14

15 **Abstract.** Dimethyl sulfide (DMS) is an important trace gas emitted from the ocean. The oxidation of DMS has long been
16 recognised as being important for global climate through the role DMS plays in setting the sulfate aerosol background in the
17 troposphere. However, the mechanisms in which DMS is oxidised are very complex and have proved elusive to accurately
18 determine in spite of decades of research. As a result the representation of DMS oxidation in global chemistry-climate models
19 is often greatly simplified.

20

21 Recent field observations, laboratory and ab initio studies have prompted renewed efforts in understanding the DMS oxidation
22 mechanism, with implications for constraining the uncertainty in the oxidation mechanism of DMS as incorporated in global
23 chemistry-climate models. Here we build on recent evidence and develop a new DMS mechanism for inclusion in the UK
24 Chemistry Aerosol (UKCA) chemistry-climate model. We compare our new mechanism (CS₂-HPMTF) to a number of
25 existing mechanisms used in UKCA (including the highly simplified 3 reactions, 2 species, mechanism used in CMIP6 studies
26 with the model) and to a range of recently developed mechanisms reported in the literature through a series of global and box
27 model experiments. Global model runs with the new mechanism enable us to simulate the global distribution of hydroperoxyl
28 methyl thioformate (HPMTF), which we calculate to have a burden of 2.6-26 Gg S (in good agreement with the literature
29 range of 0.7-18 Gg S). We show that the sinks of HPMTF dominate uncertainty in the budget, not the rate of the isomerisation
30 reaction forming it, and that based on the observed DMS/HPMTF ratio from the global surveys during the NAS Atmospheric
31 Tomography mission (ATom), rapid cloud uptake of HPMTF worsens the model-observation comparison. Our box model
32 experiments highlight that there is significant variance in simulated secondary oxidation products from DMS across
33 mechanisms used in the literature, with significant divergence in the sensitivity of the rates of formation of these products to

34 temperature exhibited; especially for methane sulfonic acid (MSA). Our global model studies show that our updated DMS
35 scheme performs better than the current scheme used in UKCA when compared against a suite of surface and aircraft
36 observations. However, sensitivity studies underscore the need for further laboratory and observational constraints.

37 **1 Introduction**

38 It is estimated that 16-28 Tg S year⁻¹ are emitted in the form of dimethyl sulfide (DMS, CH₃SCH₃) from the ocean, making
39 DMS the most abundant biological source of sulfur in the Earth system (Andreae, 1990, Tesdal et al., 2015, Bock et al., 2021).
40 Elucidating the atmospheric fate of DMS has been a long standing goal of the atmospheric chemistry research community
41 owing to a proposed biogeochemical feedback cycle (CLAW; Charlson et al. 1987), whereby DMS oxidation is key to a
42 homeostatic feedback loop. The initial steps in DMS oxidation are well understood (Barnes et al., 2006). Focusing on oxidation
43 via OH (NO₃), the most important oxidant during the daytime (nighttime), DMS is oxidised in the gas-phase through two main
44 pathways: the abstraction pathway forms the methylthiomethylperoxy radical (MTMP, CH₃SCH₂OO) in the first step, while
45 the addition pathway leads to dimethyl sulfoxide (DMSO, CH₃SOCH₃; and to a lesser extent DMSO₂) as an important
46 intermediate.

47 $\text{DMS} + \text{OH}/\text{NO}_3 \rightarrow \text{MTMP} + \text{H}_2\text{O}/\text{HNO}_3$ (abstraction)

48 $\text{DMS} + \text{OH} \rightarrow \text{DMSO} + \text{HO}_2$ (addition)

49 Ultimately, the oxidation of DMS leads to products such as H₂SO₄ and sulfate (SO₄²⁻), as these represent the highest oxidation
50 states of sulfur (S(VI)). Along the way from DMS, a number of secondary oxidation products such as sulfur dioxide (SO₂),
51 methane sulfonic acid (MSA, CH₃SO₃H) and carbonyl sulfide (OCS) can be formed, however the yields of these species
52 depend on the mechanisms involved, which themselves are a function of the chemical (e.g., levels of oxidants) and
53 environmental conditions (e.g., temperature and humidity). The yields of these products are relatively uncertain, with estimates
54 of the DMS-to-SO₂ yield spanning 14-96 % (von Glasow and Crutzen, 2004). The oxidation products can participate in aerosol
55 growth and in new particle formation, affecting the number of cloud condensation nuclei (CCN). As such DMS oxidation can
56 impact cloud formation and lifetime and hence climate; although the absolute effect is still highly uncertain due to the
57 uncertainty in the kinetics and mechanisms of DMS oxidation. Indeed, natural aerosols such as DMS contribute to large
58 uncertainties in the radiative forcing of the pre-industrial atmosphere (Carslaw et al., 2013; Fung et al., 2022).

59
60 Substantial discrepancies between different DMS oxidation mechanisms under different conditions have been found (de Bryn
61 et al., 2002; von Glasow and Crutzen, 2004). The intercomparison study by Karl et al. (2007) looked at seven different
62 chemistry schemes in a box model (using the same inputs) and observed that SO₂ mixing ratios varied from 2 to 44 ppt.
63 Differences between models are even greater when looking at MSA yield (Karl et al., 2007, Hoffmann et al., 2021). The large
64 uncertainties of product ratios indicate the need for more observational constraints for DMS chemistry in models.

65 In the UK Chemistry and Aerosol model (UKCA) two different chemistry schemes are implemented: StratTrop (Archibald et
 66 al., 2020), which is a simplified chemistry mechanism included in the UK Earth System Model (Sellar et al., 2019) and CRI-
 67 Strat2 (Archer Nicholls et al., 2021; Weber et al., 2021). The DMS oxidation mechanism in StratTrop is, like those used in
 68 many Earth System Models (ESMs), a very simple scheme (see S1.4.1 for more details). We believe modellers have opted to
 69 keep the DMS chemistry incredibly simple for two main reasons 1) numerical efficiency 2) uncertainty in what to do owing
 70 to lack of detailed DMS oxidation mechanisms that have been calibrated against laboratory data. The StratTrop DMS
 71 mechanism only includes four reactions and no intermediates for the DMS oxidation scheme.

76 Omitting intermediates might lead to a misrepresentation of the spatial distribution of oxidation products and an overestimation
 77 in their formation since the intermediates might be subject to wet and dry deposition or cloud uptake. Because a unity yield of
 78 SO_2 is assumed, a change in the distribution of oxidation products due to a changing climate cannot be evaluated.

79
 80 CRI-Strat2 (hereafter CS2) (Archer-Nicholls et al., 2021, Weber et al., 2021) is a mechanism that aims to be of intermediate
 81 complexity. CS2 includes 19 reactions and 7 intermediates (DMSO, MSIA, MTMP, CH_3S , CH_3SO , CH_3SO_2 , CH_3SO_3) as part
 82 of its DMS scheme and is primarily based on the work of von Glasow and Crutzen (2004). Whilst the CS2 DMS mechanism
 83 is much more complex than the StratTrop scheme, it represents an understanding of DMS chemistry that is far from up-to-
 84 date.

85
 86 In this work, the gas-phase DMS oxidation by OH and NO_3 in CS2 is updated according to the current scientific understanding.
 87 The greatest update is the inclusion of the recently discovered intermediate hydroperoxymethyl thioformate (HPMTF,
 88 HOCH_2SCHO), which is formed through the autoxidation of the methylthiomethyl peroxy radical (MTMP, $\text{CH}_3\text{SCH}_2\text{OO}$)
 89 in the abstraction pathway (Wu et al., 2015, Berndt et al., 2019, Veres et al. 2020). Currently, it is estimated that ~30-50% of
 90 DMS yields HPMTF (Veres et al., 2020; Novak et al. (2021); Fung et al. (2022)). There are large uncertainties about the value
 91 of $k_{\text{isom},1}$, the rate constant of the first H-shift, which is the rate determining step for HPMTF formation (**Figure 1**). (Note, given
 92 that the first isomerization step is rate limiting, the overall rate constant for isomerization is denoted k_{isom}). This determines if
 93 autoxidation can compete with or surpass the bimolecular reactions of MTMP with HO_2 and NO. The chamber study by Ye et
 94 al. (2021) estimates a probability distribution based on their measurements with one geometric standard deviation spanning an
 95 order of magnitude. The isomerization rate constant is predicted using *ab initio* methods to be strongly temperature dependent,
 96 indicating that this pathway could be more relevant under a warming climate (Wu et al., 2015; Veres et al., 2020). Following
 97 the closure of the Discussion version of this manuscript the first temperature-dependent direct kinetic study of the isomerization

98 of rate constant for MTMP to HPMTF was published (Assaf et al., 2023). In that study the authors calculate the Arrhenius
99 temperature barrier as 7278 ± 99 K, confirming the high temperature dependence of the reaction experimentally.

100
101 As of now, the fate of HPMTF in the atmosphere is largely unknown. Wu et al. (2015) postulate further oxidation with OH,
102 ultimately yielding SO₂ as the dominant product and OCS as a side product. Veres et al. (2020) observe an abrupt decrease of
103 HPMTF mixing ratio in clouds and therefore suggest that heterogeneous loss to aerosol and cloud uptake plays a big role.
104 Vermeuel et al. (2020) support this hypothesis: they find a diurnal profile of HPMTF in the vicinity of California's coast and
105 suggest this is due to the consistent diurnal profile of cloud present. This hypothesis is further supported by the study by Novak
106 et al. (2021), which looks at two case studies and concludes that cloud uptake determines the lifetime of HPMTF. Novak et
107 al. (2021) found that cloud-uptake of HPMTF reduces SO₂ production from DMS by over a third, while providing a more
108 direct pathway to sulfate formation. On the contrary, the chamber study and calculation of Henry's law constant by Wollesen
109 de Jonge et al. (2021) predict that HPMTF does not directly contribute to new particle formation or aerosol growth. Instead,
110 their study proposes aqueous oxidation by OH, ultimately still yielding gas-phase SO₂. Khan et al. (2021) stress the importance
111 of photolysis as a potential loss pathway, which might explain the observed diurnal concentrations throughout the day. Overall,
112 loss processes of HPMTF are poorly understood.

113
114 In this work, we perform a series of updates to the CS₂ DMS oxidation scheme which are evaluated against the current CS₂
115 and the very simplified DMS chemistry in StratTrop. The aim of this work is to improve the representation of DMS chemistry
116 in UKCA and determine the influence of some of the major mechanistic uncertainties on model simulated SO₂ levels compared
117 against ATom observations (Wofsy et al., 2018; Veres et al., 2020). Our study includes a comprehensive set of box model
118 studies, including an intercomparison of our new DMS scheme against other recently reported schemes in the literature, and
119 global 3D simulations with the UKCA model. To complement the work of Fung et al. (2022), sensitivity studies with variable
120 rates of production, and cloud and aerosol uptake of HPMTF are performed to investigate the effects of the uncertainty in
121 HPMTF formation and depletion on the distribution and burden of SO₂ and sulfate (given their importance in climate) using
122 a structurally different model to that they used.

123

124 **2 Methods**

125 **2.1 Model description**

126 **2.1.1 Set up**

127 **Box model**

128 For the box model experiments, BOXMOX (Knote et al., 2015), the box modelling extension to the Kinetic PreProcessor
129 (KPP) (Sandu and Sander, 2006) was used. The initial and background concentrations of the species were set to be
130 representative of the remote marine boundary layer (MBL) (and are detailed in **Table S1**). NO_x concentration was kept at
131 approximately 10 ppt, unless otherwise specified.

132 The box model set up simulates an MBL air parcel exchanging with the free troposphere. The diurnal profile of the planetary
133 boundary layer height was modelled after the diurnal profile of the MBL in Ho et al. (2015) (**Table S2**). Mixing of the air
134 within the box with the free troposphere is described by the increases of box height: it is assumed that changes in the box
135 volume are due to the influx of background air. Emissions of DMS are added at 3.48×10^9 molec. cm⁻² s⁻¹ (consistent with
136 von Glasow and Crutzen, 2004). Emissions mix instantaneously within the box. Temperature varies throughout a 24-hour
137 period between 289-297 K, with a mean of 293 K (**Table S2**). Photolysis reactions are scaled depending on the time of day,
138 and make use of the pre-calculated “J” rates obtained from the MCMv3.3.1. The simulations were run for 192 hours (8 days)
139 with 10-minute time steps. CRI v2.2 R5 (CS2) (Jenkin et al., 2019; Weber et al., 2021) was employed as the base chemical
140 mechanism. Unless otherwise specified, only reactions of the DMS scheme were changed. Neither dry nor wet deposition was
141 included in the box model experiments. The analysis of the BOXMOX simulations discussed in Section 3.1.1 and 3.2.1 focuses
142 on the continuous (hourly) output. In Section 3.1.2 and 3.2.2, simulations with a prescribed temperature (260 - 310 K, step
143 size: 5 K) were conducted. The data from day 7 and 8 of the runs was averaged to enable the effects of changes in the
144 temperature on species concentration simulated in the box model to be calculated (following Archibald et al., 2010)

145

146 **3D simulations**

147 For the 3D simulations we use UKCA, the chemistry and aerosol component of UKESM1, with a horizontal resolution of
148 $1.25^\circ \times 1.875^\circ$ with 85 vertical levels up to 85 km (Walters et al., 2019). UKCA uses the GLOMAP-mode aerosol scheme,
149 which simulates sulfate, sea salt, black carbon (BC), organic matter, and dust but does not currently simulate nitrate aerosol
150 (Mulcahy et al., 2020). Simulations were run for 18 months, using the first 6 months as spin up. In order to look at high time
151 resolution output simulations were re-run for limited time periods using the re-start files of the longer runs but outputting data
152 at hourly frequency.

153

154 Temperature and horizontal wind fields were nudged (Telford et al., 2013) in all model runs to the Era-Interim atmospheric
155 reanalysis from ECMWF (Dee et al., 2011). See the SI for further details.

156

157 The emissions used in this study for UKCA are the same as those from Archer-Nicholls et al (2021) and are those developed
 158 for the Coupled-Model Intercomparison Project 6 (CMIP6) (Collins et al., 2017). See the SI for further details. Oceanic
 159 emissions of DMS are calculated from seawater DMS concentrations (Sellar et al., 2019). In the atmosphere-only setup
 160 employed here seawater DMS concentrations for 2014 from a UKESM1 fully-coupled SSP3-70 ensemble member were
 161 prescribed. The DMS emission flux from the ocean used in the model was 16 Tg S yr⁻¹ and therefore on the low end of estimates
 162 of oceanic DMS emissions (e.g., Lana et al., 2011; Bock et al., 2021).

163
 164

165 2.1.2 Model runs

166

167 **Table 1:** Configuration of model runs in this study. The last two columns indicate whether this scheme was used for the
 168 BOXMOX experiments or the UKCA runs or both. Additional BOXMOX simulations were performed and the results of which
 169 are included in the Supplementary Information (SI) for completeness.

