12 **Abstract**

13 Brown carbon (BrC) represents an important target for the “win-win” strategy of mitigating climate
14 change and improving air quality. However, estimating co-benefits of BrC control remains difficult
15 for China, partially because current measurement results are insufficient to represent the highly
16 variable emission sources and meteorological conditions across different regions. In this study, we
17 investigated, for the first time, the diurnal variations of BrC during two distinct seasons in a
18 megacity in Northeast China. The winter campaign conducted in January of 2021 was characterized
19 by low temperatures rarely seen in other Chinese megacities (down to about $-20\text{ }^{\circ}\text{C}$). The mass
20 absorption efficiencies of BrC at 365 nm (MAE_{365}) were found to be $\sim 10\%$ higher at night. The
21 variations of MAE_{365} could not be explained by the influence of residential biomass burning
22 emissions or secondary aerosol formation, but were strongly associated with the changes of a
23 diagnostic ratio for the relative importance of coal combustion and vehicle emissions ($R_{S/N}$). Given
24 that most coal combustion activities were uninterrupted, the higher nighttime MAE_{365} in winter
25 were attributed primarily to increased emissions from heavy-duty diesel trucks. The spring

26 campaign conducted in April of 2021 was characterized by frequent occurrences of agricultural fires,
27 as supported by the intensive fire hotspots detected around Harbin and the more-than-doubled
28 levoglucosan to organic carbon ratios (LG/OC) compared to winter campaign. In spring, MAE₃₆₅
29 depended little on $R_{S/N}$ but exhibited a strong positive correlation with LG/OC, suggesting open
30 burning emissions as the dominant influencing factor for BrC's light absorption capacity. MAE₃₆₅
31 were ~70% higher at night for the spring campaign, pointing to the prevalence of nighttime
32 agricultural fires, which were presumably in response to local bans on open burning. It is noteworthy
33 that the agricultural fire emissions resulted in distinct peak at ~365 nm for the light absorption
34 spectra of BrC, and a candidates for the compounds at play was were inferred to be aromatic species
35 with nitro-functional groups $C_7H_7NO_4$. ~~Due to the presence of the ~365 nm peak, the absorption~~
36 ~~Ångström exponents could not be properly determined for the agricultural fire impacted samples.~~
37 The presence of the ~365 nm peak complicated the determination of absorption Ångström exponents
38 for the agricultural fire-impacted samples. In addition, the ~365 nm peak became much less
39 significant during the day, likely due to photo-bleaching of the relevant chromophores.

40 **1. Introduction**

41 Light-absorbing organic carbon, i.e., brown carbon (BrC), exerts important yet poorly
42 understood effects on climate and the environment (Brown et al., 2018; Zeng et al., 2020; Sand et
43 al., 2021). As a mixture of numerous organic compounds from both primary emissions and
44 secondary formation, BrC exhibits extreme complexity in spectroscopy, composition and evolution
45 (Laskin et al., 2015; Brege et al., 2021; Washenfelder et al., 2022). Measurement techniques for BrC
46 absorption mainly fell into two categories, including solvent extraction followed by light absorption
47 spectrum measurement (Chen and Bond, 2010; Hecobian et al., 2010) and apportionment of total
48 aerosol absorption to the contributions from black carbon and BrC (Yang et al., 2009; Lack et al.,
49 2012). So far, consistency between BrC results from these two types of approaches has not been
50 addressed, with variable relationships, either linear or non-linear, and unclear influencing factors
51 (Kumar et al., 2018; Zeng et al., 2022). This inconsistency introduced substantial difficulties to the
52 integration of BrC measurement results across studies and regions (Wang et al., 2022), which is
53 essential for unfolding the links between BrC sources and optical properties. In addition, efforts
54 were also made to explain BrC absorption on a molecular level. Several techniques were shown to
55 be powerful, such as electrospray ionization Fourier transform ion cyclotron resonance mass
56 spectrometry (ESI FT-ICR MS; Wozniak et al., 2008; Jiang et al., 2021; Zeng et al., 2021), high
57 performance liquid chromatography coupled with high resolution mass spectrometry
58 (HPLC/HRMS; Lin et al., 2018; Huang et al., 2022; Xu et al., 2022), and two-dimensional gas
59 chromatography with time of flight mass spectrometer (GC×GC-ToF-MS; Huo et al., 2021). These
60 techniques were more frequently applied to laboratory-generated primary or secondary BrC (e.g.,
61 Lin et al., 2015), which usually had less complex composition than ambient BrC and thus showed

