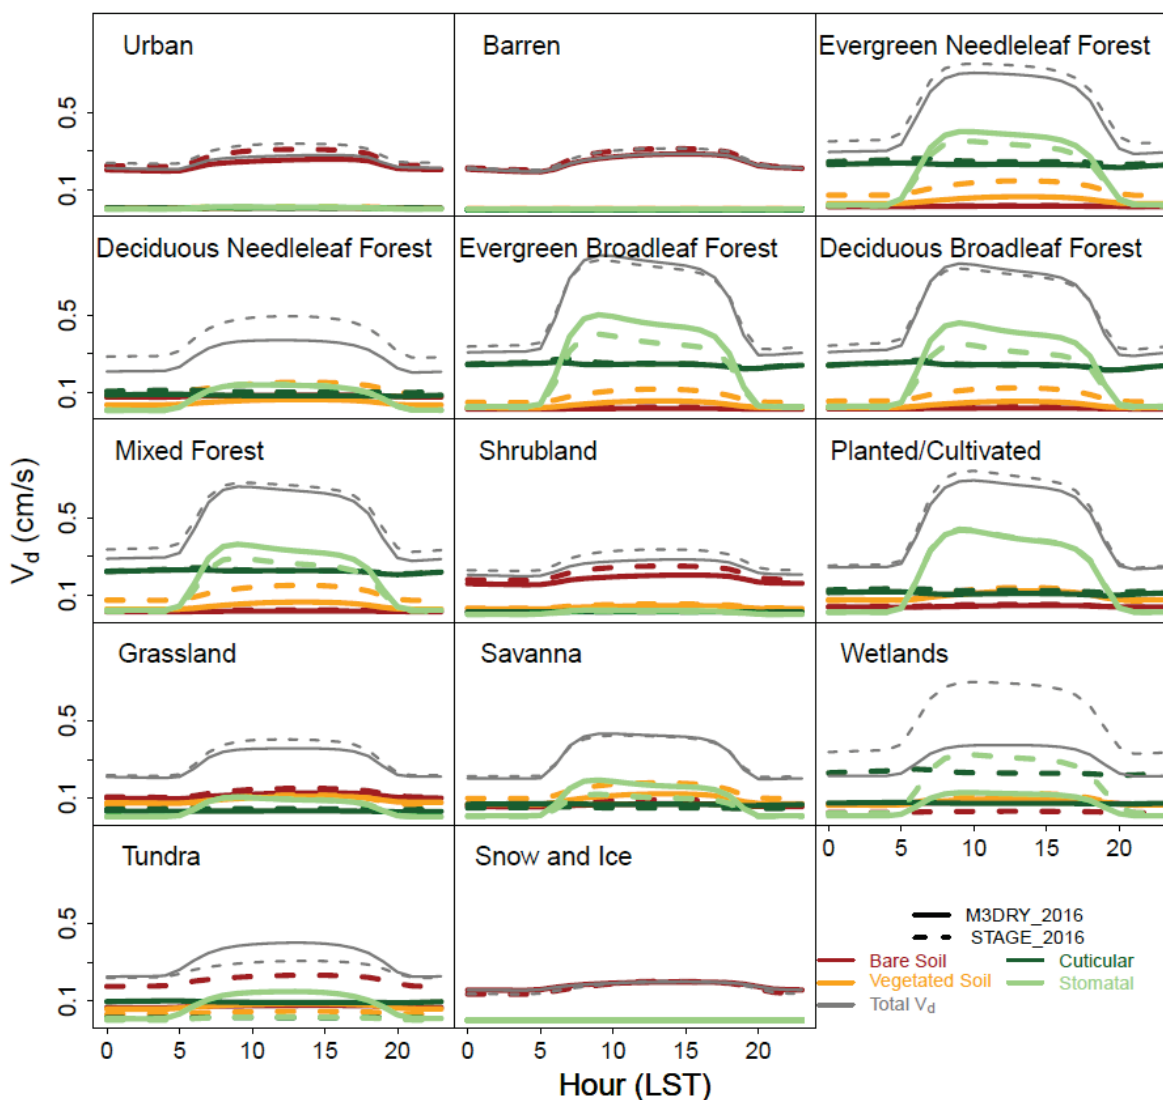

Section 2.3.1). The aggregation of the MODIS LU categories to the AQMEII4 LU categories (performed during post-processing for M3Dry and prior to the deposition calculations in STAGE as discussed in Section 2.3.2) is documented in Table S1. Note that none of the 20 MODIS LU categories correspond to the AQMEII4 herbaceous category. Figure S6 shows the prevalence of evergreen needleleaf, mixed, and deciduous forest in the northern, northeastern, and southeastern portions of the modeling domain, planted/cultivated LU in the north-central portion of the modeling domain, grassland in a belt stretching from Texas to Montana, and shrubland in the southwestern portion of the modeling domain. Figure S7 shows bar charts of the fraction of the modeling domain covered by each LU category. Separate bar charts are shown for M3DRY_2016 and STAGE_2016. While both started with the fractional coverages of the MODIS LU categories in the 12 km modeling domain, they differ in their treatment of grid cell with partial water coverage. Consistent with the approach taken in the WRF PX LSM, M3DRY_2016 treats cells with more than 10% water coverage as either all land or all water, depending on whether the fractional water coverage is below or above 50%. This is accomplished by resetting water fractions between 10% and 50% to zero and renormalizing the non-water categories to 100%, and resetting water fractions above 50% to 100% and setting non-water categories to zero. The rationale for this approach is that meteorological flux calculations are distinctly different between land and water and both WRF PX LSM and M3Dry are designed to retain that distinctiveness imposed by the underlying spatial discretization of the modeling domain. On the other hand, STAGE does not apply any special treatment to grid cells with partial water coverage. As a result of these different approaches, Figure S7 shows that a slightly larger fraction of the modeling domain is covered by water for STAGE_2016 compared to M3DRY_2016, with correspondingly slightly smaller coverages for non-water categories.