Alias	Description	Used for:	
		BOXMOX	UKCA
CS2	Base simulation, standard CRIStrat2 (or CRIv2.2R5) scheme	✓	✓
ST	StratTrop chemistry scheme ($ST - CS2 = \Delta ST$; change between ST and CS2)	✓	✓
ST~CS2	StratTrop DMS scheme but CS2 oxidants ($ST \sim CS2 - CS2 = \Delta CC$; change between CS2 and the ST DMS scheme only)	✓	-
CS2-HPMTF	CS2 + updates in Table 2 and Table 3 ($CS2\text{-HPMTF} - CS2 = \Delta UPD$; effects of all updates made to the scheme)	✓	✓
CS2-UPD-DMS	CS2 + updates in Table 2 = CS2-HPMTF - updates in Table 3 ($CS2\text{-HPMTF} - CS2\text{-UPD-DMS} = \Delta HPMTF$; effects of the isom. pathway only)	✓	-
CS2-HPMTF-CLD	CS2-HPMTF + cloud and aerosol uptake ($\gamma = 0.01$) ($CS2\text{-HPMTF-CLD} - CS2\text{-HPMTF} = \Delta CLD$; gives the effects of cloud and aerosol uptake of HPMTF)	-	✓
CS2-HPMTF-FL	CS2-HPMTF + faster total loss of HPMTF to OH ($5.5 \times 10^{-11} \text{ s}^{-1}$) ($CS2\text{-HPMTF-FL} - CS2\text{-HPMTF} = \Delta FL$; gives the effects of faster gas phase loss of HPMTF)	SI	✓
CS2-HPMTF-FP	CS2-HPMTF + isomerisation A-factor scaled by a factor of 5, see Wollesen de Jonge et al. (2021)) ($CS2\text{-HPMTF-FP} - CS2\text{-HPMTF} = \Delta FP$; gives the effects of faster HPMTF production)	SI	✓

170

171 Simulations are performed with the standard or updated DMS scheme to quantify the impacts of the mechanistic changes.
172 Details are given in **Table 1**. We chose as our base run a simulation with the CRIStrat2 chemistry scheme hereafter referred
173 to as CS2 (Weber et al., 2021). We perform two simulations with StratTrop (hereafter ST): ST is the default mechanism as
174 used in UKESM1, while ST~CS2 uses the ST DMS chemistry (R1-R4) but all other reactions (HO_x , NO_x , VOC etc) are
175 identical to CS2. This allows us to attribute the changes arising solely to differences in the oxidising capacity/environment
176 (driven by the chemistry not strongly coupled to DMS) and isolate the role due to differences in the DMS reactions themselves.
177

178 In updating the representation of DMS chemistry for UKCA a number of changes were considered. Broadly these fall into two
179 categories: 1) Incorporation of the chemistry of HPMTF (shown in red in **Figure 1**) 2) updates to other aspects of DMS
180 oxidation chemistry (shown in blue in **Figure 1**). CS2-HPMTF is used to identify the fully updated DMS mechanism (**Table**
181 **2**, **Table 3**). All other runs act as sensitivity runs. CS2-UPD-DMS allows the evaluation of only updating the standard DMS
182 chemistry (**Table 2**), without the addition of the isomerization branch and HPMTF formation (**Table 3**). CS2-HPMTF-CLD
183 adds cloud and aerosol uptake of HPMTF with subsequent sulfate formation, similar to Novak et al. (2021). With CS2-
184 HPMTF-FP and CS2-HPMTF-FL the effects of faster production and faster loss of HPMTF can be assessed.
185
186

187

188

Figure 1. Schematic summary of the changes and additions to the gas-phase DMS oxidation mechanism in CS₂. The current chemistry in CS₂ (Weber et al., 2021) is in black, changes associated with CS₂-UPD-DMS are shown in blue and changes associated with the addition of the isomerization pathway for CS₂-HPMTF in red.

189

190

191

192 **2.2 New mechanism development**

193 The current CS₂ DMS oxidation mechanism is based on von Glasow and Crutzen (2004). This mechanism is based on an
194 outdated understanding of DMS oxidation, which excludes key pathways and intermediates that are now known to be well
195 established (Barnes et al., 2006) as well as more recent pathways and products that have been shown to be important (Veres
196 et al., 2020). Our aim with the development of the new mechanism is to build upon the existing mechanism in CS₂ and to
197 update and extend it. To this end we performed a literature review and constructed a number of mechanistic variants that were
198 examined in a series of box model experiments. As with all mechanism development exercises a series of target compounds
199 were chosen to reduce the mechanism to achieve a scheme that is parsimonious; for use in a 3D chemistry-climate model. In
200 our study we chose DMS, SO₂, sulfate and HPMTF as the key target molecules for mechanism optimization. **Figure 1** shows
201 the two-step improvement of this mechanism. First, the improvement of the standard chemistry by updating rate constants for
202 existing reactions in the scheme or the addition of reactions that were missing (denoted with blue colouring in **Figure 1**), and
203 second, the addition of the HPMTF pathway (in red in **Figure 1**). The focus in this study is on gas-phase DMS oxidation by
204 OH and NO₃. Our prime focus is on the primary oxidation products (DMSO and MTMP) and their subsequent chemistry.
205 While other studies include DMS oxidation by BrO and Cl, the contribution is either negligible or there is a large uncertainty
206 attached due to substantial discrepancies between/within models and measurements of halogens and halogen oxides (Wang et
207 al., 2021; Fung et al., 2022). Moreover, UKCA doesn't currently have a comprehensive tropospheric halogen mechanism and
208 levels of BrO and Cl simulated are much lower than observations suggest.

209

210 **2.2.1 Updating the standard DMS chemistry in CRIStrat 2**

211 The H-abstraction pathway (reaction 1a,b) generates MTMP which is then further oxidised to SO₂ or CH₃SO₂ (reactions 2-7).
212 The OH-addition pathway (reaction 1c) leads to dimethyl sulfoxide (DMSO, (CH₃)₂SO) and methanesulfinic acid (MSIA,
213 CH₃S(O)OH) (reactions 8,9) and further oxidation through to CH₃SO₂ (reactions 10-12). Both pathways and the changes made
214 are summarised in **Table 2**. The newly added reactions and their respective rate constants are largely based on Atkinson et al.
215 (2004), the MCMv3.3.1 (Jenkin et al. 2015), and the primary literature therein.

216

217 The oxidation of MTMP by HO₂ (reaction 2c) was not previously included in the CS₂ mechanism, but is expected to play a
218 significant role at the low NO_x conditions over the remote ocean. Based on other RO₂ + HO₂ reactions, CH₃SCH₂OOH is the
219 expected product, which has been detected through mass spectroscopy (Butkovskaya and LeBras, 1994). Since no experimental
220 measurements exist for the kinetics of this reaction, the rate constant provided in the MCM was used. It is based on a generic
221 expression, defined on the basis of available room temperature and temperature dependent data for alkyl and β-hydroxy RO₂
222 and it is dependent on the number of carbon atoms. Further oxidation of CH₃SCH₂OOH leads to the formation of
223 methylthiolformate (MTF, CH₃SCHO) (reaction 3), a species that has been detected in chamber studies before under low NO_x

224 conditions (Arsene et al., 1999, Urbanski et al., 1998). MTF decomposes to CH_3S (reaction 4), an intermediate that is already
225 part of the CS2 DMS scheme as a reaction product of MTMP (reaction 2a,b).

226
227 CH_3S can add an O_2 to form a weakly bound adduct, CH_3SOO (reaction 5c). At 298 K at sea level, approximately one-
228 third of CH_3S is present as the CH_3SOO adduct and at colder temperatures this ratio is even greater (75% at 273 K)
229 (Turnipseed et al., 1992). CH_3SOO can decompose to CH_3 and SO_2 (reaction 6a), which proceeds through isomerization
230 to CH_3SO_2 , followed by rapid thermal decomposition (McKee, 1993, Butkovskaya and Barnes, 2002, Chen et al. 2021).
231 Previous modelling studies, such as Hoffmann et al. (2016), include the isomerization step forming CH_3SO_2 but omit the
232 decomposition. This could lead to a higher yield of MSA in those studies.

233
234 CH_3S can also be oxidised by O_3 and NO_2 to CH_3SO (reaction 5a,b). Measurements by Borissenko et al. (2003) show that
235 O_3 oxidation of CH_3SO results in a 100% yield of SO_2 at pressures over 500 Torr (0.6 bar). Since the pressure in the marine
236 boundary layer where most of DMS oxidation takes place is above this threshold, the products of reaction 7c_old were
237 updated accordingly (reaction 7c). Additionally, the branching ratios of CH_3SO oxidation by NO_2 to CH_3SO_2 and SO_2
238 were revised to also match the findings by Borissenko et al. (2003).

239
240 While some CH_3SO_2 stems from the NO_3 oxidation of CH_3SO , it is mainly formed through oxidation of MSIA (reaction
241 9a,c), especially under low NO_x conditions. CH_3SO_2 can decompose to SO_2 (reaction 10a) or be oxidised further by O_3 or
242 NO_3 to CH_3SO_3 (reaction 10b,c). CH_3SO_3 itself can react to form MSA (reaction 11a). CH_3SO_3 can also decompose to
243 SO_3 , similar to the decomposition reaction of CH_3SO_2 , although it is assumed that this reaction is more endothermic
244 (Barone et al., 1995). The rate constant cited by von Glasow and Crutzen (2004) that was previously implemented in CS2,
245 could not be found in the cited primary literature (reaction 11b_old). Here, the rate constant of the decomposition reaction
246 was updated to the rate constant used in the MCMv3.3.1, which is — as for the decomposition of CH_3SO_2 — based on
247 Barone et al. (1995). We note that a more recent study, by Cao et al. (2013), calculates the rate constant for the thermal
248 decomposition of CH_3SO_3 to be 12 s^{-1} ; a factor of 80 larger than the value adopted here based on the MCMv3.3.1.

249
250 MSA is formed either through oxidation of MSIA (reaction 9b) or through the reaction of HO_2 with CH_3SO_3 (reaction
251 11a). The default configuration of UKCA (for example as run in UKESM1) does not include any sinks for MSA and it is
252 not treated as a species, which prevents the comparison of MSA concentrations with observational results. Here, wet
253 deposition of MSA is added with a Henry's law coefficient of $1 \times 10^9 \text{ M atm}^{-1}$ (Campolongo et al., 1999; Sander 2021).
254 We note that Wollesen de Jonge et al. (2021) calculated the Henry's law coefficient to be approximately an order of
255 magnitude lower and so this might be an overestimate. Dry deposition for MSA is added based on the implemented values
256 for HCOOH in CRI. Additionally, the gas-phase oxidation of MSA by OH is added. Barnes et al. (2006) suggest this
257 pathway is expected to play a minor role.

258

259 Wet deposition was added for MSIA with Henry's law constant of $1 \times 10^8 \text{ M atm}^{-1}$ (Barnes et al., 2006). Dry deposition is
 260 omitted for DMSO and MSIA since they are expected to be relatively short-lived.

261

262

263 **Table 2:** Summary of the H-abstraction and OH-addition branches in the DMS oxidation pathway. Reactions in **bold** are
 264 newly added in this work.

No.	Reactions	Rate ($\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$)	Reference
1a	DMS + OH \rightarrow MTMP + H ₂ O	$1.12 \times 10^{-11} \exp^{(-250/T)}$	IUPAC SOx22 (upd. 2006)
1b	DMS + NO ₃ \rightarrow MTMP + HNO ₃	$1.90 \times 10^{-13} \exp^{(520/T)}$	Atkinson et al. (2004)
1c	DMS + OH \rightarrow DMSO + HO ₂	see note ^a	IUPAC SOx22 (upd. 2006)
2a	MTMP + NO \rightarrow HCHO + CH ₃ S + NO ₂	$4.90 \times 10^{-12} \exp^{(263/T)}$	von Glasow and Crutzen (2004)
2b	MTMP + MTMP \rightarrow 2 HCHO + 2 CH ₃ S	1.0×10^{-11}	von Glasow and Crutzen (2004)
2c	MTMP + HO₂ \rightarrow CH₂SCH₂OOH	$2.91 \times 10^{-13} \exp^{(1300/T)} \times 0.387$	MCMv3.3.1
3	CH₂SCH₂OOH + OH \rightarrow CH₃SCHO	7.03×10^{-11}	MCMv3.3.1
4	CH₃SCHO + OH \rightarrow CH₃S + CO	1.11×10^{-11}	MCMv3.3.1
5a	CH ₃ S + O ₃ \rightarrow CH ₃ SO	$1.15 \times 10^{-12} \exp^{(432/T)}$	Atkinson et al. (2004)
5b	CH ₃ S + NO ₂ \rightarrow CH ₃ SO + NO	$3.00 \times 10^{-12} \exp^{(210/T)}$	Atkinson et al. (2004)
5c	CH₃S + O₂ \rightarrow CH₃SOO	$1.20 \times 10^{-16} \exp^{(1580/T)} \times [\text{O}_2]$	Atkinson et al. (2004)
6a	CH₃SOO \rightarrow CH₃O₂ + SO₂	$5.60 \times 10^{+16} \exp^{(-10870/T)}$	Atkinson et al. (2004)
6b	CH₃SOO \rightarrow CH₃S + O₂	$3.50 \times 10^{+10} \exp^{(-3560/T)}$	MCMv3.3.1 (based on: McKee (1993), and Butkovskaya and Barnes (2002))
7a	CH ₃ SO + NO ₂ \rightarrow CH ₃ SO ₂ + NO	$1.2 \times 10^{-11} \times 0.75$	Borrisenko et al. (2003), Atkinson et al. (2004)
7b	CH ₃ SO + NO ₂ \rightarrow SO ₂ + CH ₃ O ₂ + NO	$1.2 \times 10^{-11} \times 0.25$	Borrisenko et al. (2003), Atkinson et al. (2004)
7c_old	CH ₃ SO + O ₃ \rightarrow CH ₃ SO ₂	6.0×10^{-13}	Von Glasow and Crutzen (2004)
7c	CH₃SO + O₃ \rightarrow CH₃O₂ + SO₂	4×10^{-13}	Borrisenko et al. (2003), IUPAC SOx61 (upd. 2006)
8	DMSO + OH \rightarrow MSIA + CH ₃ O ₂	$8.7 \times 10^{-11} \times 0.95$	von Glasow and Crutzen (2004)
9a	MSIA + OH \rightarrow CH ₃ SO ₂ + H ₂ O	$9.0 \times 10^{-11} \times 0.95$	von Glasow and Crutzen (2004)
9b	MSIA + OH \rightarrow MSA + HO ₂ + H ₂ O	$9.0 \times 10^{-11} \times 0.05$	von Glasow and Crutzen (2004)
9c	MSIA + NO ₃ \rightarrow CH ₃ SO ₂ + HNO ₃	1.0×10^{-13}	von Glasow and Crutzen (2004)
10a	CH ₃ SO ₂ \rightarrow CH ₃ O ₂ + SO ₂	$5.0 \times 10^{-13} \exp^{(-9673/T)}$	MCMv3.3.1 (based on: Barone et al. (1995))
10b	CH ₃ SO ₂ + O ₃ \rightarrow CH ₃ SO ₃	3.0×10^{-13}	von Glasow and Crutzen (2004)
10c	CH ₃ SO ₂ + NO ₂ \rightarrow CH ₃ SO ₃ + NO	2.2×10^{-12}	Atkinson et al. (2004)
11a	CH ₃ SO ₃ + HO ₂ \rightarrow MSA	5.0×10^{-11}	von Glasow and Crutzen (2004)
11b_old	CH ₃ SO ₃ \rightarrow CH ₃ O ₂ + H ₂ SO ₄	$1.36 \times 10^{14} \exp^{(-11071/T)}$	von Glasow and Crutzen (2004)
11b	CH₃SO₃ \rightarrow CH₃O₂ + SO₃	$5.0 \times 10^{13} \exp^{(-9946/T)}$	MCMv3.3.1 (based on: Barone et al. (1995))

$$265 \quad {}^a 9.5 \times 10^{-39} \exp^{(5270/T)} \times [\text{O}_2] / (1 + 7.5 \times 10^{-29} \exp^{(5610/T)} \times [\text{O}_2])$$