62 relatively high fraction of resolvable chromophores, e.g., up to ~85% for those emitted by biomass
63 burning (Huang et al., 2022).

64 The absorbing nature of BrC makes it a non-negligible contributor to positive radiative forcing
65 (Saleh, 2020), while the considerable contribution of organic aerosol to fine particulate matter
66 (PM_{2.5}) makes BrC an important source of air pollution (Wang et al., 2019). Consequently, BrC
67 represents a key species for the “win-win” strategy of mitigating climate change and improving air
68 quality. Given the highly variable emission sources and meteorological conditions across different
69 regions in China, field observational results on BrC are far from being enough to constrain air
70 quality and climate models, limiting the ability to evaluate the co-benefits of BrC control. In this
71 study, we focused on a largely unexplored city cluster, the Harbin-Changchun (HC) metropolitan
72 area in Northeast China. Compared to other regions with intensive studies of BrC as well as other
73 air pollutants (e.g., the North China Plain), HC was characterized by extremely cold winter and
74 strong impacts of biomass burning on top of other anthropogenic emissions (e.g., from coal
75 combustion). The first feature was related to the relatively high latitudes of HC. For example, as the
76 northernmost megacity in China, Harbin has an average temperature of about -20°C in January,
77 significantly lower than that of Beijing (~0 °C). The second feature was related to the massive
78 agricultural sector in HC. Until recently, open burning was still an irreplaceable approach for the
79 disposal of crop residues in this region, presumably because the amount of agricultural wastes was
80 too huge for the capacity of sustainable use. The agricultural fires frequently resulted in heavily-
81 polluted episodes with high PM_{2.5} concentrations rarely encountered in other Chinese megacities
82 (e.g., hourly-average of ~1000 µg/m³ in Harbin; Li et al., 2019). These two features highlighted the
83 uniqueness of HC for haze studies in China.

84 This measurement report, for the first time, presented field observational results on the diurnal
85 variations of BrC during two distinct seasons, i.e., a frigid winter and an agricultural fire-impacted
86 spring, in the central city of HC. Drivers for the diurnal variations were discussed based on
87 indicators of various sources. Particularly, the agricultural fires were found to result in unique
88 absorption spectra of brown carbon. This study provided implications for parameterization of BrC
89 in climate models.

90 **2. Methods**

91 **2.1 Field sampling**

92 Daytime and nighttime PM_{2.5} samples were collected on the campus of Harbin Institute of
93 Technology (HIT) during winter and spring of 2021. HIT was surrounded by residential and
94 commercial areas, without major industrial sources nearby, and thus represented a typical urban site.
95 The sampling was done by a mass flow controlled high-volume sampler (TE-6070BLX-2.5-HVS;
96 Tisch Environmental, Inc., OH, USA), which was operated at a flow rate of 1.13 m³/min using pre-
97 baked quartz-fiber filters (8" × 10", 2500 QAT-UP; Pall Corporation, NY, USA). **To avoid rush hours**
98 **and considering the relatively early sunset time in winter (~16:00–17:00), ~~Daytime~~ daytime** and
99 nighttime samples were collected from 9:00 to 16:00 and from 21:00 to 5:00 of the next day,
100 respectively. The winter campaign covered the entire January of 2021, and the spring campaign was
101 conducted during 10–30 April, 2021.