First, we investigate summer and winter average diurnal cycles of LU-specific component resistances in the context of the grid-scale resistance shown in Figure 6 and discussed in Section 3.2.1. Figure S8 shows that R_s conductances are higher for M3Dry than STAGE during summer for all forest types, agricultural land, savanna, and tundra, i.e. common LU types within the modeling domain (Figures S6 and S7). Only wetlands have higher R_s conductance for STAGE than M3dry, with the remaining LU categories having similar R_s conductances for both schemes. This is consistent with the grid scale domain-average summer R_s conductance being higher for M3Dry than STAGE (Figure 6). Only small differences are seen in winter for both the grid-scale (Figure 6) and LU-specific (Figure S8) stomatal conductances. The higher domain-average grid-scale $1/R_{cut}$ conductance for M3Dry during winter (Figure 6) is driven by the higher cuticular conductance values for evergreen needleleaf forest, mixed forest, and agricultural land (Figure S9), particularly since these LU types cover a substantial portion of the domain (Figures S6-S7). Figure S10 shows that the higher domain-average grid-scale in-canopy convective conductance ($1/R_{dc}$) for STAGE during both summer and winter (Figure 6) is present for almost all LU categories with the exception of snow and ice which (along with barren) uses a placeholder value to represent the non-existent canopy and which is present in very few grid cells in the domain (Figure S7). LU-specific $R_{can,qlsb}$ conductances ($1/R_{can,qlsb}$) are higher for STAGE than M3Dry for almost all LU categories in both summer and winter (Figure S11) while the opposite is the case for $R_{gnd,qlsb}$ (Figure S12). This demonstrates that the same behavior noted for the grid-scale $R_{can,qlsb}$ and $R_{gnd,qlsb}$ conductances (Figure 6) was not driven

by differences in their representation by M3Dry vs. STAGE for select LU categories only but rather resulted from consistent
 520 differences in representation across all LU categories. LU-specific R_a conductances ($1/R_a$) are generally very similar between
 STAGE and M3Dry with the exception of urban and tundra for which M3Dry is higher than STAGE and wetlands for which
 STAGE is higher than M3Dry (Figure S13). This general similarity between M3Dry and STAGE is consistent with the net
 grid scale domain-average R_a conductances shown in Figure 6. Differences between grid-scale and LU-weighted aggregated
 LU-specific R_a are investigated further in the next section.

525

Figure 8. Summer domain average diurnal cycles of LU-specific O_3 effective conductances and total deposition velocities for M3DRY_2016 and STAGE_2016. Next, we investigate the effects of the differences in the LU-specific component resistances discussed above on LU-specific effective conductances and effective fluxes, i.e. pathway-specific V_d and dry deposition fluxes.

Figure 8 depicts summer average diurnals of LU-specific effective conductances and total V_d for O_3 for both M3Dry and
530 STAGE, averaged over all grid cells with a non-zero fractional coverage for a given LU category. As expected, these diurnal
cycles illustrate that both total V_d and the relative importance of the different effective conductance pathways varies between
LU categories for both M3Dry and STAGE as a result of different underlying surface characteristics like VEGF, vegetation
type, etc. for the different LU categories. Total V_d during daytime varies by a factor of 2 between the LU categories with the
lowest values (urban, barren, and snow and ice) and those with the highest values (evergreen needleleaf and broadleaf forest,
535 deciduous forest). Effective conductances for the bare soil pathway dominate for the urban, barren, and shrubland LU
categories while conductances for the cuticular and stomatal pathways dominate for the forest LU categories, especially during
daytime. Results also show that the M3Dry vs. STAGE differences are most pronounced for the stomatal and vegetated soil
pathway for the forest LU categories, with M3Dry estimating larger effective conductances for the stomatal pathway and
STAGE estimating larger effective conductances for the vegetated soil pathway for these LU categories. Higher effective
540 conductances for the bare soil pathway in STAGE are particularly noticeable for the urban, shrubland, and tundra LU
categories. When considering how these differences in LU-specific effective conductances impact the grid-scale summertime
effective conductances shown in Figures 4a and 5a, the abundance and spatial distribution of each LU category (Figures S6
and S7) needs to be taken into account. For example, given the abundance of the evergreen needleleaf forest, deciduous
broadleaf forest, and mixed forest categories over the eastern and northern portions of the modeling domain, the higher M3Dry
545 stomatal conductances and lower M3Dry vegetated soil conductances for these LU categories shown in Figure 8 can explain
the spatial pattern of the corresponding M3Dry vs. STAGE grid-scale differences for these two pathways shown in Figure 4a.

The analysis above provided diagnostic insights into the M3Dry vs. STAGE differences in grid-scale effective conductances
shown in Figures 4 – 5 and discussed in Section 3.2.1. Analogously, Figures 9a-b shows annual and summer domain-total LU-
specific effective fluxes for O_3 to provide further insights into the corresponding grid-scale effective fluxes shown in the left
550 two bars of Figure 7b and also discussed in Section 3.2.1. For annual total deposition, the overall slightly larger grid-scale O_3
deposition flux for STAGE (Figure 7b) is present for almost all LU categories, with only a few categories (e.g. evergreen
needleleaf and broadleaf forest) showing no discernible differences between M3Dry and STAGE. Likewise, the generally
larger contribution of the stomatal and cuticular deposition pathways in M3Dry and bare and vegetated soil in STAGE are
present for most LU categories, but the differences in the magnitude of the individual deposition pathways are especially
555 pronounced for the evergreen needleleaf forest, mixed forest, and agricultural LU categories. Considering effective fluxes for
summertime only, the greater importance of the cuticular and stomatal pathways during this season for LU categories most
strongly affected by seasonal variations in LAI (deciduous broadleaf forest and planted/cultivated, see Table 4), along with the
greater importance of these pathways in M3Dry compared to STAGE, yield greater overall estimated deposition to these LU
categories for M3Dry compared to STAGE. In contrast, for several other LU categories (e.g. evergreen needleleaf and mixed
560 forest, shrubland, and grassland), STAGE still estimates higher deposition even during summertime, largely due to its higher
estimated deposition to vegetated and bare soil and the dominance of these pathways for several of these LU categories

565

(shrubland and grassland). Overall, Figure 9 demonstrates that even though overall annual total O₃ deposition fluxes estimated by M3Dry and STAGE are fairly similar (Figure 7b), pathway-specific fluxes to individual LU types can vary more substantially on both annual and seasonal scales which might affect estimates of O₃ damages to sensitive vegetation.