266

267 2.2.2 The addition of the isomerization branch

268 Following the discovery of HPMTF (Veres et al., 2020) the pathway forming this molecule has now been well established
 269 (Wu et al., 2015; Veres et al., 2020; Berndt et al., 2019; Ye et al., 2021). The reactions of the isomerization branch that were
 270 added to CS₂ (summarised in **Figure 1** and **Table 3**) were identified as those most important in determining SO₂ and HPMTF
 271 concentrations through sensitivity studies conducted using our box model setup. Details of these box model sensitivity studies
 272 (and the discarded reaction pathways that were found to not be significant) are included in the supplement. In this sense,
 273 species like HOOCH₂SCH₂OOH, included in the studies by Khan et al. (2021) were neglected from our mechanism as this
 274 was found to have minor impact on the SO₂ and HPMTF simulated in the box model experiments. The reactions that were
 275 added include the autoxidation of MTMP to HPMTF in one step (reaction 2d) and the oxidation of HPMTF by OH, forming
 276 OCS (reaction 13b) and HOOCH₂S (reaction 13a) with further oxidation to SO₂ (reactions 14-16). The equilibrium with the
 277 O₂-adduct, HOOCH₂SOO, and its subsequent decomposition (reaction 14c, 15a,b) was included with kinetics equivalent to
 278 CH₃SOO (reaction 5c, 6a,b). Photolysis was found to be a minor pathway of HPMTF loss in our marine boundary layer box
 279 model setup (< 10%) and was omitted from the final mechanism used here; contrary to the importance of photolysis of HPMTF
 280 found by Khan et al. (2021).

281

282 Dry deposition of HPMTF is set using the same parameters in UKCA as other soluble gas-phase compounds, such as CH₃OOH
 283 and H₂O₂, which yield an average deposition velocity similar to the observations of Vermeuel et al. (2020) of 0.75 cm s⁻¹. For
 284 wet deposition of HPMTF, the Henry's law coefficient calculated by Wollesen de Jonge et al. (2021) was used.

285

286 For the sensitivity runs described in **Table 1**, some changes are made to the values in **Table 3**. In DMS-HPMTF-FP, the rate
 287 constant of reaction 2d is scaled by a factor of 5.0: Berndt et al. (2019) experimentally determined the rate constant at 295 K
 288 as 0.23 s⁻¹. Here the A-factor is scaled to match this value, while keeping the temperature dependence calculated by Veres et
 289 al. (2020) (following Wollesen de Jonge et al. (2021)). DMS-HPMTF-FL uses a rate constant 5.5 times faster for the total loss
 290 of HPMTF to OH (reaction 13a,b), which was recommended as an upper bound by Vermeuel et al. (2020) and following Khan
 291 et al. (2021). This range, between the base rate constant and the faster loss, puts us in the middle of the value experimentally
 292 determined by Ye et al. (2022). In the remaining sensitivity run CS₂-HPMTF-CLD, heterogeneous uptake to both clouds and
 293 aerosols was added with reactive uptake coefficient (γ) of 0.01 (following Novak et al., 2021).

294

295 **Table 3:** Summary of the isomerization branch of the H-abstraction pathway. Rate constants referenced to this work are
 296 described in Section 2.2

No.	Reaction	Rate (cm ³ molecule ⁻¹ s ⁻¹)	Reference
2d	MTMP → HPMTF + OH	see note ^a	Veres et al. (2020)
13a	HPMTF + OH → HOOCH ₂ S + H ₂ O + CO	1.0×10 ⁻¹¹ × 0.9	this work
13b	HPMTF + OH → OCS + OH + HCHO + H ₂ O	1.0×10 ⁻¹¹ × 0.1	this work

297 ^a 2.24×10⁺¹¹ exp^(-9800/T) exp^{(1.03e8/(T×T×T))}

298

299 2.3 Description of observational data

300 2.3.1 The NASA Atmospheric Tomography (ATom) mission

301 An observational dataset used to compare with the model simulations stems from the fourth flight campaign of the NASA
 302 Atmospheric Tomography mission (ATom-4). ATom-4 took place during April and May 2018, and completed a global circuit
 303 around the Americas: from the Arctic to the Antarctic over the remote Pacific and Atlantic Ocean at varying altitudes up to 12
 304 km. A vast number of atmospheric species were measured, including DMS, HPMTF, and SO₂ (Wofsy et al., 2018).

305

306 In order to compare the 3D model outputs with the data from the ATom-4 campaign, the hourly outputs from the respective
 307 model runs were interpolated in regards to time and space to generate the data along the flight path. Only model data at times
 308 where valid atmospheric measurements were available are taken into account, resulting in 313 data points for DMS (Whole
 309 Air Sampling) and 36,652 for SO₂ (Laser Induced Fluorescence).

310

311 2.3.2 Surface observations

312 Other observational measurements are monthly averages (mean) from the years 1990 to 1999 for DMS measurements made
 313 on Amsterdam Island (37°S, 77°E) in the southern Indian Ocean (Sciare et al., 2000) and the monthly means from 1991 to
 314 1995 for sulfate at the Dumont d'Urville station (66°S, 140°E) at the coast of Antarctica (Minikin et al., 1998). The diel profile
 315 of HPMTF as measured at Scripps Pier in July 2018 was taken from Vermeuel et al. (2020). See the SI for the analysis of the
 316 modelled and observed DMS mixing ratios.

317 **3 Comparison of DMS oxidation pathways (BOXMOX)**

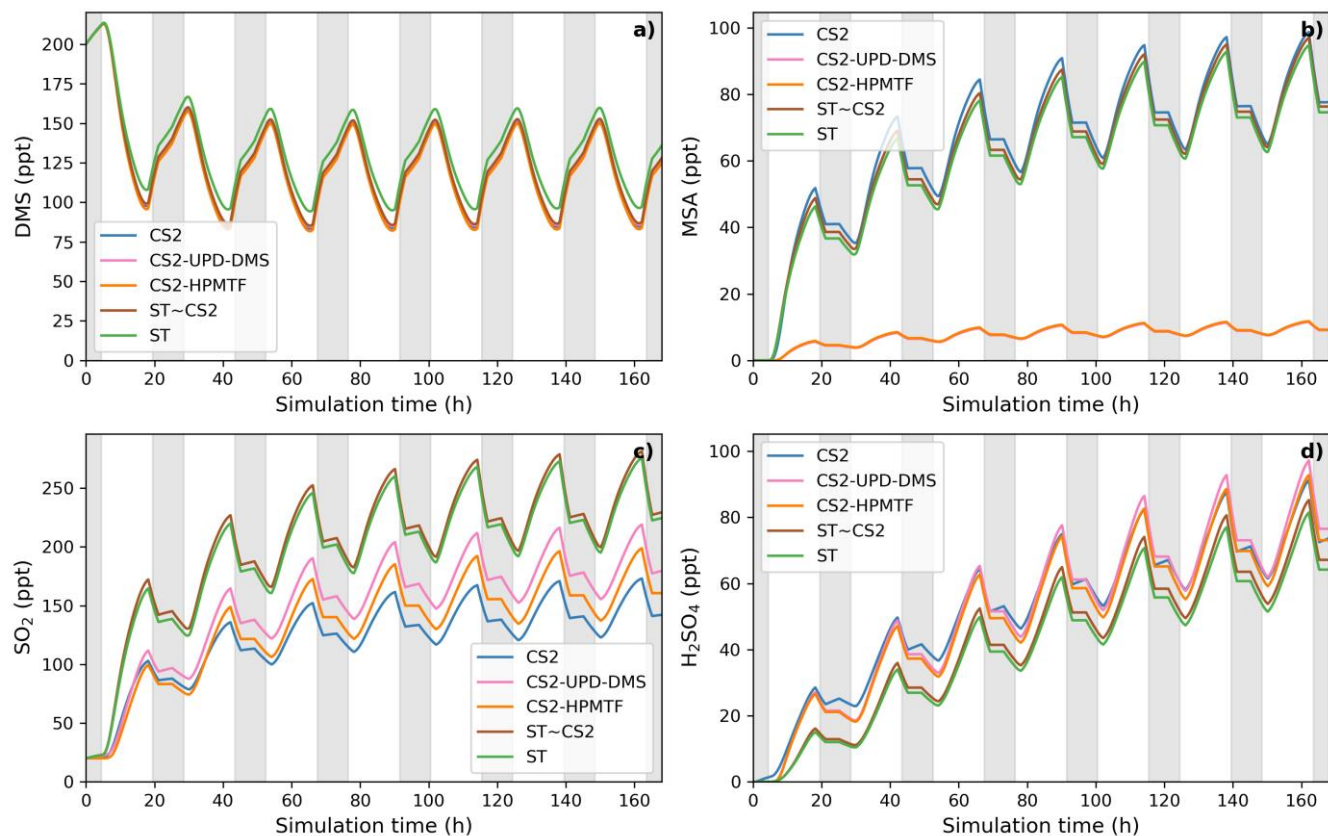

318 Here we present the results of a series of box model simulations using the BOXMOX model (Weber et al., 2020). With
319 BOXMOX we look at the diversity in results from simulations using a range of mechanisms, including our newly developed
320 mechanism. These simulations are not constrained to observations or simulation chamber data. The set-up of the BOXMOX
321 simulations is described in Section 2.1.1. We focus the analysis here on DMS and its major oxidation products and the effects
322 of temperature and $[\text{NO}_x]$ on these. Section 3.1 compares DMS mechanisms based around the CS2 and ST schemes used in
323 UKCA (**Table 1**). In Section 3.2 our newly developed mechanism is compared to other DMS mechanisms from recent literature
324 that also include HPMTF formation.

325 **3.1 Comparison of DMS mechanisms used for UKCA**

326 **3.1.1 Time series analysis**

327 The BOXMOX set up allows a quasi steady-state to be achieved for a number of key sulfur species with the main exception
328 being H_2SO_4 , which builds up over time in the model as the model is run without aerosol formation and aerosol microphysics
329 included (**Figure 2**). The DMS concentration simulated with different DMS mechanisms used in UKCA is simulated to be
330 very similar throughout all model runs; the small variations stem from different oxidant concentrations or small differences in
331 the rate constants used for the initiation reaction in the different mechanisms (**Figure 2a**). For instance, the ST run has higher
332 DMS concentration because the NO_x concentration is lower (as is OH) and less DMS is oxidised.

333 The SO_2 concentration is increased and MSA is significantly decreased in the updated CS2 runs (CS2-HPMTF and CS2-UPD-
334 DMS) compared to CS2 (**Figure 2b,c**). Comparing CS2-HPMTF and CS2-UPD-DMS, we can see that this pattern (increased
335 SO_2 and decreased MSA) is due to reaction 7c, which directly forms SO_2 and suppresses CH_3SO_2 , consequently lowering
336 MSA formation. The SO_2 concentration is lower in CS2-HPMTF compared to CS2-UPD-DMS because the addition of
337 HPMTF produces OCS which acts as a long-lived sulfur reservoir. While MSA concentration is very similar between CS2 and
338 ST, SO_2 concentration is not. This is primarily explained through the difference in the treatment of MSA and SO_2 production
339 in CS2 and ST. MSA is not treated as a reactive species in CS2 and ST (in so much as there are no further reactions of MSA
340 after its production). In ST and ST~CS2, 100% of DMS yields SO_2 , regardless of the amount of MSA production. However,
341 as more MSA is produced in CS2 the SO_2 yield is lowered. In spite of higher SO_2 concentrations in the ST DMS schemes, this
342 trend does not translate to H_2SO_4 concentration (**Figure 2d**). SO_2 is a relatively long-lived species (~2 days in our model but
343 with a range from 0.5-2.5 days (Lee et al., (2011))) and can therefore be lost through the mixing processes with the background
344 air in the BOXMOX setup. In CS2, CH_3SO_3 decomposition provides a direct pathway to H_2SO_4 production. In the updated
345 CS2 schemes (CS2-UPD-DMS and CS2-HPMTF) SO_3 production with instantaneous transformation to H_2SO_4 is included.
346 The slower rate constant in CS2 for the decomposition of CH_3SO_3 (11b_old) is compensated by a higher production of CH_3SO_3 .

347

348

349

350

351

352

Figure 2: BOXMOX-simulated gas-phase concentrations as a function of time for a selection of species simulated with the different DMS gas-phase oxidation schemes used in UKCA configurations (oxidation by OH and NO₃). Grey areas denote nighttime, when no photolysis reactions are taking place. Average NO_x concentration is approximately 10 ppt, with an average temperature of 293 K (range: 289 – 297 K).

353

3.1.2 Sensitivity of UKCA DMS schemes to temperature

354

355

356

357

358

359

360

As described in Section 2.1.1, a series of BOXMOX experiments were performed perturbing the temperature profile in the model (**Figure 3**).

As temperature increases in the box model, the steady-state DMS concentration increases in all simulations. This is mainly because the DMS oxidation by OH addition is negatively temperature dependent. For most models, DMS concentration increases by 85-93 ppt throughout the temperature range from 260 K to 310 K, except the ST run where at temperatures over 290 K, a stronger increase of DMS concentration is found, with a total increase of 106 ppt. This could be due to different

361 oxidant concentrations in the model runs using the ST mechanism and independent of the DMS scheme since this stronger
362 increase is not found with CS2-ST.

363 Although the kinetics, and therefore temperature dependence, of DMS loss is comparable across the different schemes, the
364 dependence of MSA and SO₂ on temperature differ significantly.