102 **2.2 Laboratory analysis**

103 Two punches with diameters of 20 mm were taken from each sample, combined and then
104 extracted by deionized water. The water extract was analyzed using a Dionex ion chromatography
105 system (ICS-5000⁺; Thermo Fisher Scientific Inc., MA, USA). Levoglucosan, an organic tracer for

106 biomass burning, was determined by the high-performance anion-exchange chromatography
107 coupled to pulsed amperometric detection (HPAEC-PAD) method (Engling et al., 2006; Yttri et al.,
108 2015). Inorganic ions such as nitrate, sulfate, chloride, ammonium and potassium were also
109 measured. Linear regression of the total cation concentration on that of total anion (both in $\mu\text{eq}/\text{m}^3$)
110 led to a slope of 1.14 ± 0.01 (intercept was set as zero; $r = 0.99$), indicating a neutralized feature of
111 the Harbin aerosols.

112 Two punches with diameters of 47 mm were taken from each sample and used to determine
113 carbon fractions. Following the method developed by Chen and Bond (2010) and refined by Cheng
114 et al. (2016), one punch was directly measured for organic carbon and elemental carbon, while the
115 other punch was immersed in methanol (HPLC grade; Fisher Scientific Company L.L.C., NJ, USA)
116 for an hour without stirring or sonication, dried in air for another hour, and then analyzed. Both
117 punches were measured by a Thermal/Optical Carbon Analyzer (DRI-2001; Atmoslytic Inc., CA,
118 USA), which was operated with two commonly-used temperature protocols (i.e., IMPROVE-A and
119 NIOSH) and transmittance charring correction. The difference of total carbon (TC) concentrations
120 between the untreated and extracted punches ($\text{TC}_{\text{untreated}} - \text{TC}_{\text{extracted}}$) was used to represent the
121 amount of organic carbon that is soluble in methanol (MSOC), following the method developed by
122 ~~Chen and Bond (2010) and refined by Cheng et al. (2016)~~. Given that the TC measurement was
123 independent of the temperature protocol used, both $\text{TC}_{\text{untreated}}$ and $\text{TC}_{\text{extracted}}$ were determined as the
124 averages of total carbon results from IMPROVE-A and NIOSH. A benefit of this approach was that
125 the uncertainty of MSOC (σ) could be estimated for each sample based on the parallel TC
126 measurements by different protocols:

$$127 \quad \sigma = \sqrt{(\text{SD of } \text{TC}_{\text{untreated}})^2 + (\text{SD of } \text{TC}_{\text{extracted}})^2} / (\text{TC}_{\text{untreated}} - \text{TC}_{\text{extracted}})$$

128 where SD indicates standard deviation. In this study, σ averaged $3.3 \pm 2.9\%$ with a median of 2.4%.
129 In addition, organic compounds that are in-soluble in methanol, i.e., MIOC, was measured as the
130 organic carbon concentration of the extracted punch. Unless stated otherwise, (i) OC involved in
131 the following discussions indicates the sum of MSOC and MIOC, and correspondingly, EC indicates
132 elemental carbon measured by the extracted punch; and (ii) all the carbonaceous aerosol
133 concentrations are based on IMPROVE-A, except MSOC which did not rely on analytical protocol.
134 The MSOC to OC ratios averaged 0.90 ± 0.05 , indicating an overall high extraction efficiency of
135 methanol for dissolving organic aerosols.

136 Light absorption spectra of the methanol extracts were measured over the wavelength (λ) range
137 of 200–1110 nm, using a spectrophotometer coupled with a 2.5-m long liquid waveguide capillary
138 cell (LWCC; World Precision Instrument, FL, USA). The spectrophotometer, consisting of a DH-
139 mini UV-VIS-NIR light source and a Maya2000 Pro spectrometer (Ocean Optics Inc., FL, USA),
140 provided wavelength-resolved optical attenuation (ATN_λ) of the dissolved BrC, which could then
141 be converted to BrC absorption coefficient [$(b_{\text{abs}})_\lambda$] (Hecobian et al., 2010). The ratio of $(b_{\text{abs}})_\lambda$ to
142 MSOC concentration was considered the bulk mass absorption efficiency (MAE_λ) of brown carbon,
143 given the close-to-one MSOC/OC. The wavelength dependence of BrC absorption was determined
144 based on $\ln(ATN_\lambda)$ and $\ln(\lambda)$, and was expressed as the absorption Ångström exponent (AAE). The
145 AAE calculation was performed over 310–460 nm, the same λ range adopted by previous studies
146 conducted at the same site using the same laboratory analysis procedures (Cheng et al., 2022a).