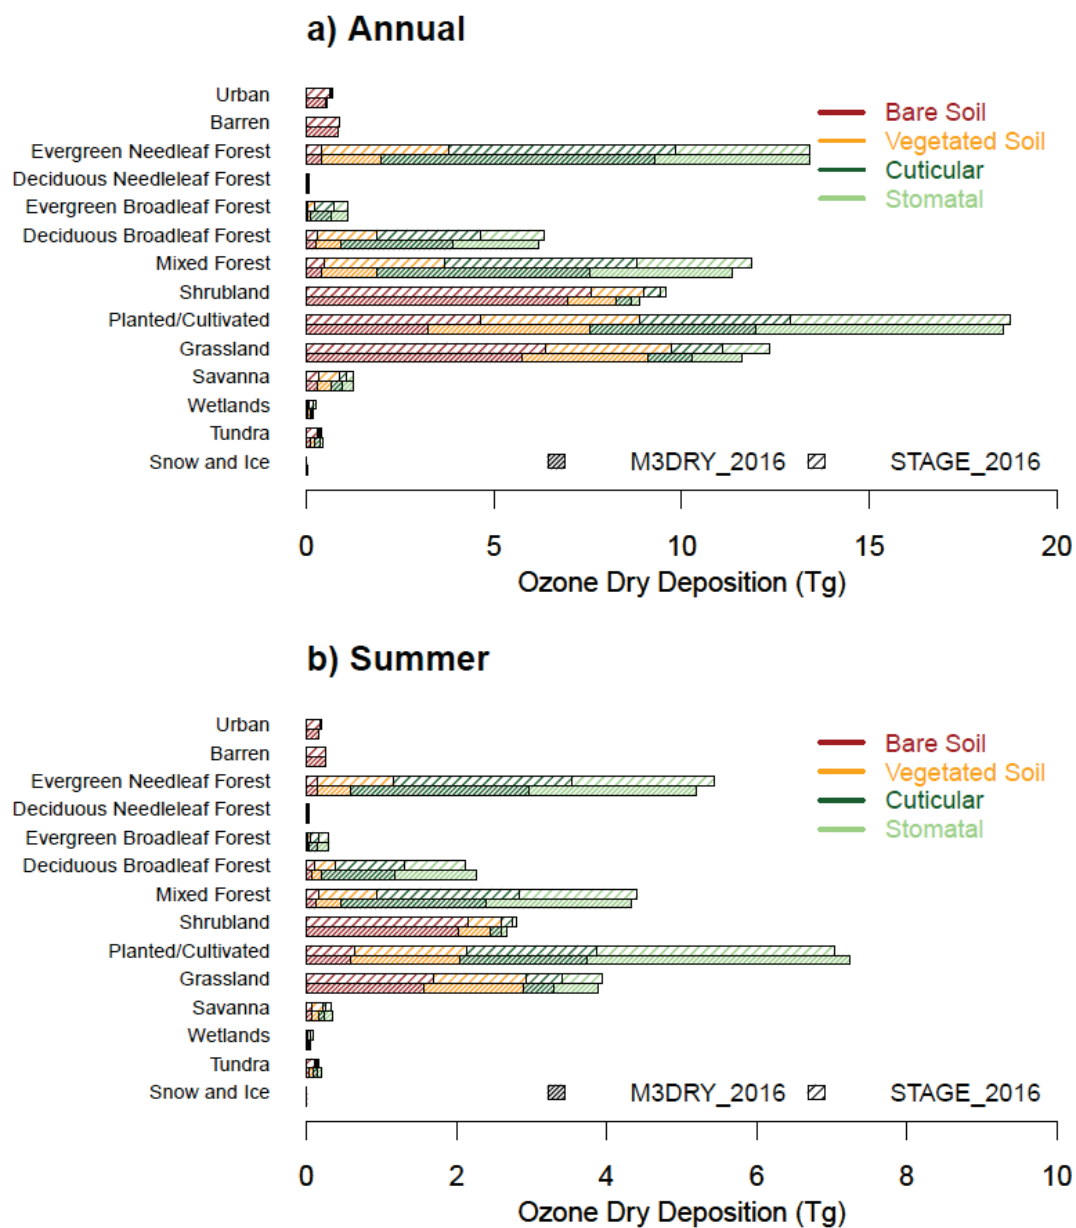

Figure 9. Land-use specific domain-wide (excl. water cells) pathway-specific O₃ dry deposition fluxes (“effective fluxes”), a) annual and b) summer

570 3.2.3 Impact of different approaches for handling subgrid LU variations and LU aggregation in M3Dry and STAGE

Both WRF PX LSM (M3Dry) and STAGE rely on LU-specific parameters prescribed in look-up tables to account for subgrid-scale LU variations when performing grid-scale calculations. As discussed in Sections 2.3.1 and 2.3.2, the WRF PX LSM bases grid-scale calculations on LU-weighted aggregated parameters from such LU-specific look-up table values and CMAQ M3Dry then directly uses these calculations in its grid-scale deposition calculations, maintaining consistency with WRF PX
 575 LSM. On the other hand, CMAQ STAGE and the M3Dry post-processor developed for AQMEII4 perform LU-specific deposition calculations using the look-up table values for each LU type, and in the case of CMAQ STAGE then use these LU-specific deposition calculations to calculate grid-scale deposition, maintaining consistency between LU-specific and grid-scale deposition but potentially differing from WRF PX LSM for variables like R_a , R_s , and u_* (note that starting with CMAQv5.4 released in October 2022, STAGE normalizes R_a , R_s , and u_* to match the aggregated grid-scale values to the grid-scale values
 580 calculated in the LSM of the driving meteorological model). To provide further context for these differences, Table 4 documents several of these LU-specific look-up table parameters used in deposition calculations, i.e. LAI, VEGF, and z_0 . Values are shown for the 20 LU category MODIS configuration of WRF PX LSM and M3Dry, the 16 LU category AQMEII4 configuration of STAGE used in this study, and the 20 LU category MODIS configuration in the unmodified version of STAGE used for sensitivity simulation STAGE_REF_2016 discussed below. The boldfaced table entries indicate instances where
 585 parameter values differed from WRF PX LSM (and M3Dry) for the STAGE AQMEII4 and/or STAGE MODIS configuration. For example, STAGE prescribes lower z_0 for the urban and tundra categories for both the AQMEII4 and MODIS configurations and higher z_0 for wetlands for the AQMEII4 configuration. These differences in z_0 are consistent with the $1/R_a$ differences for these three LU categories shown in Figure S13. The higher wetlands z_0 specified in STAGE results in lower R_a and higher $1/R_a$ compared to M3Dry while the reverse is true for the tundra and urban categories.