365

366 Most MSA is formed from the OH-addition channel, which is favoured at low temperatures (Barnes et al., 2006). Therefore,
367 the MSA concentration is higher at lower temperatures across all the UKCA DMS schemes considered (**Figure 3b**). In the ST
368 schemes (ST and ST~CS2), MSA decreases by around 88% (-189 ppt and -197 ppt) throughout the temperature range
369 considered, while in all the CS2 schemes MSA is shown to be much more sensitive to temperature, decreasing by >96% (CS2:
370 -300 ppt, CS2-UPD-DMS: -222 ppt, CS2-HPMTF: -222 ppt). In particular the CS2 family of mechanisms shows pronounced
371 temperature sensitivity between 270 to 290 K. We attribute this to differences in the rate constant of DMS oxidation through
372 the OH-addition channel (see **Table 2** and **S1.3.1**). The average MSA concentration for the UKCA schemes diverges most in
373 the temperature range between 270 - 300 K.

374

375 The difference in SO₂ concentrations between the CS2 schemes and ST schemes are greatest at lower temperature (**Figure**
376 **3e**), with the ST and CS2-ST schemes simulating ~ 5 times (+200 ppt) the SO₂ that is simulated in the other schemes based
377 around CS2. In the ST schemes SO₂ concentration either stays at a similar level across the whole temperature range (ST: +3%)
378 or slightly decreases (ST~CS2: -9%). Conversely, the CS2 family of schemes show a positive temperature dependence (i.e.,
379 $+\frac{d[X]}{dT}$), across the temperature range, especially in the range of relevant atmospheric temperatures from 270 to 290 K. SO₂
380 increases by 298% in CS2, 84% in CS2-UPD-DMS and 79% CS2-HPMTF. In the CS2 schemes, more DMS reacts through
381 the addition pathway which favours the production of MSA, instead of SO₂ therefore reducing the SO₂ concentration. In ST,
382 the addition pathway still leads to 100% SO₂ formation, making the average SO₂ concentration less dependent on temperature.
383 Experimental findings (Arsene et al., 1999) and field measurements (Sciare et al., 2001) both show a positive temperature
384 dependence of SO₂ concentration. This trend is only reproduced by the DMS schemes based on the CS2 mechanistic features
385 (i.e. not the very simple mechanism used in ST), indicating that the ST DMS chemistry is likely insufficient to explain
386 laboratory and field observations, particularly in cold environments and under climate change.

387

388 In these box model experiments only gas phase losses and mixing of species with background air are considered. Under the
389 conditions of our simulations, we find that the MTMP isomerization pathway mainly yields SO₂, as does the rest of the
390 abstraction pathway. Therefore, the addition of the isomerization branch does not have a significant impact on the temperature
391 dependence of SO₂ concentration (comparing CS2-UPD-DMS and CS2-HPMTF), even though the isomerization step itself is
392 greatly temperature dependent.

Figure 3: Temperature dependence of average a) DMS, b) MSA, and c) SO_2 concentration after a quasi steady-state is reached in the box model simulations using the DMS schemes for UKCA.

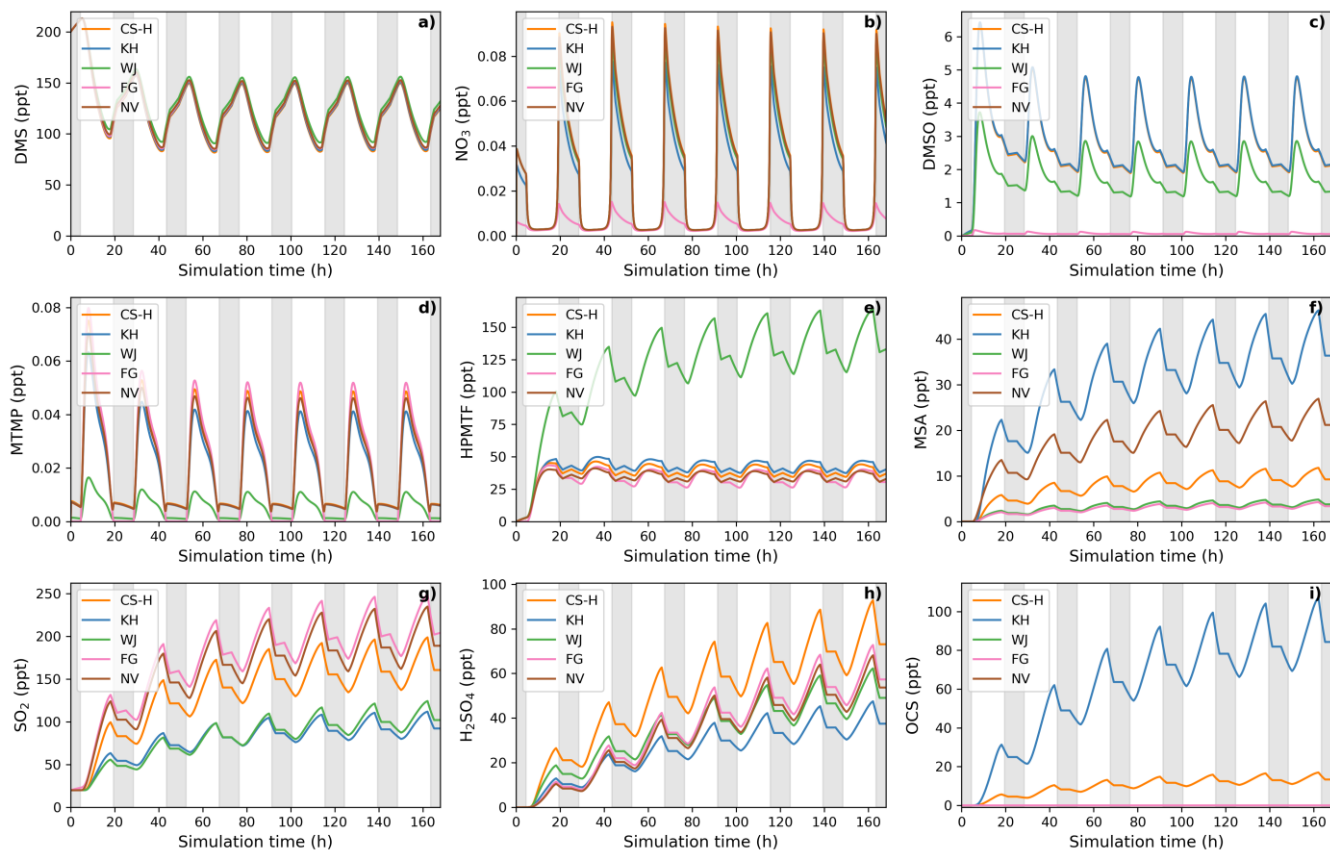

3.2 Comparison with DMS schemes that include HPMTF from the recent literature

Here, four recently published DMS schemes that also include the isomerization pathway and formation of HPMTF are compared with our new mechanism, CS2-HPMTF (*CS-H*, 36 reactions in DMS scheme), as follows. To make the studies comparable, only DMS oxidation by NO_3 and OH and gas-phase reactions are considered. The implementation of these chemical schemes in BOXMOX can be found in the *Supporting Information SI.3*.

- *Fung et al. (2022) (FG)*: This scheme includes 32 reactions for the DMS oxidation chemistry. The H-abstraction pathway is based on the MCM, while the rate constants in the OH-addition pathway mostly stem from Burkholder et al. (2015) or a scaled up version of those. The rate constant of MTMP isomerization to HPMTF is based on Veres et al. (2020).
- *Wollesen de Jonge et al. (2021) (WJ)*: This scheme is the most complex and consists of 98 reactions, including reactions from the MCM and from Hoffmann et al. (2016). The isomerization branch mostly uses the rate constants by Wu et al. (2015), except the first isomerization rate constant, which is a combination of Veres et al. (2020) and Berndt et al. (2019).
- *Khan et al. (2021) (KH)*: This scheme is based on Khan et al. (2016), which is equivalent to the DMS chemistry in CS2 (CRI v2 R5). The mechanism was modified to include the isomerization pathway and photolysis loss and temperature dependent OH oxidation of HPMTF by the authors. In total, the DMS chemistry consists of 38 reactions, 5 of which are photolysis reactions.
- *Novak et al. (2021) (NV)*: This is a simplified scheme that aims to only include the intermediates necessary for HPMTF formation and consists of only 10 reactions. DMS therefore either directly yields MSA (without DMSO formation) or first forms MTMP, which isomerizes to form HPMTF or is oxidised to SO_2 .

418 Using this ensemble of gas-phase DMS oxidation schemes in BOXMOX simulations leads to significant differences in the
 419 concentrations of important oxidation intermediates and products, even though DMS concentration is similar across all models
 420 (**Figure 4**).

421 3.2.1 Time series analysis of different DMS-HPMTF schemes

422
 423 **Figure 4:** Gas-phase concentrations as a function of time for different DMS gas-phase oxidation schemes (oxidation by OH
 424 and NO_3). Average NO_x concentration is approximately 10 ppt, with an average temperature of 293 K (range: 289 – 297 K).
 425 Grey areas denote nighttime when no photolysis reactions are taking place.

426
 427
 428 The depletion of DMS due to OH and NO_3 oxidation is similar across most models (**Figure 4a**) since the major oxidants are
 429 relatively constrained by the box model experiment set up (see Section 2.1.1) and they mostly rely on IUPAC or JPL
 430 recommended values (Atkinson et al., 2004; Burkholder et al., 2015). One exception is NO_3 oxidation in the FG scheme, which
 431 uses a rate constant a factor of approximately 6 higher than the JPL recommendation. On the one hand, this does not affect
 432 DMS concentration, since OH oxidation of DMS plays a greater role, on the other hand, the concentration of NO_3 in the FG

433 scheme's simulation run is controlled by the greater NO₃ oxidation rate (**Figure 4b**). WJ includes the intermediate
434 CH₃S(OH)CH₃ and its decomposition back to DMS (based on Hoffmann et al., (2016)), which in their experiments improved
435 the fit between their measured and modelled DMS concentration. Here, this does not have any significant impact on DMS
436 concentration, compared to all the other schemes.

437
438 Significant differences between the models can be found for the DMSO concentration (**Figure 4c**). KH and CS-H have the
439 highest DMSO concentration since all DMS that is oxidised through the OH-addition pathway yields DMSO. This is not the
440 case for WJ, where CH₃SOH and to a small part DMSO₂ are also possible products. In the FG simulation, DMSO concentration
441 is close to zero, which is due to a much faster loss of DMSO; a rate constant a factor of 15 faster than experimental
442 measurements by Urbanski et al. (1998). NV does not include DMSO as an intermediate. Since the lifetime of DMSO was
443 found to be several hours (Urbanski et al., 1998; Ye et al. 2021), deposition of DMSO could act as a significant sink of
444 atmospheric sulfur (as found by Chen et al. (2018)). Fast oxidation of DMSO in FG, or omitting the species in NV, might
445 therefore lead to an over-estimation of other DMS oxidation products in those schemes.

446
447 Regarding the intermediate MTMP, WJ shows the greatest deviation from the ensemble (**Figure 4d**). The MTMP concentration
448 never exceeds 0.02 ppt in WJ, while the other mechanisms simulate concentrations over three times higher. WJ employs a
449 faster isomerization rate constant of MTMP to HPMTF. They scale the A-factor by 5 to get a rate constant that is a combination
450 of the theoretical calculations by Veres et al. (2020) and the experimental findings by Berndt et al. (2019). Additionally, they
451 include more oxidation reactions of MTMP (such as oxidation by NO₃) but since the isomerization to HPMTF already
452 outcompetes most oxidation reactions anyway (>97%), we found them to play a negligible role (<0.1%). In the FG scheme,
453 DMS + NO₃ leads to immediate SO₂ formation, without prior MTMP formation. Therefore, no MTMP is produced during the
454 nighttime, when NO₃ oxidation becomes relevant. Under conditions with low NO_x (around 10 ppt in this experiment) this does
455 not have significant impacts but at higher NO_x concentrations this leads to a major deviation from the other simulations (**Figure**
456 **5a**, 100 ppt NO_x). At night, CS-H, KH, and NV reach MTMP concentrations of 0.07 ppt, allowing nighttime HPMTF
457 formation, while FG stays zero.

458
459 All model simulations, except WJ, are very similar in HPMTF concentration (**Figure 4e**). The fast isomerization rate constant
460 in WJ is one of the reasons HPMTF concentration is on average more than 3 times higher than the other model simulations.
461 The other reason is a much slower oxidation of HPMTF by OH. While most models use a value of (or close to) 1.11×10^{-11}
462 cm³ molecule⁻¹ s⁻¹, recommended by Vermeuel et al. (2020), WJ use the much slower rate constant calculated by Wu et al.
463 (2015), 1.4×10^{-12} cm³ molecule⁻¹ s⁻¹. This rate constant is also used in the KH scheme but it additionally includes HPMTF
464 depletion by photolysis which ultimately leads to the similar HPMTF concentration as in CS-H, FG, and NV. The addition of
465 the photolysis reactions in KH does not affect the diel profile of HPMTF, even though those account for 81% of chemical loss
466 of HPMTF in their scheme. It is therefore unlikely that the observed diel profile of HPMTF by Vermeuel et al. (2020) and

467 Khan et al. (2021) can be explained solely by considering loss of HPMTF to aldehyde and hydroperoxide photolysis. Reducing
 468 HPMTF formation to one isomerization reaction without any side reactions as is done in this work and NV, does also not affect
 469 the diel profile of HPMTF significantly.

470 The effect of higher NO_x conditions on the diel profile of HPMTF varies significantly between the different schemes (10 ppt
 471 NO_x in **Figure 4** vs. 100 ppt NO_x in **Figure 5**). Higher NO_x concentration leads to more DMS oxidation by NO_3 at night and
 472 the subsequent increase in MTMP concentration and therefore HPMTF concentration during the night hours in the CS-H, WJ,
 473 KH, and NV simulations. At low NO_x , HPMTF concentration stayed more or less stable throughout the nighttime and increased
 474 in the morning, reaching a plateau in the afternoon, and dropping in the evening (**Figure 4e**). Under higher NO_x conditions,
 475 HPMTF increases in these mechanisms throughout the night and decreases throughout the day when it is oxidised by OH
 476 (**Figure 5b**). In the WJ simulation, the diel profile has more plateaus and small deviances but the overall trend still fits the
 477 described pattern. This is not true for FG, where DMS oxidation by NO_3 leads directly to SO_2 formation.

478

479

480 **Figure 5:** BOXMOX simulations where the average NO_x concentration is approximately 100 ppt (a factor 10 greater than for
 481 the results presented in **Figure 4**). **(a)** MTMP, **(b)** HPMTF, and **(c)** SO_2 concentration as a function of time for different DMS
 482 gas-phase oxidation schemes (oxidation by OH and NO_3). Average temperature of 293 K (range: 289 – 297 K). Grey areas
 483 denote nighttime when no photolysis reactions are taking place.

484

485 While the diel profile of MSA looks similar for all simulations, the average concentrations do not (**Figure 4f**). The highest
 486 average steady-state MSA concentration is reached in the KH simulation, which is a factor of 10 higher than the lowest average
 487 concentration in the FG simulation. In our experimental setup, most of the simulations we performed with the different
 488 mechanisms do not include any (significant) gas-phase chemical loss pathway for MSA; MSA is only lost through mixing and
 489 transport out of the “box”. Therefore, the concentration of MSA is a direct reflection of MSA production in the respective
 490 simulations.