147 **2.3 Additional data sets used**

148 Air quality data and meteorological data were obtained with a time resolution of 1 hour from
149 the China National Environmental Monitoring Center (CNEMC; <https://air.cnemc.cn:18007/>, last

150 access: 1 January, 2023) and Weather Underground (<https://www.wunderground.com/>, last access:
151 1 January, 2023), respectively. CNEMC operated 12 monitoring sites in Harbin, with 3 of them
152 located within ~5 km from the HIT sampling site. The reconstructed PM_{2.5} masses, which were
153 derived from observational results on aerosol compositions at HIT, were generally in line with the
154 fine particle concentrations directly measured at the nearby CNEMC sites. Here the reconstructed
155 PM_{2.5} was calculated as the sum of organic matter ($1.6 \times \text{OC}$), elemental carbon and inorganic ions.
156 Comparison of the reconstructed and directly-measured PM_{2.5} concentrations showed relative
157 standard deviations of 9–11% (in terms of median value) for the three CNEMC sites nearby,
158 demonstrating HIT as a representative urban site for Harbin. In this study, only the air quality data
159 from the nearest CNEMC site, i.e., Taiping Hongwei Park, were further investigated together with
160 the aerosol components measured at HIT.

161 **3. Results and discussion**

162 **3.1 Why was the wintertime brown carbon more absorbing at night?**

163 The wavelength-resolved b_{abs} and MAE were primarily explored at 365 nm, and the
164 corresponding values were referred to as $(b_{\text{abs}})_{365}$ and MAE₃₆₅, respectively. $(b_{\text{abs}})_{365}$ and MSOC
165 correlated strongly for the winter campaign (Figure 1a), that the linear regression of $(b_{\text{abs}})_{365}$ against
166 MSOC led to an r value of 0.97 and a slope of $1.63 \pm 0.02 \text{ m}^2/\text{gC}$ (with the intercept set as zero;
167 MAE₃₆₅ averaged $1.55 \pm 0.18 \text{ m}^2/\text{gC}$). However, as shown in Figure 1b, the nighttime samples were
168 found to exhibit slightly higher MAE₃₆₅ values (averaging $1.61 \pm 0.15 \text{ m}^2/\text{gC}$) than the daytime ones
169 (averaging $1.48 \pm 0.18 \text{ m}^2/\text{gC}$), with significant differences at the 95% confidence level (2-tailed p
170 = 0.004). with averages of 1.61 ± 0.15 and $1.48 \pm 0.18 \text{ m}^2/\text{gC}$, respectively (Figure 1b). In this study,
171 we did not perform source apportionment analysis for brown carbon due to the relatively small

172 number of samples collected. Instead, several indirect indicators were introduced to interpret the
173 diurnal variations of MAE₃₆₅. [Statistical results for the comparisons performed in the following](#)
174 [discussions are summarized in Table S1.](#)