Table 4. LU-specific look-up table parameter values for seasonal minimum and maximum Leaf Area Index (LAI), seasonal minimum and maximum vegetation fraction (VEGF), and surface roughness (z_0) used in the dry deposition calculations. See the beginning of Section 3.2.2 for details on the differences between the “PX LSM / M3DRY”, “STAGE”, and “STAGE REF” columns for each variable. The boldfaced table entries indicate instances where parameter values differed between the WRF PX LSM (also used in M3DRY) and the STAGE AQMEII4 and/or STAGE reference configuration.

Figures S14 and S15 compare grid-scale vs LU-weighted aggregates of LU-specific values for u_* and R_a for both M3Dry and STAGE. For M3Dry, the sum of the LU-weighted aggregated u_* estimates matches the grid-scale values within 10%, with generally larger values for the aggregated estimates. For STAGE_2016 and STAGE_REF_2016, the aggregated values also typically fall within 10% of the grid-scale values, but differences can be both positive and negative. For R_a , differences between the LU-weighted aggregated and grid-scale values can reach 25% for all cases examined here, with generally higher values for the LU-weighted aggregated R_a values which is consistent with Figure 6.

Figure 10 compares seasonal mean O_3 Vd and mixing ratio differences between STAGE_2016 and STAGE_REF_2016 to assess the impact of performing STAGE deposition calculations on the more aggregated 16 category AQMEII4 LU classification scheme (see section 2.3.2) rather than the 20 category MODIS LU classification scheme used in the WRF PX LSM. Results show that the use of the AQMEII4 LU classification scheme can cause seasonal mean O_3 Vd increases of 0.02 – 0.06 cm/s and corresponding season mean O_3 mixing ratio decreases of 0.5 – 1 ppb mostly over the eastern and northern portions of the modeling domain. The location of these changes suggests that they are likely at least partially due to the

610 collapsing of two MODIS agricultural LU categories (croplands and crop/natural mosaic) with different look-up table values to a single AQMEII4 agricultural LU category (see Table 4 and Figure S6).