491

492 KH simulates the highest production of MSA (similar to CS2), where MSA is formed through the addition ($\text{MSIA} + \text{OH} \rightarrow$
 493 $0.05 \text{ MSA} + 0.95 \text{ CH}_3\text{SO}_2$, reaction 9b,c) and the abstraction channel ($\text{CH}_3\text{SO} + \text{O}_3 \rightarrow \text{CH}_3\text{SO}_2$, reaction 7c_old) of DMS
 494 oxidation, with CH_3SO_2 partly being oxidised to CH_3SO_3 and then to MSA (reactions 10b,c, 11a). The decomposition of

495 CH_3SO_3 to H_2SO_4 in KH is slower than in other mechanisms, increasing the branching ratio for MSA formation in their
496 mechanism. In NV, the simulation with the second highest average MSA concentration, the only source of MSA is the direct
497 production of MSA through OH oxidation through the addition channel, where 25% of DMS forms MSA. In both, CS-H and
498 WJ, the abstraction pathway mostly produces SO_2 and only contributes negligible amounts to CH_3SO_2 formation, hence MSA.
499 Similar to KH, the oxidation of DMS through the addition pathway in CS-H and WJ yields CH_3SO_2 of which a part forms
500 MSA. However, not all of the CH_3SO_2 results in MSA, some of it also decomposes to SO_2 or yields SO_3 . This explains the
501 lower concentration of MSA in CS-H and WJ compared with NV. The reason why CS-H has a higher MSA concentration than
502 WJ is because of the inclusion of reaction 9b (**Table 2**), which yields MSA directly and is not part of the WJ scheme.
503 The lowest MSA concentration is found in FG and WJ, where 60% of the OH-addition pathway directly produces SO_2 . Out of
504 the 40% of DMS that forms DMSO in this pathway, only a fraction yields MSA.
505

506 To harmonise the results and aid interpretability, the same rates (based on CS2) are used for the loss processes of SO_2 in all
507 the mechanisms considered here, therefore the concentration of SO_2 can be used as a proxy for SO_2 production, just as for
508 MSA. The highest SO_2 concentration can be seen in schemes that have the smallest number of intermediates or the most direct
509 pathways from DMS to SO_2 , in NV and FG (**Figure 4g**). Fewer intermediates result in less opportunities for the formation of
510 side products or less long-lived species that can be lost through transport or deposition. For instance, in WJ HPMTF is lost
511 through mixing with the background before it can form SO_2 . Likewise, KH has a higher ratio of MSA and OCS production,
512 which lowers the SO_2 yield. The diel profile of SO_2 concentration is in most simulations not affected by higher NO_x
513 concentrations, with the general trend being an increase of SO_2 concentration during the day and a decrease at night (**Figure**
514 **5c**). The only exception is the FG simulation, where we see a clear increase through part of the night, due to the reaction DMS
515 $+ \text{NO}_3 \rightarrow \text{SO}_2$.

516
517 The H_2SO_4 concentration is influenced by SO_2 production and CH_3SO_3 production and the rate of decomposition of SO_3 to
518 H_2SO_4 . CS-H has the highest average H_2SO_4 concentration and KH the lowest; all other models are very similar to each other
519 (**Figure 4h**). In general, higher SO_2 concentration leads to more H_2SO_4 , since SO_2 is first oxidised to SO_3 and then to H_2SO_4
520 with the same rates across all schemes. However, all models except NV include an additional pathway of H_2SO_4 formation: in
521 KH and FG, H_2SO_4 is directly formed from CH_3SO_3 , while in CS-H and WJ CH_3SO_3 decomposes to SO_3 first, which then
522 instantly reacts to H_2SO_4 . In KH, the rate constant for the decomposition of CH_3SO_3 at 295 K is a factor of 15 slower than in
523 the other models. Since the SO_2 concentration is also relatively low, it explains why KH has the lowest H_2SO_4 concentration
524 of all schemes when reaching steady-state. CS-H results in a higher H_2SO_4 concentration than FG or NV even though those
525 models have a higher SO_2 concentration. The reason is a higher production of CH_3SO_3 that is then decomposed to SO_3 and
526 H_2SO_4 .

527

528 Similar to the other products of the DMS scheme, the concentration of OCS is a reflection of its production. OCS is only
529 produced from oxidation of HPMTF by OH and, in the KH scheme, through photolysis of HPMTF. In KH, 60% of HPMTF
530 forms OCS, resulting in the highest OCS concentration (**Figure 4i**). This stems mainly from the large contribution of the
531 photolysis reactions. Potentially, the rate constant of OH oxidation of HPMTF in KH is too low and therefore OCS might be
532 overestimated. In CS-H, 10% of HPMTF is oxidised to OCS, resulting in an OCS concentration that is on average 5.5 times
533 lower than KH. FG and WJ both use the theoretically determined branching ratio by Wu et al. (2020), which results in only
534 0.007% of HPMTF being oxidised to OCS at 295 K. NV does not include this pathway. Very recent evidence suggests that
535 there is a small (2%) but prompt source of OCS following the formation (and decomposition) of HPMTF as well as a significant
536 OCS yield (13%) from the HPMTF + OH reaction (Jernigan et al., 2022). These new data were not assessed (or included) in
537 this work but we estimate that inclusion of these mechanistic pathways would result in OCS yields higher than CS-H and the
538 other mechanisms (which have used a very small yield in the past) but consistently lower than that simulated by KH.
539 To summarise, the intercomparison of recent gas-phase DMS oxidation mechanisms complements and extends earlier studies
540 on DMS (Karl et al., 2007). Recent gas-phase DMS oxidation schemes used in modelling studies lead to a wide range in results
541 of key DMS oxidation products, with moderate Nox levels (~ 0.1 ppb) leading to greater divergence than low Nox levels (~
542 10 of ppt). A similar situation was found for isoprene by Archibald et al. (2010) and significant efforts have been employed to
543 improve our understanding of isoprene oxidation through theoretical and laboratory experiments (e.g., Jenkin et al., 2015;
544 Wennberg et al., 2018). We now focus on the role of temperature on the divergences seen thus far.

545

546 **3.2.2 Temperature dependence of different DMS-HPMTF schemes**

547 **Figure 6** shows that even though the temperature dependence of average DMS concentration is similar across all schemes, the
548 temperature dependence of average SO₂ and MSA concentration differs from scheme to scheme significantly. Most of the
549 general trends were found to be similar and in line with the trends observed for the UKCA schemes and have been explained
550 there (Section 3.1.2, **Figure 3**).

551

552 While WJ has the highest absolute change in HPMTF concentration throughout the temperature range (+131 ppt, +380%;
553 **Figure 6b**), CS-H, KH, and NV show higher relative change (+43-48 pp, +763-892%). Since FG is missing the DMS oxidation
554 by NO₃ as a potential pathway to HPMTF (via MTMP), HPMTF in FG is least affected by temperature (+34 ppt, +256%).

555

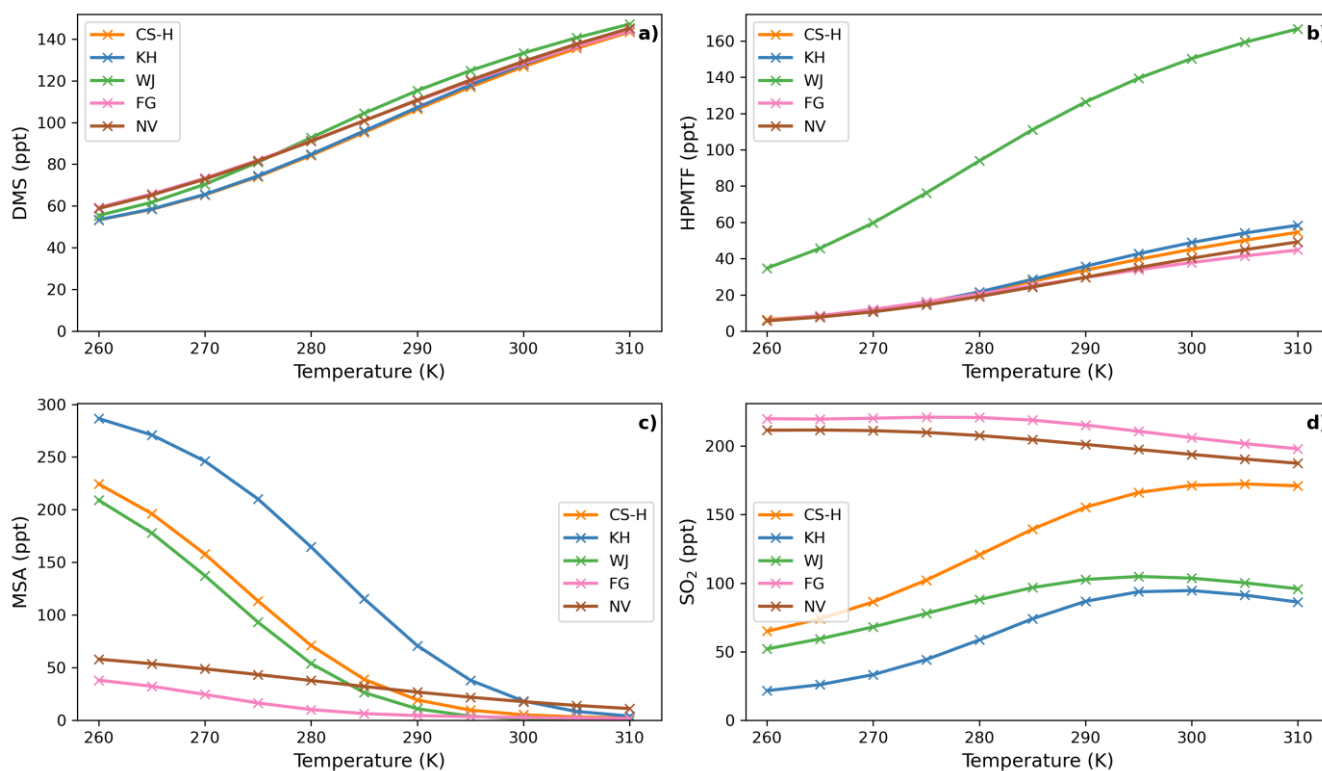

556 MSA is even more affected by temperature than HPMTF (**Figure 6c**). Its concentration shows a strong negative temperature
557 dependence in all simulations (**Figure 6c**). The magnitude of MSA-temperature dependence differs from scheme to scheme.
558 The smallest changes can be observed in NV (-47 ppt from 260 – 310 K), where only 25% of DMS that is oxidised through
559 the OH-addition pathway forms MSA. Similarly in FG (-67 ppt from 260 – 310 K), where only 40% of the OH-addition

560 pathway forms DMSO and then potentially MSA. The largest temperature dependence can be found in the KH simulation,
 561 with a change of MSA concentration of -282 ppt from 260 K to 310 K, which is very similar to CS2 (**Figure 3c**).

562

563 In almost all schemes, SO₂ concentration increases with temperature (**Figure 6d**). The greatest positive change happens
 564 between the atmospheric relevant temperatures 270 and 290 K. KH and CS-H show the greatest increase in this temperature
 565 range with +53 ppt (+160%) and +69 ppt (+80%), respectively (WJ: +34 ppt (51%)). Starting at 295 K, SO₂ concentration
 566 plateaus with further increasing temperature and even declines slightly in some simulations (Figure 6d). NV and FG are the
 567 only models which show a decrease in SO₂ throughout the entire temperature range of 260 – 310 K (NV: -24 ppt, -11%, FG:
 568 -22 ppt, -10%), similar to ST~CS2 in **Figure 2d**. This could be due to previously mentioned simplifications in the DMS
 569 additional channel, where DMSO is either completely omitted or rapidly oxidised further.

570

571

572 **Figure 6:** Temperature dependence of average (a) DMS, (b) HPMTF, (c) MSA, and (d) SO₂ concentration in different DMS
 573 oxidation schemes after a quasi steady-state is reached in the box model simulation. Average Nox is approximately 10 ppt.

574

575 These results demonstrate limited consensus on gas-phase DMS oxidation, similar to the earlier work of Karl et al., 2007.
 576 Importantly in the context of the role of DMS in chemistry-aerosol-climate feedbacks, we have further shown that this

577 uncertainty across mechanisms is amplified when assessing temperature sensitivity of the products of DMS oxidation. Small
578 uncertainties in the rate of reactions or the omission of intermediates can have significant effects on the resulting product
579 concentrations, as we have shown through our systematic work updating the CRI-Strat DMS scheme. All models studied tend
580 to agree on the rates of oxidation of DMS, largely controlled for by the fairly uniform treatment of the initial oxidation step.
581 However, we saw (in Figure 5) that there is large divergence at high No_x levels for MTMP and subsequently HPMTF and
582 SO_2 . In part this divergence could be reduced by better constraining the MTMP self- and cross-reactions, but in the case of
583 Fung et al. (2022) including MTMP as a product of the $\text{NO}_3 + \text{DMS}$ reaction would help it converge with the other models.
584 The effects of climate change are that it is likely that global mean surface temperature will remain higher than the pre-industrial
585 baseline for some time to come. As a result, the simulations would all suggest an increase in the amount of HPMTF formed
586 relative to other major oxidation products, especially, MSA, and most likely an overall increase in SO_2 . However, our box-
587 modelling study highlights how uncertain the situation is within the context of the current literature. At present there is a need
588 for more laboratory data and more focused sensitivity studies to isolate the major sources of uncertainty that are common
589 across DMS oxidation mechanisms and constrain them. Strikingly we see that the ST and CS2 mechanistic variants used for
590 UKCA studies span the wide range of SO_2 -Temperature and MSA-Temperature sensitivities as the recently reported updated
591 DMS mechanisms. We now move on to discuss our work implementing the CS2-H mechanism into our global chemistry-
592 climate model.