175 The first indicator was the levoglucosan to OC ratio (LG/OC; on a basis of carbon mass, the
176 same hereinafter). In general, higher LG/OC values indicate a stronger contribution of biomass
177 burning (BB) emissions to OC. The BB activities in January could be attributed primarily to
178 household use of biofuels, e.g., for heating and cooking. This is because (i) few fire hotspot was
179 detected in Harbin and surrounding regions throughout the winter campaign (Figure 2a), and (ii) the
180 relationship between LG and water-soluble potassium (K⁺), another commonly-used BB tracer, did
181 not show evidence for apparent influence of open burning (Figure 3a). As suggested by previous
182 studies conducted during heating season in Harbin (Cheng et al., 2022b), the LG to K⁺ ratios were
183 relatively low and constant (~0.5) with the absence of agricultural fires, but became substantially
184 higher (typically above 1.0) during open burning episodes. This pattern was attributed to the
185 relatively low combustion efficiencies (CE) of agricultural fires, which favored the increase of LG
186 emissions but would not change K⁺ emissions significantly (Gao et al., 2003). It should be noted
187 that in Cheng et al. (2022b), CE were not directly measured for different types of burning activities
188 and instead were investigated based on the ratios of BB organic carbon to BB elemental carbon (R_{BB} ,
189 derived from positive matrix factorization, i.e., PMF, analysis). Substantial increases of R_{BB} were
190 repeatedly observed during open burning episodes occurring in different seasons, e.g., winter or
191 spring depending on the regulatory policies. Thus the agricultural fires were inferred to have
192 relatively low CE levels [compared to residential burning of crop residues](#) (Cheng et al., 2022b), as
193 BB source emission studies typically showed a decreasing trend for the emission ratio of organic

194 carbon to elemental carbon with increasing combustion efficiency (Pokhrel et al., 2016; McClure et
195 al., 2020). Actually, crop residues burned on farmland were usually not intentionally dried and thus
196 could have relatively high water contents. This may partially explain the relatively low CE of
197 agricultural fires. In the present study, LG correlated strongly with K^+ for the entire January ($r =$
198 0.96 , with a slope, i.e., $\Delta LG/\Delta K^+$, of 0.55 ± 0.02 ; Figure 3a) and the LG to K^+ ratios averaged 0.46
199 ± 0.11 , pointing to the dominance of residential burning in BB emissions. In addition, the residential
200 burning activities were more intensive at night, as can be seen from the elevated LG/OC compared
201 to daytime results ($1.10 \pm 0.26\%$ vs. $0.88 \pm 0.22\%$, 2-tailed $p = 0.001$; Figure 1c). Comparison of
202 the LG to EC ratios between the nighttime and daytime samples (0.22 ± 0.06 vs. 0.15 ± 0.05 , 2-
203 tailed $p = 0.000$) reached the same conclusion. Indeed, biomass burning could emit a number of
204 strong chromophores such as nitrogen-containing aromatic compounds (Mohr et al., 2013; Lin et
205 al., 2016, 2017; Xie et al., 2019; Salvador et al., 2021). However, for the January samples, MAE_{365}
206 did not show clear dependence on LG/OC or LG/EC ($r = 0.42$ and 0.12 , respectively; Figure 1e),
207 suggesting that in addition to BB emissions, there must exist other factors that were more
208 responsible for the diurnal variations of wintertime MAE_{365} .

209 The second indicator was $R_{S/N}$, defined as the ratio of (n-sulfur dioxide + n-sulfate) to (n-
210 nitrogen dioxide + n-nitrate), where “n” indicates molar concentration. Given that sulfate and nitrate
211 are typically considered as secondary, $R_{S/N}$ could be roughly traced back to the emission ratios of
212 sulfur dioxide (SO_2) to nitrogen oxides (NO_x), i.e., $E_{S/N}$, from combustion of various types of fuels
213 (e.g., coal, gasoline, diesel and biomass). Previous studies suggested that $E_{S/N}$ differed substantially
214 between emissions from vehicles, coal combustion and biomass burning. In China, the fuel quality
215 standards have been greatly strengthened for on-road vehicles since early 2000s, e.g., the maximum