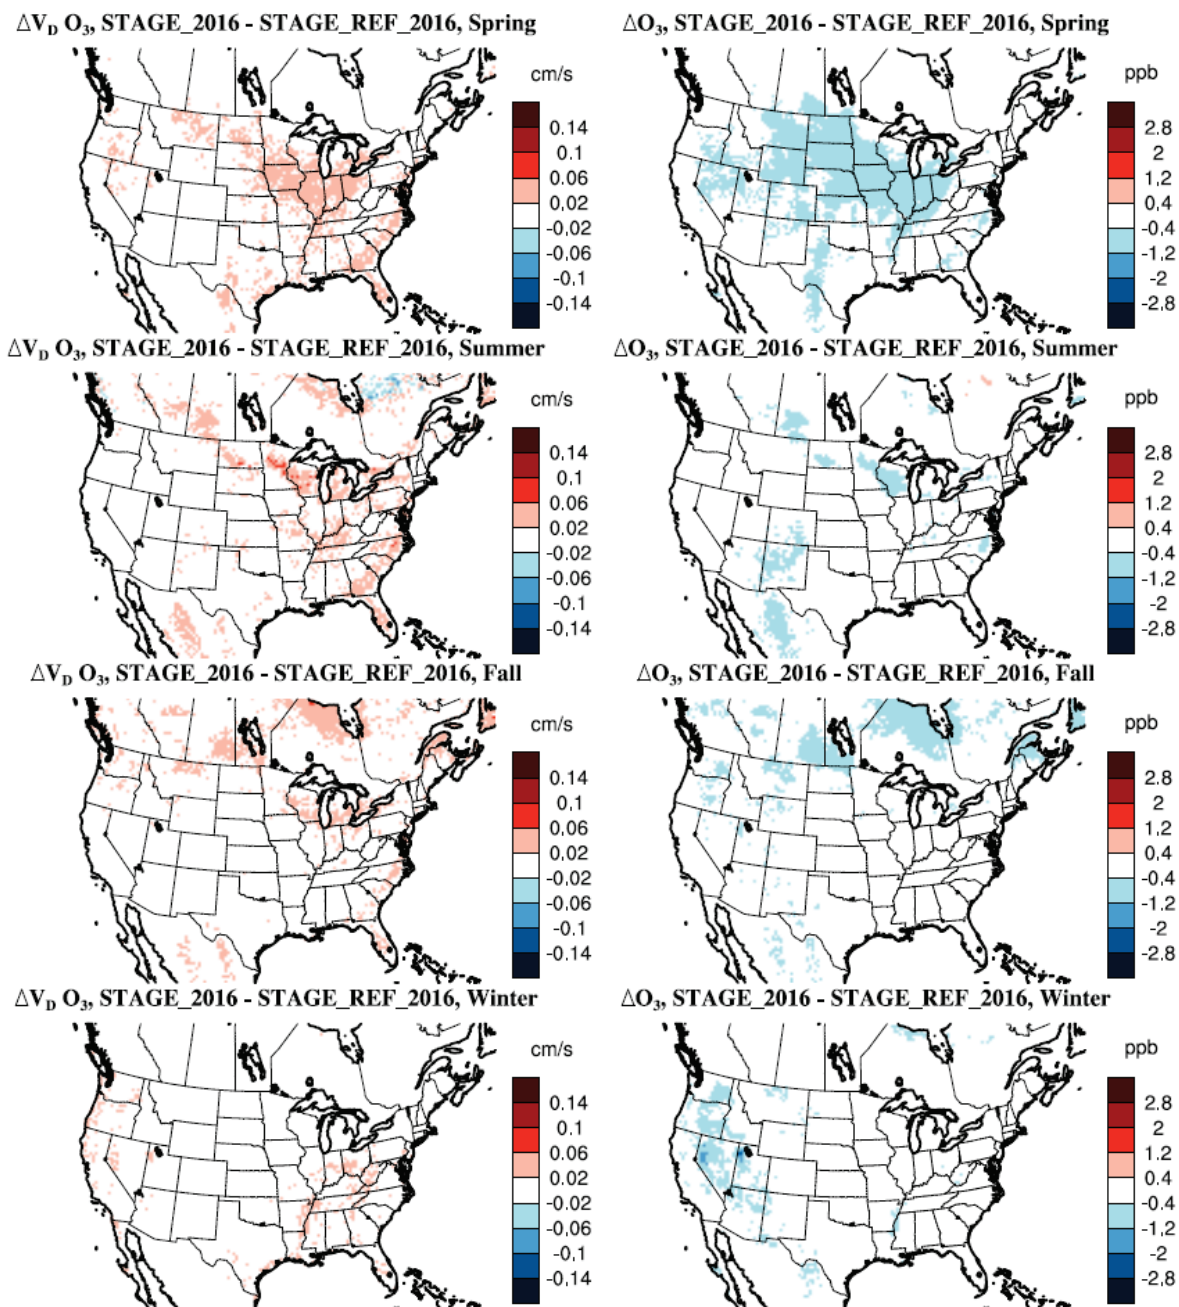

Figure 10. Differences in seasonal mean O₃ deposition velocities and mixing ratios STAGE_2016 minus STAGE_2016_REF.

615 The results presented in this section showed that differences in LU-specific look-up table values between different deposition schemes and/or between the WRF PX LSM calculations and the deposition scheme calculations within CMAQ as well as the aggregation of the MODIS LU categories to the AQMEII4 LU categories in the STAGE deposition calculations can introduce differences in the estimated V_d and resulting mixing ratios. In the next section, we investigate the effects of using a different underlying LU classification scheme in both the WRF PX LSM calculations and the CMAQ M3Dry calculations.

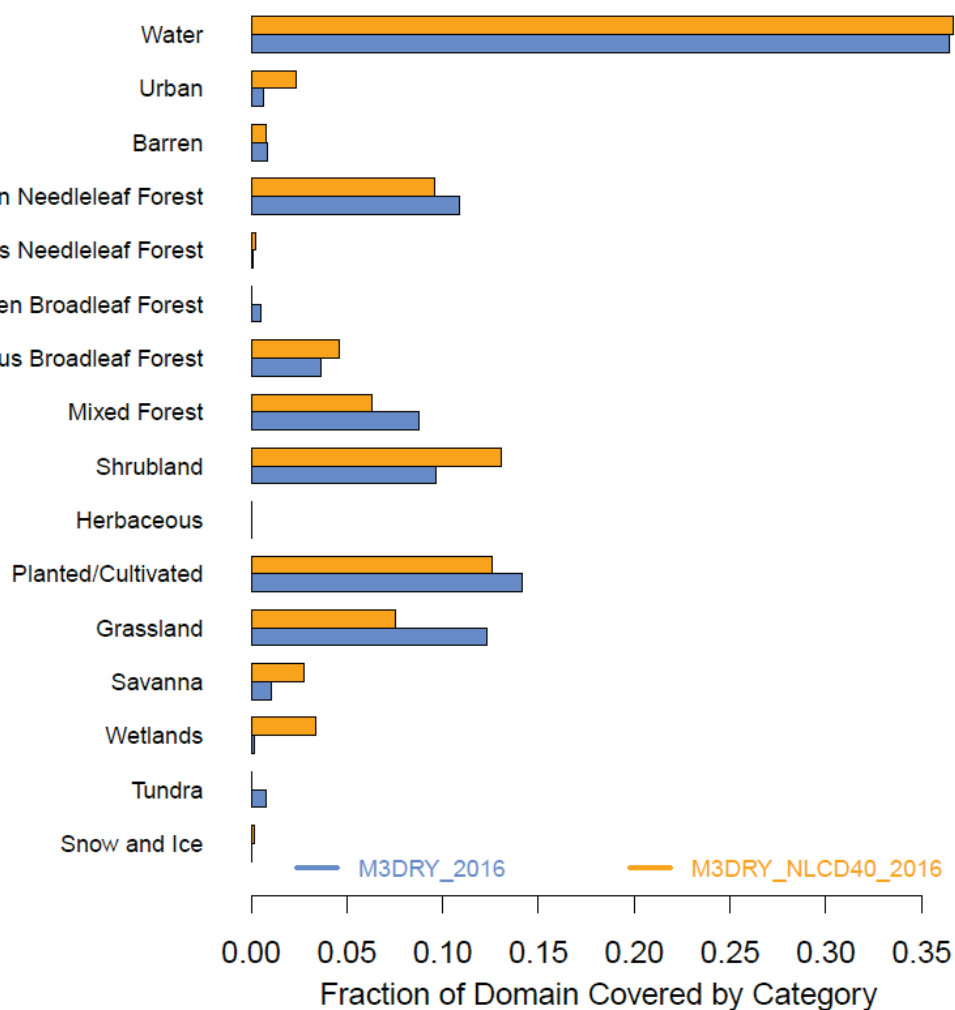

620 3.3 Impacts of Land-Use Classification Scheme

In this section, we compare the effects of replacing the MODIS dataset to represent LU in both WRFv4.1.1 and CMAQ M3Dry with the National Land Cover Dataset (NLCD) (Dewitz and U.S. Geological Survey, 2021; Yang et al., 2018). Similar comparisons between the U.S. Geological Survey (USGS) and NLCD LU datasets in WRF have previously been presented by Mallard et al. (2018). In contrast to the changes discussed in the previous section, the differences between MODIS and NLCD
625 are due to different underlying remote sensing data, their spatial resolution, and different approaches for their classification into distinct LU categories. Specifically, the MODIS LU categorization scheme as implemented in WRFv4.1.1 uses 20 categories following the IGBP land cover classification scheme (Loveland et al. 1999), has a native underlying spatial resolution of 500m, is based on a 2001 – 2010 climatology of MODIS satellite data, and features no geophysical boundaries in LU classification categories between the U.S., Canada, and Mexico. In contrast, the NLCD LU characterization scheme as
630 implemented in WRFv4.1.1 uses 40 categories and is hereafter referred to as NLCD40. The first 20 of these categories mirror those of the MODIS scheme and are used for areas outside of the U.S. where NLCD data is not available. The remaining categories are used over the U.S. and follow a modified Anderson land cover classification scheme (Homer et al., 2015, Yang et al., 2021), are based on a native underlying spatial resolution of 30m, and are derived from NLCD satellite data for the year 2011 (Homer et al., 2015). The combination of the NLCD and MODIS satellite data for use in WRF across North America is
635 described by Ran et al. (2010).