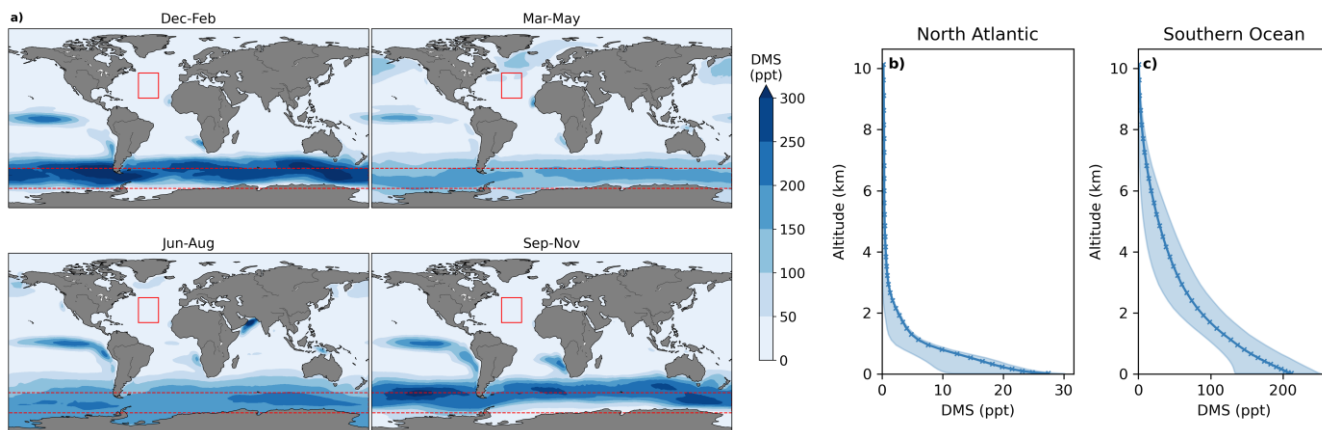

593 **4 Results from 3D model simulations using UKCA**

594 Here we present our results from the incorporation of the new CS2-H DMS mechanism described above in the 3D UKCA
595 chemistry climate model. As described in Section 2.1, we performed a series of 12-month nudged simulations with UKCA for
596 the year 2018 using 6 model simulations, with different mechanistic variants (**Table 1**). As a reminder, we use the CS2
597 simulation (Archer-Nicholls et al., 2021) as the “base” simulation, to which mechanistic improvements are made. More details
598 can be found in the SI in Section 2.

599 **4.1 Distribution of key sulfur species (DMS, HPMTF, SO_2 and sulfate).**

600 The annual mean global DMS burden was found to be between 63-66 Gg S in all model simulations. DMS concentration
601 follows a seasonal modulation with maximums in the warmer months, which coincide with phytoplankton blooms (**Fig. 7a**).
602 **Figure 7b** and **7c** show the annual mean vertical profiles in the central North Atlantic region and the Southern Ocean (see
603 figure caption for bounding areas). These regions are focused on owing to the differences shown in the mixing ratios of key
604 species and the importance of these two regions to global climate (e.g., Sutton et al., 2018; Caldeira and Duffy 2000). In the
605 Southern Ocean, DMS mixing ratios vary between 100 and >300 ppt. On the other hand, in the North Atlantic region analysed,
606 DMS concentrations rarely reach over 50 ppt. Here, <1 ppt DMS is found above the boundary layer (above 1000 m), while in
607 the Southern Ocean DMS decreases more slowly up-to the tropopause (~ 8000 m). These differences in DMS distribution are

608 a complex function of the local heterogeneity of the DMS source from the ocean and differences in the lifetime of DMS due
 609 to different simulated cloud and oxidising environments (with the North Atlantic generally being a region of greater oxidising
 610 capacity than the Southern Ocean (Archer-Nicholls et al., 2021; Griffiths et al., 2021))
 611

612
 613 **Figure 7:** a) Global distribution of DMS mixing ratios in the lower troposphere (< 2 km) over the oceans in CS2. Annual mean
 614 vertical distribution of DMS in b) the Central North Atlantic (30-50°E, 20-45°N, denoted with the red rectangle in panel a)
 615 and in c) the Southern Ocean (50-70°S, denoted with the red dashed rectangle in panel a). The envelopes represent the
 616 interquartile range of the model simulation results. Note the order of magnitude difference in the DMS concentrations between
 617 the North Atlantic and Southern Ocean.

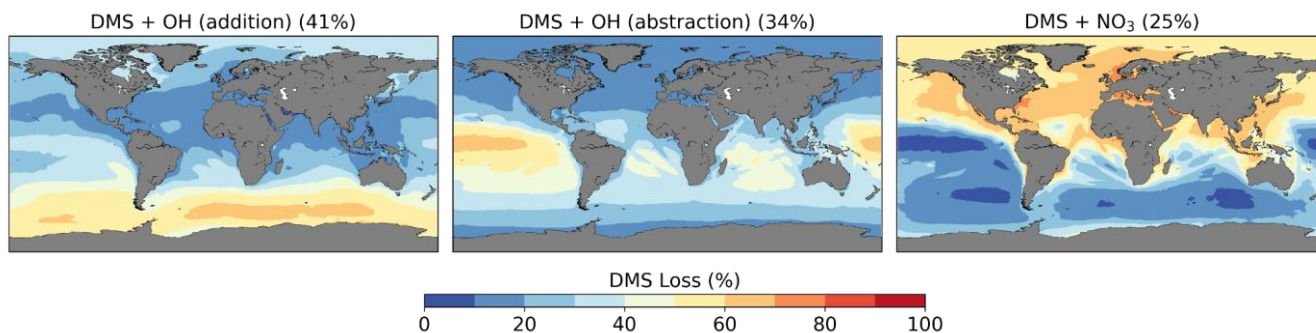

618
 619 There is a significant bias in the simulated DMS mixing ratios compared with observations, which we note has been seen in
 620 several other modelling studies (e.g., Fung et al. (2022)) and is driven not by the DMS chemistry but by the oceanic emissions,
 621 in our case by the bias in the UKESM derived DMS emissions field (Bhatti et al., 2023). See the SI for further details.

622
 623

624 4.1.1 Oxidation of DMS

625 We calculate a global average tropospheric lifetime of 1.5 days for DMS. **Figure 8** shows the global distribution of the different
 626 DMS oxidation pathways in the base run (these results are not affected by the different DMS mechanism variants we use as
 627 these reactions were not updated and there is only a weak feedback of DMS oxidation products on DMS oxidation itself). 75%
 628 of DMS is oxidised by OH (41% via the OH-addition channel and 34% via the H-abstraction channel) and 25% by NO₃.
 629 Oxidation by NO₃ is dominant in the Northern Hemisphere, especially close to the coast and over ship routes. In the Southern
 630 Hemisphere, where DMS emissions are highest, the contribution is less than 20%. The addition pathway of OH oxidation is
 631 favoured at lower temperatures, explaining the trend of higher DMSO formation at high latitudes.

632

633

634 **Figure 8:** Spatial distribution of mean percentage of DMS oxidation via DMS + OH (addition), DMS + OH (abstraction), and
 635 DMS + NO₃ in the CS2 base run. The percentage in brackets denotes the contribution of this channel to the global chemical
 636 loss of DMS. Only values above the ocean are shown.

637

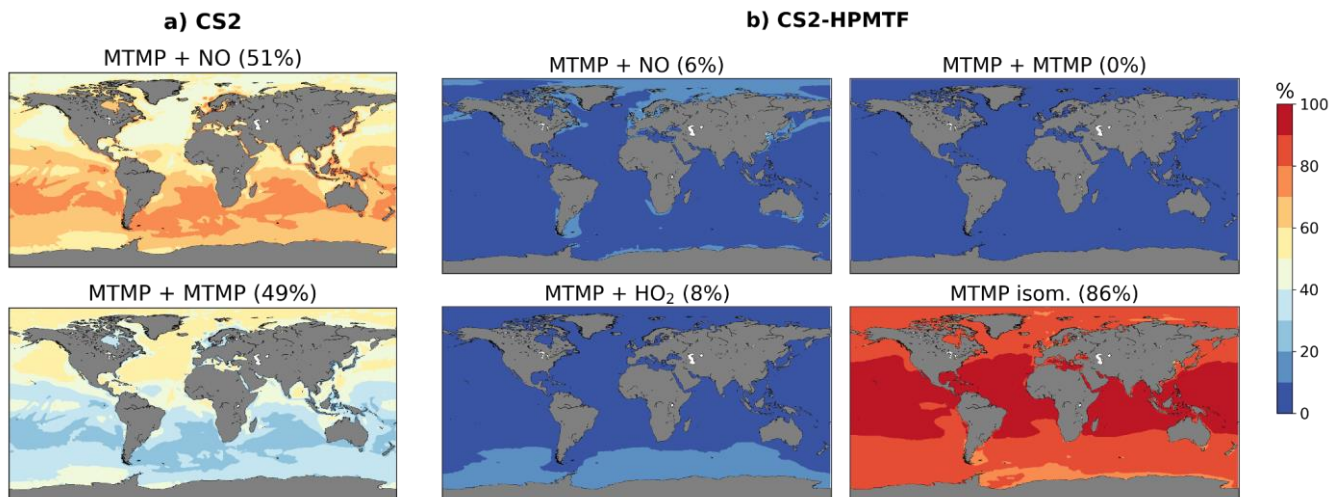

638

639

640 4.2 DMS Oxidation products

641 59% of DMS forms MTMP, the first intermediate of the abstraction pathway. In CS2, MTMP is oxidised by NO (51%) or
 642 reacts with itself (49%) to form CH₃S (**Figure 9a**) which is further oxidised to SO₂, H₂SO₄, and MSA. This is clearly wrong
 643 and a failure of the CS2 scheme. With the updates implemented in CS2-HPMTF, 86% of MTMP isomerizes to HPMTF, while
 644 8% is oxidised by HO₂, and only 6% by NO (**Figure 9b**). The self-reaction becomes negligible with the additional loss
 645 processes of MTMP, significantly lowering MTMP concentrations. The global tropospheric lifetime of MTMP is reduced from
 646 26 min to less than one minute.

647

648

649

650

651

652

653

654

4.2.1 Modelled HPMTF

655

656

657

658

659

660

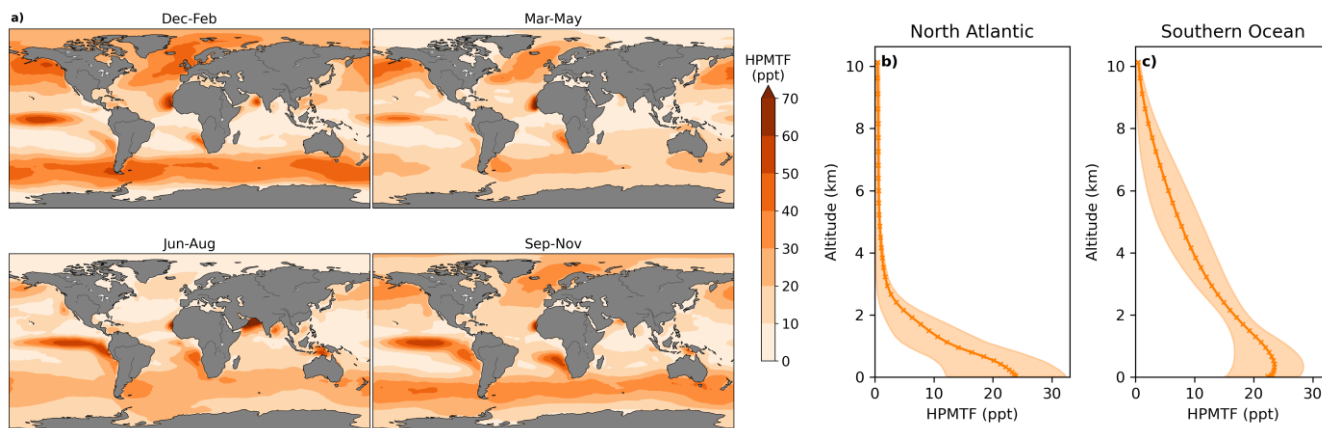

661

662

663

664

In CS2-HPMTF 51% of DMS forms HPMTF. The general patterns of the global distribution of HPMTF are similar to those of DMS in **Figure 10**, except that relatively higher concentrations of DMS are reached in the Southern Ocean. There, temperatures are lower and therefore the OH-abstraction pathway, as well as the strongly temperature-dependent isomerization reaction from MTMP to HPMTF are disfavoured. At the surface, the annual mean HPMTF concentration is similar in the North Atlantic and the Southern Ocean with approximately 20 ppt. However, in the North Atlantic, the variability throughout space and time is greater (bigger interquartile range). Further, the vertical profiles differ visibly: In the North Atlantic HPMTF concentration decreases in the boundary layer and above 2500 m HPMTF concentration is virtually zero (**Figure 10b**). In the Southern Ocean, the concentration decreases more slowly and only reaches zero at 10000 m (**Figure 10c**). The HPMTF burden in CS2-HPMTF is 24 Gg S and HPMTF has a lifetime of 26 hours

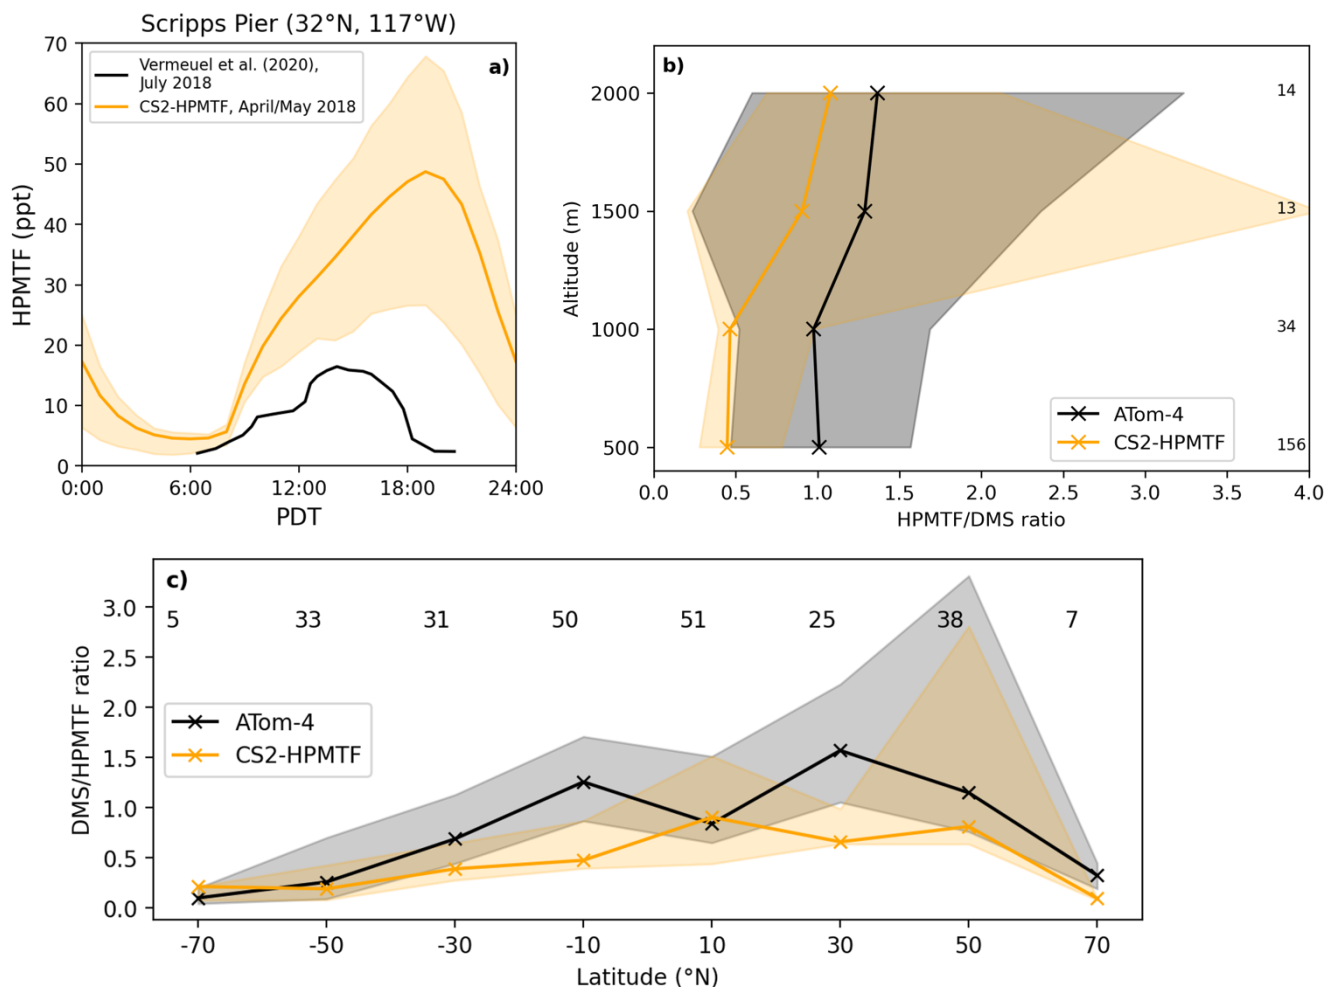

665
 666 **Figure 10:** Seasonal average **a)** Global distribution of HPMTF mixing ratios in the lower troposphere (< 2 km) over the
 667 ocean in CS2-HPMTF. Annual means of the vertical distribution of HPMTF are shown in **b)** the Central North Atlantic (30-
 668 50°E, 20-45°N) and **c)** the Southern Ocean (50-70°S). The envelopes represent the interquartile range of the model data.