216 sulfur content allowed in diesel was reduced from 2000 ppm (required by the China I standard
217 implemented in 2002) to 10 ppm (required by the China V standard implemented in 2017). Thus,
218 recent studies on vehicular exhausts typically suggested that the SO₂ emission factors (EF-SO₂)
219 were about two orders of magnitude lower than those of NO_x (EF-NO_x; Zhang et al., 2015; Li et
220 al., 2019) and consequently, the corresponding $E_{S/N}$ should be approximately $\sim 10^{-2}$. EF-SO₂ were
221 also usually lower than EF-NO_x for biomass burning (Zhang et al., 2000; McMeeking et al., 2009;
222 Liu et al., 2016; Wu et al., 2022), but their differences were not as large as those observed in vehicle
223 emissions, leading to $E_{S/N}$ values of $\sim 10^{-1}$. Unlike vehicles or biomass burning, coal combustion
224 usually resulted in higher EF-SO₂ compared to EF-NO_x (Zhang et al., 2000; Du et al., 2017; Li et
225 al., 2017), which could be translated to $E_{S/N}$ values of above one. On the other hand, primary species
226 could be transformed rapidly during atmospheric aging, e.g., a sharp loss of NO_x and a
227 corresponding burst in nitrate were observed shortly after emission when tracking plumes from
228 diesel trucks (Shen et al., 2021) and agricultural fires (Akagi et al., 2012; Liu et al., 2016). Thus it
229 should be acceptable to assume that for the pollutants emitted by a specific source, the $R_{S/N}$ of aged
230 plumes was generally comparable with the $E_{S/N}$ of fresh emissions.

231 The ambient $R_{S/N}$ averaged 0.6 ± 0.2 during the winter campaign, differing substantially from
232 the $E_{S/N}$ of coal combustion or vehicle emissions but in the same order of magnitude as the $E_{S/N}$ of
233 biomass burning. Actually, no evidence supported BB emissions as a major regulating factor for
234 $R_{S/N}$, e.g., as indicated by the insignificant correlations between $R_{S/N}$ and LG/EC ($r = 0.24$ and 0.01
235 for the daytime and nighttime samples, respectively). Then $R_{S/N}$ was expected to be more sensitive
236 to the changes of coal combustion and vehicle emissions, e.g., increase of coal combustion
237 emissions would effectively elevate $R_{S/N}$ whereas higher vehicle emissions favor the decrease of

238 $R_{S/N}$. During the winter campaign, lower $R_{S/N}$ were observed at night (Figure 1d), averaging $0.5 \pm$
239 0.1 compared to an average $R_{S/N}$ of 0.7 ± 0.2 for the daytime samples (2-tailed $p = 0.000$). In
240 principle, this pattern could be caused by decreased coal combustion emissions and/or increased
241 vehicle emissions at night. However, it seemed that the former did not play an important role, since
242 many coal combustion activities (e.g., those for heating supply, power generation and some
243 industrial processes) were uninterrupted, i.e., would not be stopped at night (Lian et al., 2020; Chu
244 et al., 2021; Yuan et al., 2021). Then the most likely cause for the lower nighttime $R_{S/N}$ was increased
245 vehicle emissions. According to the Road Traffic Regulations released by Harbin, heavy-duty diesel
246 trucks (HDDT), which are known to include high- or super-emitters (Dallmann et al., 2012), are
247 allowed to run on the roads in the main urban area only from 21:00 to 5:00 of the next day. This to
248 a large extent explains the inference on the increase of vehicle emissions during nighttime. MAE_{365}
249 exhibited a clear negative dependence on $R_{S/N}$ for all the winter samples (Figure 1f), suggesting
250 vehicle emissions, especially those from HDDT, as a dominant influencing factor for MAE_{365} (under
251 the precondition of relatively stable coal combustion emissions).

252 The last two indicators were associated with secondary aerosol formation, including the sulfur
253 oxidation ratio (SOR) and the nitrogen oxidation ratio (NOR) defined as $n\text{-sulfate}/(n\text{-sulfate} + n\text{-}$
254 $SO_2)$ and $n\text{-nitrate}/(n\text{-nitrate} + n\text{-NO}_2)$, respectively. The entire winter campaign experienced low
255 temperatures, which averaged -16 ± 5 and -21 ± 6 °C for the daytime and nighttime samples,
256 respectively. In general, the transformation of gaseous precursors to secondary inorganic ions was
257 inefficient in the frigid atmosphere, as indicated by the overall low levels of both SOR and NOR.
258 However, both indicators exhibited noticeable differences between daytime and nighttime samples.
259 The diurnal variation of SOR was found to be associated with the higher relative humidity (RH)