Table S1 contains a listing of the 20 MODIS and 40 NLCD40 LU categories used in WRFv4.1.1 and CMAQ M3Dry and their mapping to the aggregated 16 AQMEII4 LU categories (Galmarini et al., 2021) used for analysis purposes. As noted in Section 2.3.1, the CMAQ M3Dry calculations and post-processor estimates of LU-specific and aggregated diagnostic variables were performed using native LU categories from the MODIS and NLCD40 schemes. Aggregation to the 16 category AQMEII4 LU
640 scheme was then performed through LU-weighted averaging of equivalent categories using the mappings from Table S1. None of the MODIS or NLCD40 LU categories correspond to the AQMEII4 herbaceous category. Figure 11 shows the domain-wide fractional coverage of the AQMEII4 LU categories aggregated from the MODIS and NLCD40 categories while Figure S16 shows maps of differences for each of these 16 LU categories between the MODIS and NLCD40 configurations. The barchart in Figure 11 shows that MODIS has overall higher fractional coverage than NLCD40 for the evergreen needleleaf forest, mixed
645 forest, planted/cultivated, and grassland categories and lower fractional coverage for the urban, shrubland, savanna, and wetlands categories. However, the maps in Figure S16 show a more nuanced picture, with both positive and negative

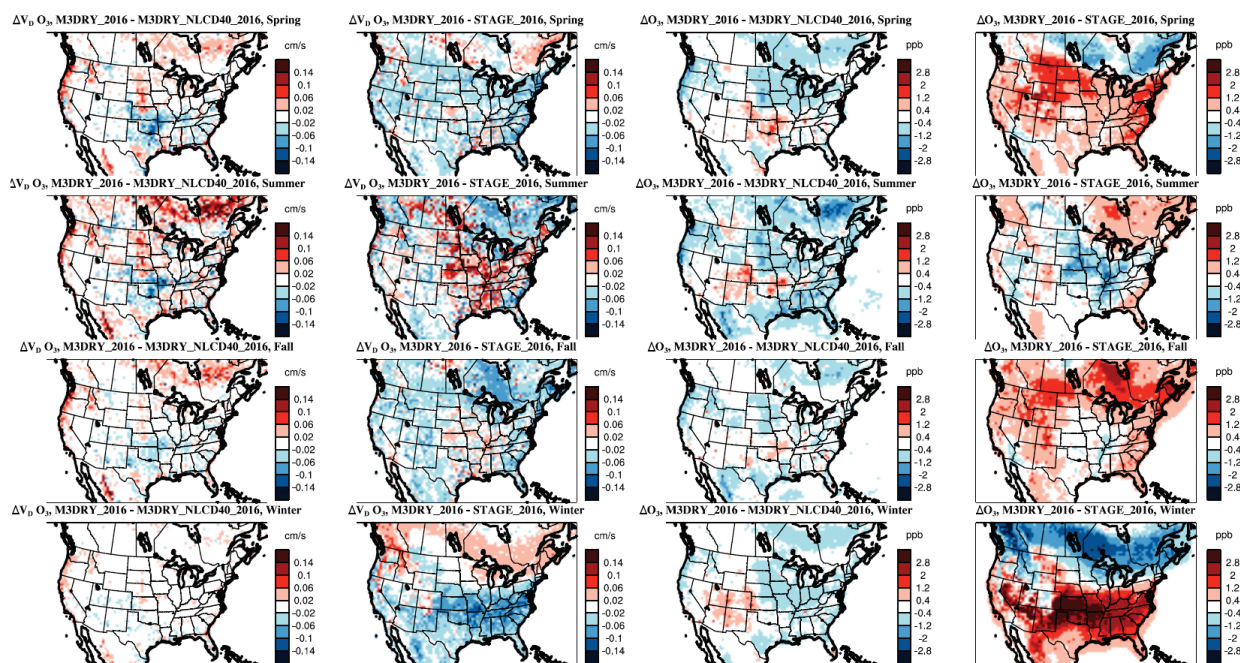

650 differences in the forest categories. For example, MODIS generally has higher evergreen needleleaf forest fractions than NLCD40 over Canada and lower fractions over the U.S. with the exception of the West Coast. The higher planted/cultivated fractions in MODIS are most pronounced over the central and northern U.S. while the higher grassland fractions are most pronounced over the Western U.S. MODIS urban and wetland fractions are lower than NLCD40 at most grid cells although the magnitude of the difference varies. For shrublands and savanna, MODIS fractions are generally lower than NLCD40 fractions but exceptions exist in the Southeastern U.S. and portions of Canada.

655 **Figure 11:** Domainwide fractional coverage of the 16 AQMEII4 land-use categories (Galmarini et al., 2021) in the M3DRY_2016 (using MODIS LU in WRF PX LSM) and M3DRY_NLCD40_2016 (using NLCD40 LU in WRF PX LSM) simulations. None of the 20 MODIS land-use categories correspond to the AQMEII4 herbaceous category.

Figure 12 shows differences in seasonal mean O_3 V_d and mixing ratios between M3DRY_2016 and M3DRY_NLCD40_2016 in columns 1 and 3 to quantify the effects of using different LU schemes on these variables. Results show that the M3DRY_2016 simulation using MODIS LU tends to have higher O_3 V_d (and correspondingly lower mixing ratios) than the M3DRY_NLCD40_2016 simulation using NLCD40 LU for most seasons and regions. The differences in LU cause seasonal mean O_3 mixing ratio differences on the order of 1 ppb across large portions of the domain, with the differences generally largest during summer and in areas characterized by the largest differences in the fractional coverages of the forest, planted/cultivated, and grassland LU categories. Columns 2 and 4 of Figure 12 also show corresponding differences in seasonal mean O_3 V_d and mixing ratios between M3DRY_2016 and STAGE_2016 (the same data already depicted in Figure 3) to provide a side-by-side contrast of the LU effect on these variables with the dry deposition scheme effect. While the M3Dry vs. STAGE differences generally are larger than the MODIS vs. NLCD40 differences outside the summer season, the magnitude of both effects is comparable during summer.