670 Comparison of HPMTF with observations

671 Since DMS in the model is likely overestimated, the same would be expected for HPMTF. **Figure 11a** shows that the
 672 implemented loss processes in CS2-HPMTF already lead to a diel profile of HPMTF that is similar to the one measured by
 673 Vermeuel et al. (2020) (where no DMS measurements were made), without the need to add aqueous loss or photolysis. While
 674 DMS at low altitudes was overestimated by a factor of 5 in the model (see SI), the maximum HPMTF is only 3.7 times higher
 675 than the highest measurement in the diel profile at Scripps Pier (**Figure 11a**). For the comparison with ATom-4 data (**Figure**
 676 **11b,c**), the DMS/HPMTF is used to account for the discrepancy between DMS concentrations observed and in the model. The
 677 model generally underestimates the HPMTF/DMS ratio. For instance, up until 1000 m, the ratio in the model is half of the
 678 measured ratio. These results indicate that loss processes of HPMTF might still be too fast in the model or the oxidation of
 679 DMS too slow. The CS2 oxidants have been evaluated before (Archer-Nicholls et al., 2021) and were found to be higher in
 680 the boundary layer than in ST simulations used in CMIP6 studies but well within the spread of other models (Griffiths et al.,
 681 2021; Stevenson et al., 2020).

682

683

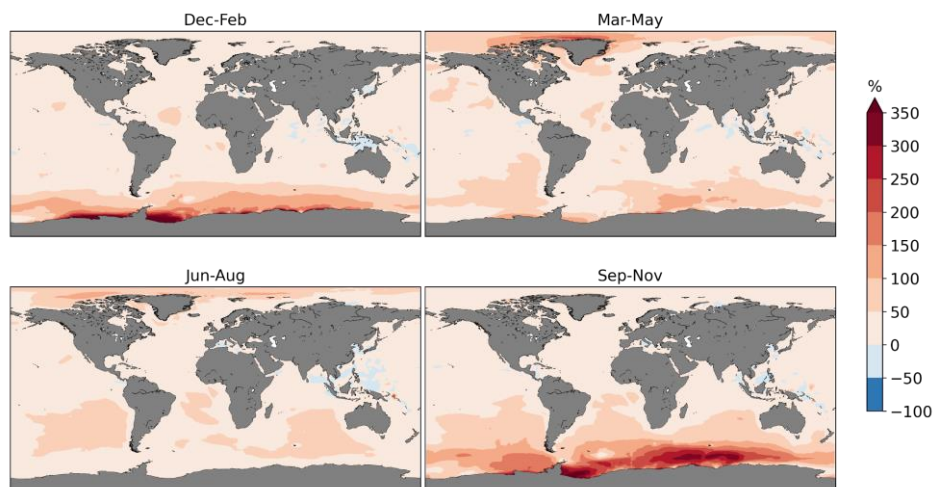

684 **Figure 11:** **a)** Comparison of the diel profile of HPMTF at the Scripps Pier at the California Coast (32°N, 117°W). The
 685 observational data (Vermeuel et al., 2020) is the mean of measurements from July 26 to August 3, 2018, while the model
 686 output is the mean from April/May 2018. **(b)** Vertically binned (500 m) and **(c)** latitudinally binned (20°) median
 687 DMS/HPMTF ratio along the ATom-4 flight path. The envelopes represent the interquartile range of the measurements and
 688 the respective model results while the numbers on the side/on top give the number of measurements in the respective bin.

689

690 4.2.2 Modelled SO₂ and sulfate

691 In CS2-HPMTF the SO₂ burden is increased by 5.6% compared with CS2, to 391 Gg S (**Table 4**). While this percentage seems
 692 low, a significant contribution to the SO₂ burden stems from anthropogenic sources and is mainly located above the land. The
 693 increase of SO₂ over the remote ocean, especially over the Southern Ocean, can reach up to 400% (**Figure 12**). At high

694 latitudes, the new chemistry implemented in CS2-HPMTF also introduces a stronger seasonality to SO₂, whereby SO₂
 695 concentration is higher in respective warmer months than in CS2 (**Figure 12, Figure S10a**). Comparison of CS2-HPMTF with
 696 ST reveals that the SO₂ burden is 9.2% higher in the ST run, which uses a 100% SO₂ yield from DMS (**Figure S8** in the SI).
 697 The global annual tropospheric sulfate burden is increased in CS2-HPMTF by 3.7% compared with CS2, to 604 Gg S.
 698 However, the sulfate burden is 5.3% higher in ST than in CS2-HPMTF (**Table 4**).
 699
 700

701
 702 **Figure 12:** Relative difference in SO₂ mixing ratios in the lower troposphere (< 2 km) between CS2-HPMTF and the base run
 703 CS2 (CS2-HPMTF - CS2). Only values above the ocean are shown.

704
 705
 706

707 **Comparison to observed SO₂ and sulfate**

708 **Figure 13a** shows the monthly means of observed non-sea-salt sulfate (nss-sulfate) concentration at Dumont d'Urville station
 709 (66°S, 140°E) between 1991 and 1995 (Minikin et al., 1998) and compares it to the sulfate concentration in the three different
 710 UKCA model runs. The seasonal changes in sulfate concentrations are reproduced by CS2-HPMTF and ST, but not by CS2.
 711 From April to September all three runs match the observations adequately well. Earlier in the year, the results from the ST run
 712 match the observations best, while later in the year CS2-HPMTF reproduces the measurements better.

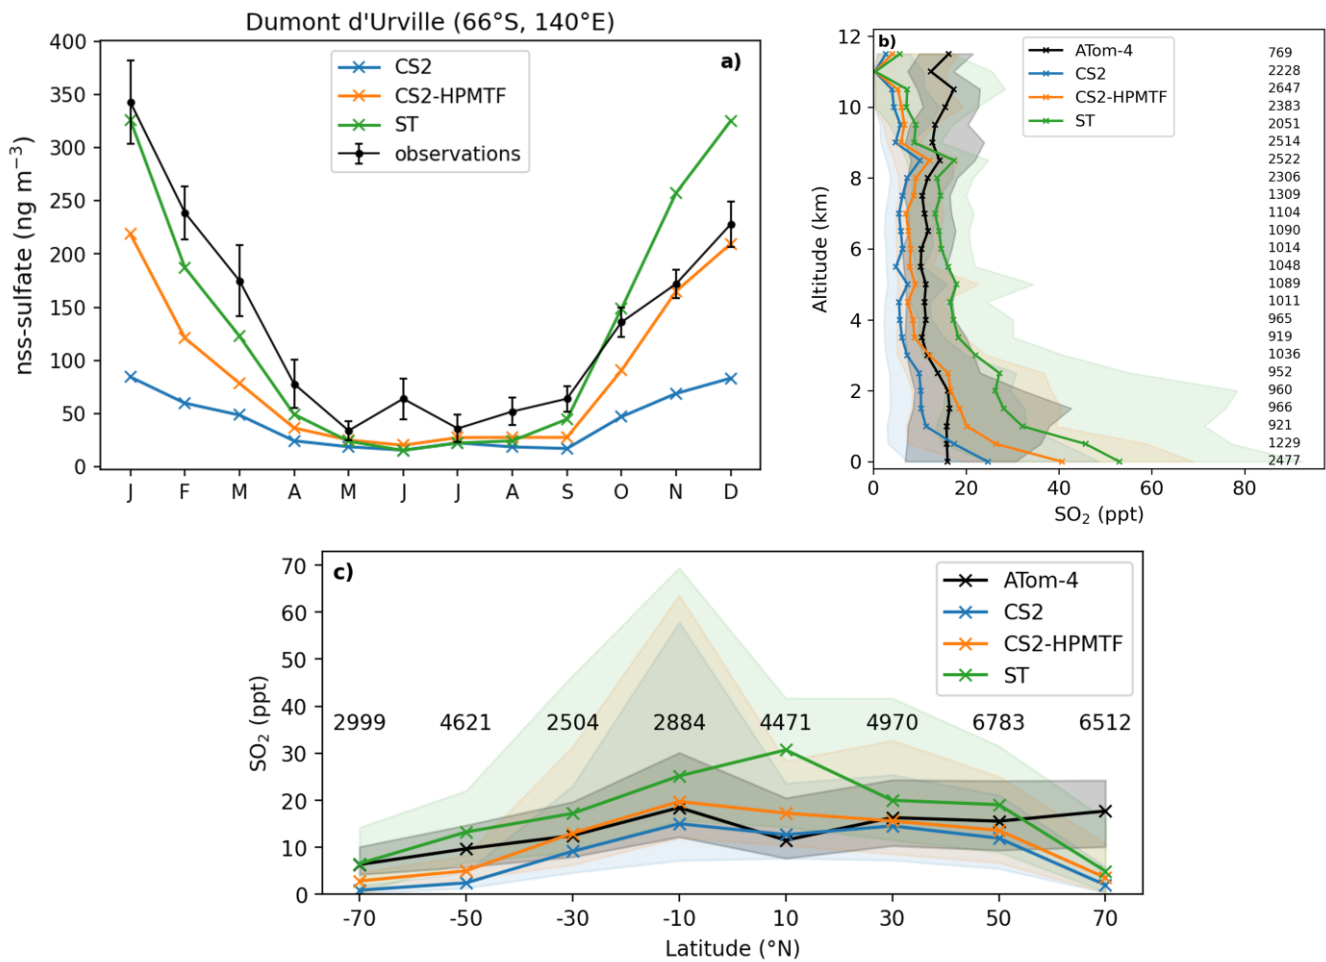

713

714 **Figure 13b,c** show SO₂ measurements along the ATom-4 flight path in comparison with the modelled SO₂ concentrations. In
 715 the boundary layer, all runs over-predict SO₂ in comparison to the ATom-4 data (**Figure 13b**). In addition to wet and dry
 716 deposition (Faloona 2009; Ranjithkumar et al., 2021), vertical mixing has been identified as a major source of uncertainty in
 717 models (Gerbig et al., 2008) and could provide an explanation for the mismatch between the simulation results and

718 observations. At altitudes above 1.8 km, CS2-HPMTF is able to reflect SO₂ concentrations better than the other schemes.
 719 Above 9 km, the simulations underestimate SO₂, potentially indicating issues with convective transport. Overall, in the ATom-
 720 4 observations, SO₂ stays broadly constant with altitude, suggesting significant secondary sources or efficient vertical transport,
 721 while in the simulations it decreases. Additionally, the interquartile ranges of the concentrations in each bin are bigger,
 722 indicating a greater variance of model results than measured values. Overall, the mean SO₂ concentrations by the models in
 723 each latitude bin predict the mean observation values well (**Figure 13c**). However, the variation of values is again greater in
 724 the model, especially at low latitudes. The underestimation of SO₂ at 70°N could be due to an underestimation of the influence
 725 of anthropogenic SO₂ emissions or unrealistic deposition of SO₂ (Hardacre et al., 2021). Alternatively, the SO₂ production
 726 from DMS might be too slow still.

727

728

729

730 **Figure 13: a)** Comparison of nss-sulfate concentration at the Dumont d’Urville Station (66°S, 140°E) at the coast of Antarctica.
 731 The observational data stems from Minikin et al. (1998) and represents the monthly mean concentrations and their standard
 732 deviations for the years 1991-1995. **(b)** Vertically binned (500 m) and **(c)** latitudinally binned (20°) median SO₂ mixing ratio
 733 along the ATom-4 flight path. The envelopes represent the interquartile range of the measurements and the respective model
 734 results while the numbers on the side/on top give the number of measurements in the respective bin.

735
 736

737 4.3 Sensitivity runs

738 To improve our understanding of the variability of the model results, based on the uncertainties of HPMTF formation and loss,
 739 three sensitivity runs were conducted (CS2-HPMTF-CLD, CS2-HPMTF-FL, CS2-HPMTF-FP, **Table 1**). Loss of HPMTF to
 740 clouds was proposed to be a major loss pathway by Veres et al. (2020) and Vermeuel et al. (2020). CS2-HPMTF-CLD adds
 741 cloud and aqueous uptake of HPMTF with a reactive uptake coefficient, γ , of 0.01, used in the study by Novak et al. (2021).
 742 Jernigan et al. (2022) recently established a rate constant for oxidation of HPMTF by OH as $1.4 (0.27-2.4) \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$
 743 through constrained chamber modelling using a rate constant for the formation of HPMTF as 0.1 s^{-1} . Ye et al. (2022) also
 744 measured the rate constant for this reaction. In their study they derived a rate constant of $2.1 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ and an
 745 isomerization rate constant, k_{isom} , of $0.13 \pm 0.03 \text{ s}^{-1}$ at 295 K. Whilst, further laboratory studies would be helpful in constraining
 746 the rate constant for OH + HPMTF, we recommend future work go into constraining the products of this reaction. Vermeuel
 747 et al. (2020) found the theoretically calculated rate constant $1.4 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ by Wu et al. (2015) too slow and
 748 proposed a rate constant of $1.11 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ instead, based on structurally similar molecules and modelling of their
 749 ground-based observations, similar to what we used in CS2-HPMTF. They recommend an upper limit of $5.1 \times 10^{-11} \text{ cm}^3$
 750 $\text{molecule}^{-1} \text{ s}^{-1}$ for the HPMTF+OH rate constant. Khan et al. (2021) and Novak et al. (2021) use $5.5 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ for
 751 sensitivity tests, which was also employed in CS2-HPMTF-FL. Further, the study by Ye et al. (2021) looked at the uncertainty
 752 of the HPMTF isomerization rate. They estimate the isomerization rate constant as 0.09 s^{-1} ($0.03-0.3 \text{ s}^{-1}$, $1\sigma_g$ geometric standard
 753 deviation at 293 K). Veres et al. (2020) are on the lower end of this range (0.041 s^{-1}) and Berndt et al. (2019) at the higher end
 754 (0.23 s^{-1}). The CS2-HPMTF-FP simulation scales the rate constant of Veres et al. (2020) by a factor of 5 to match Berndt’s
 755 measurements at 295 K to examine the effects of higher HPMTF production. This rate constant was also used by Wollesen de
 756 Jonge et al. (2021) in their study. The annual mean of global tropospheric burdens of relevant species in these sensitivity runs
 757 are compared in **Table 4**.