670 **Figure 12.** Differences in seasonal mean O_3 deposition velocities (columns 1 and 2) and mixing ratios (columns 3 and 4) M3DRY_2016 minus M3DRY_NLCD40_2016 (columns 1 and 3) and M3DRY_2016 minus STAGE_2016 (columns 2 and 4)

To assess the impacts of the LU-induced differences in V_d and mixing concentrations on effective fluxes and total dry deposition not only for O_3 but also other species, Figure 13 shows annual total domain-wide pathway-specific dry deposition effective fluxes over all non-water grid cells for O_3 , H_2O_2 , $HCHO$, SO_2 , and oxidized nitrogen species for M3DRY_2016 and

675

M3DRY_NLCD40_2016. Note that like in equivalent Figure 7b comparing M3DRY_2016 and STAGE_2016, O₃ dry deposition values are divided by a factor 10 to use the same y-axis as for the other pollutants. Overall, the use of MODIS vs. NLCD40 results in only very minor differences in domain-total dry deposition for all species analyzed here. However, the small domain total annual differences of these grid-scale deposition fluxes likely mask larger differences existing in different regions and seasons such as those shown for O₃ V_d and mixing ratios in Figure 12 as well as differences existing for LU-specific fluxes examined below. Moreover, there is a tendency for slightly larger effective fluxes through the bare soil pathway and slightly lower effective fluxes through the cuticular and stomatal for the M3DRY_NLCD40_2016 simulation, indicating that the choice of LU datasets can result in different estimates of dry deposition fluxes through specific pathways.

685

Figure 13: Grid-scale annual total domain-wide (excl. water cells) pathway-specific dry deposition fluxes (“effective fluxes”) for O₃, H₂O₂, HCHO, SO₂, and oxidized nitrogen species for M3DRY_2016 and M3DRY_NLCD40_2016. O₃ dry deposition values are divided by a factor 10 to use the same y-axis as for the other pollutants. (compare to Figure 7b)

690 Figure 14 further disaggregates the grid-scale effective fluxes shown in Figure 13 by LU category using O_3 as an example. Consistent with the differences in fractional coverage for the different LU categories between MODIS and NLCD40 shown in Figure 11, domain-total O_3 deposition fluxes to the evergreen needleleaf forest, mixed forest, planted/cultivated, and grassland

Figure 14. Land-use specific annual total domain-wide (excl. water cells) pathway-specific O_3 dry deposition fluxes (“effective fluxes”) for M3DRY_2016 and M3DRY_NLCD40_2016. (compare to Figure 9)

695 categories are higher for M3DRY_2016 than M3DRY_NLCD40_2016 while the opposite is the case for the urban, shrubland, savanna, and wetlands categories. For example, the fraction of the modeling domain classified as urban is 1% for MODIS and 2.4% for NLCD40, resulting in higher deposition estimates for this category in the M3DRY_NLCD40_2016 simulations. Moreover, because of the higher underlying spatial resolution of the NLCD satellite data and the inclusion of lower density developed areas characterized by more vegetation in the urban LU category, this category has higher estimated effective fluxes through the stomatal and cuticular pathways in the M3DRY_NLCD40_2016 simulated compared to the M3DRY_2016 simulations. Overall, this demonstrates that the deposition impacts of LU differences are caused both by differences in the fractional coverages and spatial distributions of different LU categories as well as their characterization in terms of variables like VEGF, z_0 , etc. in WRF PX LSM look-up tables which are partially tied to the spatial resolution of the underlying satellite datasets.

705 4 Summary and Discussion

The model evaluation results presented in Section 3.1 demonstrate that the AQMEII4 CMAQ simulations perform similarly to other comparable regional-scale modeling studies (Emery et al., 2017; Kelly et al., 2019; Simon et al., 2012; Appel et al., 2021). The analysis of several sensitivity simulations indicates that the choice of lateral boundary conditions was the largest driver of differences in mean model concentrations and biases compared to the corresponding CMAQv5.3.1 simulations analyzed in Appel et al. (2021). Moreover, the results also indicate that while the choice of the M3Dry vs. STAGE dry deposition option can impact CMAQ performance, these impacts tend to be smaller than those caused by choices of model input data sets and particularly boundary conditions to represent the large-scale chemical environment.

The analysis of O_3 V_d and mixing ratios showed that during summer, M3Dry has higher V_d and lower mixing ratios than STAGE for much of the eastern U.S. while the reverse is the case over eastern Canada and along the West Coast. In contrast, during winter STAGE has higher V_d and lower mixing ratios than M3Dry over most of the southern half of the modeling domain while the reverse is the case for much of the northern U.S. and southern Canada. The differences in seasonal mean mixing ratios reach 2-3 ppb in a number of locations, indicating that the effects of different dry deposition schemes can be more pronounced locally than in the spatially aggregated model evaluation metrics presented in Section 3.1. When using grid-scale effective conductances to further analyze the differences in O_3 V_d , the comparison between M3Dry and STAGE showed generally higher summertime stomatal and wintertime cuticular effective conductances for M3Dry and generally higher soil effective conductances (both vegetated and bare) for STAGE in both summer and winter. On a domain-wide basis, the stomatal effective conductance accounted for about half of the total O_3 V_d during daytime hours in summer for both schemes, though regional variations in these contributions exist due to variations in vegetation coverage. Examining grid-scale component resistances for O_3 shows that values for summertime $1/R_s$ and wintertime $1/R_{cut}$ differ between M3Dry and STAGE, with the higher values of these inverted resistances in M3Dry causing higher effective conductances for these pathways compared to

STAGE. Extending the concept of effective conductances to effective fluxes, annual domain total O₃ dry deposition flux results show the larger contributions from the vegetated and bare soil pathways for STAGE and the larger contributions from the stomatal and cuticular pathways for M3Dry.

730 In contrast to O₃, most other pollutants show larger effective conductances and effective fluxes for the bare soil and sum of bare and vegetated soil pathways for M3Dry than STAGE. The cuticular effective flux is larger for M3Dry than STAGE for HCHO, SO₂, HNO₄, and organic nitrates, smaller for M3Dry than STAGE for H₂O₂ and HNO₃, and similar between M3Dry and STAGE for other species. Stomatal effective fluxes are small for all species except O₃, HCHO, and SO₂ for both M3Dry and STAGE. Domain-wide annual total dry deposition fluxes differ the most between M3Dry and STAGE for HCHO and organic nitrate.