758

759 **Table 4:** Global annual mean tropospheric burdens of atmospheric sulfur species in UKCA base and sensitivity runs (first half
 760 of the table) and comparison to literature values (second half of the table, same acronyms as in Section 3)

Run	HPMTF burden (Gg S)	SO ₂ burden (Gg S)	Sulfate burden (Gg S)

762 4.3.1 HPMTF

763 The HPMTF burden varies between 2.6 and 26.5 Gg S among the sensitivity runs (**Table 4**). Compared to CS2-HPMTF, faster
764 OH oxidation reduces the HPMTF burden by -62% to 8.9 Gg S, while the addition of cloud and aqueous uptake to the scheme
765 reduces it by -91% to only 2.6 Gg S. Yet, a factor of 5 higher production rate constant of HPMTF only leads to a 12% increase
766 of HPMTF burden to 26.5 Gg S; suggesting that the steady-state distribution of HPMTF is controlled by the loss rate, not the
767 rate of production of HPMTF. With the isomerization rate constant recommended by Veres et al. (2020), 51% of DMS forms
768 HPMTF (86% of MTMP); with the faster rate in CS2-HPMTF-FP it is 57% (96% of MTMP). Since the use of the isomerization
769 rate from Veres et al. (2020) already outcompetes the bimolecular reactions of MTMP, scaling the A-factor does not have a
770 significant effect on the HPMTF yield from DMS. Overall, it can be estimated that globally 50-60% of DMS forms HPMTF
771 (however, if more DMS is oxidised through the addition channel by BrO or multiphase reactions, this ratio could be lower).
772 Consequently, HPMTF formation seems to be well constrained and the major uncertainties lie with the loss of HPMTF, which
773 warrant additional measurements.

774
775 Similar to **Figure 11**, the HPMTF:DMS ratio is used in **Figure 14** to compare the results of the sensitivity model runs with
776 ATom-4 observations. In general, schemes with a higher production and slower loss of HPMTF match the observations better,
777 however, they still underestimate the measured ratios. A comparison was made to HPMTF:DMS ratios measured with no
778 clouds present. Under these clear-sky conditions, when cloud uptake of HPMTF should not play a role in the measurements,
779 observed ratios were even higher, leading to a greater difference between model results (which include clouds) and
780 observations.

781

782

783 **Figure 14:** Vertically binned (500 m) median HPMTF/DMS ratio along the ATom-4 flight path for **a)** full sky and **b)** clear
 784 sky, where measurements made in clouds are omitted. The envelopes represent the interquartile range of the measurements
 785 and the respective model results, while values on the side give the number of measurements in the respective bin. Note that
 786 the model data is the same in both panels.

787

788 4.3.2 SO₂

789 The SO₂ burden varies between 367.3 Gg S in CS2-HPMTF-CLD and 392.6 GgS in CS2-HPMTF-FL, suggesting that the SO₂
 790 burden is relatively unaffected by the chemical sensitivities explored when compared with the much larger SO₂ burden simulated
 791 with ST (469.7 Gg S); mainly due to the 100% DMS-SO₂ yield (**Table 4**).

792

793 CS2-HPMTF, CS2-HPMTF-FL, and CS2-HPMTF-FP have a higher SO₂ burden than CS2 since the changes to the abstraction
 794 pathway (reaction 6a, 7c) and the addition of the isomerization pathway lead to more direct SO₂ production. Faster OH
 795 oxidation of HPMTF in CS2-HPMTF-FL reduces the amount of HPMTF deposited and therefore increases the SO₂ burden
 796 slightly (by 0.5%) compared to CS2-HPMTF. The faster production of HPMTF in CS2-HPMTF-FP reduces SO₂ burden
 797 marginally (-0.3%), due to more sulfur now being deposited as HPMTF or forming OCS. The addition of cloud and
 798 heterogeneous loss in CS2-HPMTF-CLD leads to immediate sulfate production instead of SO₂ formation, reducing the SO₂
 799 burden by -6% compared to CS2-HPMTF, resulting in the lowest SO₂ burden in all runs considered.

800

801 4.4.3 Sulfate

802 In the sensitivity runs, the sulfate burdens are all higher than in the CS2 run (582.3 Gg S) and lower than in the ST run (635.9
 803 Gg S). The variation by approximately 15 Gg S, from 591.2 Gg S in CS2-HPMTF-CLD to 605.6 Gg S in CS2-HPMTF-FL, is

804 smaller than the variation in sulfate burden simulated by similar mechanistic sensitivity tests by Novak et al. (2021) (~24 Gg),
805 suggesting some structural dependence on the results of the sensitivity tests (e.g., resolution, other model parameters). The
806 sulfate burdens in CS2-HPMTF-FL and CS2-HPMTF-FP behave similarly to CS2-HPMTF. Since CS2-HPMTF-CLD added
807 direct sulfate formation, a higher sulfate burden was expected. However, this was not seen in the experiments. Inspection of
808 the sulfate aerosol distribution shows that CS2-HPMTF-CLD leads to an increase in the coarse mode sulfate and a concomitant
809 reduction in sulfate aerosol lifetime (through an increase in wet deposition).

810

811

812 **5 Discussion**

813 The results described above demonstrate the global scale changes in the distribution of DMS and its oxidation products, through
814 the incorporation of improved mechanistic updates into the UKCA model. Here we discuss our results in the context of the
815 existing literature.

816 **5.1 DMS**

817 The DMS burden of 63-66 Gg S in this work is in good agreement with recent modelling studies (50 Gg S in Fung et al. (2022),
818 74 Gg S in Chen et al. (2018)). However, as shown in the supplement, S2.1.1, the modelled DMS concentrations do not match
819 observational measurements. One explanation could be underestimation of DMS oxidation. Here, only oxidation by OH and
820 NO₃ is included. However, Fung et al. (2022), who include oxidation by BrO, O₃ and Cl (accounting in total for 20% of DMS
821 depletion), also found that their model over-predicted DMS mixing ratios compared to the ATom-4 measurements. Inadequate
822 representation of DMS concentrations in seawater and therefore emissions contribute to the largest uncertainties in the sulfur
823 budget (Tesdal et al., 2016; Bock et al., 2021) and could explain most of the difference. Additionally, physical differences
824 between model and observation, such as wind speed and temperature, and a poor space resolution of Whole Air Sampling
825 might also play a role. Crucially, more long-term observations of DMS in the atmosphere are needed to complement works
826 that have collated oceanic DMS observations (e.g., Lana et al., 2011).

827

828 Here, in all model runs 75% of DMS is oxidised by OH and 25% by NO₃. Other studies found global contributions of OH
829 between 50-70% and NO₃ 15-30% (Boucher et al., 2003; Berglen et al., 2004; Breider et al., 2010; Khan et al., 2016; Chen et
830 al., 2018; Fung et al., 2022). The lower contribution of OH oxidation to DMS removal is explained by the addition of other
831 pathways, such as oxidation by BrO, Cl and multiphase reactions. Consequently, the lifetime of 1.5 days for DMS in this work
832 is longer than some other studies including these reactions (e.g., 0.8 days in Fung et al. (2022) and 1.2 days in Chen et al.
833 (2018)). Nonetheless, it is well within the range of 0.9 to 5 days (with a mean of 2 days) of the models examined in Faloon
834 (2009).

835

836

837 **5.2 HPMTF**

838 In CS₂-HPMTF 51% of DMS forms HPMTF. With a faster formation of HPMTF, found in laboratory experiments, this yield
839 increases to 57% in our model. The yield could possibly be lower if other oxidation reactions of DMS are included that follow
840 the OH addition pathway (multiphase reactions, oxidation by BrO), which was omitted in this work. Veres et al. (2020), Novak
841 et al. (2021) and Fung et al. (2022) estimated that at least 30-46% of DMS was forming HPMTF, based on observationally
842 constrained modelling of *in situ* or laboratory data. Even though the rate of HPMTF formation is uncertain (Ye et al., 2021),
843 it does not significantly affect the HPMTF yield from DMS, since it already outcompetes most other reactions of MTMP. For
844 HPMTF formation, uncertainty seems to lie mainly at the branching ratio of the addition and the abstraction pathway of DMS.
845 Indeed, the uncertainty in the HPMTF burden stems from the uncertainty in the loss pathways and their respective contribution
846 to HPMTF loss. Our model results agree well with the HPMTF burdens obtained by other global modelling studies, both in
847 absolute values but also the relative changes we find in the sensitivity study (**Table 4**) (e.g., Fung et al. (2022)): In our
848 sensitivity study a faster oxidation of HPMTF to OH lead to a decrease of 62% of the HPMTF burden, in Khan et al. (2021) it
849 was 60%. In this work the addition of aqueous uptake of HPMTF reduced the burden by 91%, very similar to the reduction
850 simulated in Novak et al. (2021) (96%).

851

852 **5.3 MSA**

853 The tropospheric MSA burden is 40 Gg S in CS₂-HPMTF with a lifetime of 6 days. This falls within the range of 13-40 Gg S
854 and a lifetime of 5-7 days found in previous model studies (Pham et al., 1995; Chin et al., 1996, 2000; Cosme et al., 2002;
855 Hezel et al., 2011). However, newer studies include more multiphase processes and usually tend to have shorter lifetimes and
856 lower MSA burdens. Both the scheme in Fung et al. (2022) and Chen et al. (2018), include the loss of MSA to aqueous OH
857 oxidation, resulting in lifetimes of 0.6 days and 2.2 days and a burden of 8 Gg S and 20 Gg S, respectively.

858 **5.4 SO₂ and Sulfate**

859 Comparing SO₂ and sulfate burdens with other modelling studies is more challenging, since those species can have other
860 sources apart from DMS. That said, our SO₂ obtained in the various runs based on the CS₂ scheme are comparable to Fung et
861 al. (2022), while the ST burden is significantly higher. However, the SO₂ burden from Novak et al. (2021) is much lower. This
862 difference cannot be explained solely by differences in the DMS oxidation mechanism; more likely, the difference is in
863 anthropogenic SO₂ emissions.

864 The sulfate burden in all our runs fall within the range found in other recent modelling studies (Chen et al. 2018; Novak et al.,
865 2021; Fung et al., 2022). Considering the relative change due to the addition of the isomerization pathway, the increase in
866 sulfate burden from CS₂ to CS₂-HPMTF is only 3.7% in our study, Fung et al. (2022) found an increase of 8.8%, when they

867 added HPMTF chemistry. However, unlike their results, we find strong seasonality in the additional sulfate produced,
868 especially in the Southern Hemisphere. The addition of cloud uptake and direct sulfate formation in CS2-HPMTF-CLD
869 decreased the sulfate burden in our study by (-)2.2%, in Novak et al. (2021) this change in mechanism lead to an increase of
870 sulfate by 4.5%.

871

872 **5.5 Comparison with BOXMOX results.**

873 In Section 3 and Section 4 we have shown the results of BOXMOX and UKCA simulations using different DMS mechanistic
874 variants respectively. Whilst the same mechanistic variants have been assessed in both model setups, it is not possible to
875 directly compare the results of the two sets of experiments because of the large differences in the model setups used. However,
876 some qualitative comparisons can be made. For MSA, Section 3.1 (Figure 2) suggests that the MSA simulated with CS2-
877 HPMTF should be much lower than CS2; as is calculated in Section 4.2.2 (a 70% reduction). For SO₂, both the BOXMOX
878 and UKCA results agree in the ordering of simulations, ST, CS2 and CS2-HPMTF; with ST simulating significantly more SO₂
879 than the other mechanisms. However, whereas BOXMOX simulations suggest that H₂SO₄ is predicted to be higher in CS2 and
880 CS2-HPMTF than ST, the UKCA model runs suggest that ST has the greatest burden of sulfate; highlighting the complexity
881 of making inference on aerosols from gas phase precursors in box model studies.

882

883 **6 Conclusion**

884 DMS remains an important molecule in our understanding of the background aerosol budget and the uncertainty of aerosols
885 to climate change (Carslaw et al., 2013). In this study we have used a combination of box modelling experiments and global
886 3D model experiments to explore the sensitivities of the DMS oxidation mechanism in the UKCA model. This work has
887 delivered a new DMS oxidation mechanism for use within the CRI-Strat framework of UKCA (Archer-Nicholls et al., 2021;
888 Weber et al., 2021), which is a significant advancement and improvement over the mechanism used in CMIP6 studies
889 (Archibald et al., 2020). Our new DMS mechanism includes many of the recently discovered and proposed oxidation pathways
890 for DMS and through the series of experiments we have performed, we have been able to benchmark this scheme against other
891 recently reported schemes in the literature. Whilst future studies building on the ever expanding database of laboratory studies
892 (e.g., Ye et al., 2021; Jernigan et al., 2022) are required to refine the DMS oxidation mechanism further, with the current
893 availability of observational data, it is not possible to fully constrain the uncertain parameters in the DMS oxidation
894 mechanism. Hence there is a priority for more observational based studies that combine ship, ground-based and aircraft
895 platforms optimally. Fung et al. (2021) have shown that there are consequences for radiative forcing by updating the DMS
896 mechanism in the CESM model, and follow up work will investigate these changes with UKCA.

897

898 This study adds to the few other mechanism intercomparisons that exist in the literature, spanning back more than 25 years
899 (Capaldo and Pandis 1997; Karl et al., 2007). Similar to these other studies we find that MSA is particularly uncertain when it
900 comes to the results obtained using the range of mechanisms that we investigated. Further work should explicitly focus on
901 reducing uncertainty in the MSA budget in the atmosphere, especially given its potential importance in reconstructing paleo-
902 sea ice (Thomas et al., 2019).

903
904 In many ways, the recent advances in DMS oxidation chemistry are similar to isoprene chemistry, where over a decade ago
905 the discovery of uni-molecular isomerisation reactions resulted in a step-change in our understanding of isoprene. As with
906 isoprene, ever more complex and faithful descriptions of DMS chemistry will be delivered over the coming years. But the
907 biggest challenge (as for isoprene) will remain in reducing and accurately distilling down this complex chemistry for use in
908 global model studies, and in characterising the sources of DMS into the atmosphere (which for isoprene have only recently
909 been possibly directly e.g., Wells et al., 2020).