735 Extending the analysis of grid-scale dry deposition diagnostics further to specific LU categories, results show that total V_d during daytime varies by a factor of 2 between the LU categories with the lowest values (urban, barren, and snow and ice) and those with the highest values (evergreen needleleaf and broadleaf forest, deciduous forest). Effective conductances for the bare soil pathway dominate for the urban, barren, and shrubland LU categories while conductances for the cuticular and stomatal pathways dominate for the forest LU categories, especially during daytime. Results also show that the M3Dry vs. STAGE
740 differences are most pronounced for the stomatal and vegetated soil pathway for the forest LU categories, with M3Dry estimating larger effective conductances for the stomatal pathway and STAGE estimating larger effective conductances for the vegetated soil pathway for these LU categories. Higher effective conductances for the bare soil pathway in STAGE are particularly noticeable for the urban, shrubland, and tundra LU categories. For annual total deposition, the overall slightly larger grid-scale O₃ deposition flux for STAGE is present for almost all LU categories. Considering effective fluxes for
745 summertime only, the greater importance of the cuticular and stomatal pathways during this season for LU categories most strongly affected by seasonal variations in LAI, along with the greater importance of these pathways in M3Dry compared to STAGE, yield greater overall estimated deposition to these LU categories for M3Dry compared to STAGE. Additional analysis showed that minor differences in LU-specific look-up table values between different deposition schemes as well as the aggregation of the MODIS LU categories to the AQMEII4 LU categories in the STAGE deposition calculations can also
750 contribute to differences in the estimated V_d and resulting mixing ratios. Overall, the analysis of LU-specific diagnostic variables for both the entire year and summer only revealed that even though annual total O₃ deposition fluxes estimated by M3Dry and STAGE are fairly similar, pathway-specific fluxes to individual LU types can vary more substantially on both annual and seasonal scales which is likely to affect estimates of O₃ damages to sensitive vegetation.

755 A comparison of two simulations differing only in their LU classification scheme (MODIS vs. NLCD40) showed that the differences in LU cause seasonal mean O₃ mixing ratio differences on the order of 1 ppb across large portions of the domain, with the differences generally largest during summer and in areas characterized by the largest differences in the fractional coverages of the forest, planted/cultivated, and grassland LU categories. These differences are generally smaller than the

M3Dry vs. STAGE differences outside the summer season but have a similar magnitude during summer. When considering LU-specific effective fluxes for both simulations, results show that domain-total O₃ deposition fluxes to the evergreen
760 needleleaf forest, mixed forest, planted/cultivated, and grassland categories are higher for the simulation using MODIS LU
than the simulation using NLCD40 LU while the opposite is the case for the urban, shrubland, savanna, and wetlands
categories. Moreover, because of the higher underlying spatial resolution of the NLCD satellite data and the inclusion of lower
density developed areas characterized by more vegetation in the urban LU category, this category has higher estimated
effective fluxes through the stomatal and cuticular pathways in the M3DRY_NLCD40_2016 simulated compared to the
765 M3DRY_2016 simulations. Results indicate that the deposition impacts of LU differences are caused both by differences in
the fractional coverages and spatial distributions of different LU categories as well as their characterization in terms of
variables like VEGF, z₀, etc. in look-up tables used in the LSM and deposition scheme.

Refining the representation of dry deposition in regional modeling systems is an area of ongoing research, leveraging new
insights from observational datasets, field scale modeling, and model intercomparisons such as those performed in AQMEII4
770 (Galmarini et al., 2021; Clifton et al., in preparation). For example, both the M3Dry and STAGE deposition schemes in CMAQ
have updated the representation of aerosol dry deposition in the recent release of CMAQv5.4 in October 2022 (U.S. EPA,
2022; Pleim et al., 2022) while STAGE has also been revised to normalize R_a, R_s, and u_{*} to grid-scale values from the LSM
used in the driving meteorological model. The analyses and results presented in this study serve as an example of how the
diagnostic grid-scale and LU-specific dry deposition variables adopted for AQMEII4 can provide insights into a key model
775 process affecting simulated pollutant budgets and ecosystem impacts of atmospheric pollution. It is expected that the
forthcoming diagnostic analyses of results from all AQMEII4 grid models as well as a potentially more wide-spread adoption
of such diagnostic variables in other modeling studies will serve the modeling community in their future development efforts.
Additionally, it is hoped that the ongoing point intercomparison of the M3Dry and STAGE schemes implemented in CMAQ
with schemes implemented in other models (Clifton et al., in preparation), along with planned point model simulations to
780 quantify the sensitivity of specific resistances and conductances in different schemes towards individual meteorological, soil,
and biophysical forcing variables can help guide future model development efforts.

Code availability

The CMAQ version 5.3.1 (<https://doi.org/10.5281/zenodo.3585898>) code is available from the CMAQ GitHub site
(<https://github.com/USEPA/CMAQ>). The AMET code is available from the AMET GitHub site
785 (<https://github.com/USEPA/AMET>)

Data availability

All data used in this work are available upon request from the authors. Please contact the corresponding author to request any data related to this work.

Author contributions

790 CH led the development of this manuscript, performed all CMAQ simulations, and conducted most of the analyses presented
in Section 3. JOB and JEP developed code to adapt the CMAQ STAGE and M3Dry dry deposition schemes to provide
diagnostic variables for AQMEII4 through directly modifying CMAQ (STAGE) or creating a post-processor (M3Dry). RCG
performed the WRF simulations used as inputs to all CMAQ simulations. CH, DBS and RM helped conceptualize both the
AQMEII4 model intercomparison framework and the CMAQ model simulations and analyses presented in this study. KMF
795 and KWA contributed to the model evaluation analysis presented in Section 3.1. All authors contributed to the writing and
editing of the manuscript.

Special issue statement

This manuscript is part of the special issue “AQMEII4: a detailed assessment of atmospheric deposition processes from point
models to regional-scale models”.

805 Acknowledgments

We gratefully acknowledge members of the AQMEII4 steering committee (Olivia Clifton, Paul Makar, Christopher Holmes, Lisa Emberson, Johannes Flemming, Sam Silva, Johannes Bieser, Jason Ducker, and Martijn Schaap) and AQMEII4 co-chair Stefano Galmarini for facilitating the analysis described in this manuscript by designing and coordinating regional-scale air quality model simulations that provide diagnostic insights into modeled dry deposition.