260 levels at night (Figure 4a). For the vast majority of winter samples, RH fell into the ranges of 60–
261 80 and 70–90% during daytime and nighttime, respectively. SOR were largely unchanged when RH
262 increased from 60–70% to 70–80% during the day, whereas for the common RH range shared by
263 the daytime and nighttime samples (i.e., 70–80%), SOR ~~were slightly~~ tended to be slightly lower at
264 night, likely due to the drop of temperatures. In addition, a positive dependence of SOR on RH was
265 evident for the nighttime samples. Although SOR showed almost the same median values (~0.1) for
266 the RH ranges of 70–80 and 80–90% at night, relatively high SOR levels of above 0.2 were more
267 frequently observed in the latter case. Such high SOR were rarely seen during the day, indicating
268 that RH played a more important role than temperature in sulfate formation. The enhanced sulfate
269 formation at high RH was presumably through heterogeneous reactions (Su et al., 2020; Liu et al.,
270 2021), since the low temperatures encountered during the winter campaign did not rule out the
271 presence of aerosol water, e.g., liquid water was observed to remain super-cooled in clouds down to
272 temperatures of as low as $-40\text{ }^{\circ}\text{C}$ (Tabazadeh et al., 2002). Compared to SOR, different patterns of
273 diurnal variation were observed for NOR (Figure 4b). First, the difference between daytime and
274 nighttime NOR was more significant for the RH range of 70–80%, e.g., as indicated by the larger
275 decrease of median NOR at night (0.06, compared to a corresponding value of 0.02 for SOR).
276 Second, the nighttime NOR elevated substantially as RH increased from 70–80% to 80–90%, but
277 still with lower levels compared to the daytime results. Given that relatively low temperatures favor
278 the partitioning of semi-volatile nitrate into aerosol phase, the less efficient nitrate formation at night
279 could not be explained by the partitioning process and instead should be primarily attributed to
280 reduced photooxidation of NO_2 (Chen et al., 2020). Based on a synthesis of the diurnal variations
281 observed for SOR and NOR, the nighttime samples were characterized by enhanced heterogeneous

282 chemistry, which did not require sunlight as indicated by the RH-dependent increase of SOR under
283 dark conditions, and weakened photochemical reactions. The overall effect of these two factors on
284 secondary organic aerosol (SOA) formation was inconclusive and thus it remained difficult to
285 **robustly** unfold the role of SOA in the diurnal variations of MAE₃₆₅. Actually, it appeared that
286 MAE₃₆₅ was not strongly influenced by SOA during the winter campaign. For example, when RH
287 increased from 70–80% to 80–90% at night, the MAE₃₆₅ were nearly constant (e.g., with the same
288 average value of 1.6 m²/gC for the two RH ranges) despite the enhancement of heterogeneous
289 chemistry.

290 **3.2 Why did the springtime MAE₃₆₅ show more significant diurnal variations?**

291 Compared to the wintertime results, the average MAE₃₆₅ was lower in spring (1.33 vs. 1.55
292 m²/gC) but the corresponding standard deviation was much higher (0.62 vs. 0.18 m²/gC), indicating
293 that the spring samples varied more significantly with respect to the absorption capacity of brown
294 carbon (Figure 5a). This feature could also be seen from the more pronounced diurnal variations of
295 MAE₃₆₅ observed in spring (Figure 5b), e.g., the nighttime MAE₃₆₅ were on average ~70% (**2-tailed**
296 ***p* = 0.000**) and 10% (**2-tailed *p* = 0.004**) larger than the daytime values during the spring and winter
297 measurement periods, respectively. For the winter campaign, the slightly elevated MAE₃₆₅ at night
298 had been primarily attributed to increased vehicle emissions, as indicated by a ~35% decrease of
299 *R*_{S/N}. In spring, *R*_{S/N} were also lower at night (**2-tailed *p* = 0.000**), by ~40% compared to the daytime
300 results (Figure 5d). Given that the two campaigns showed comparable discrepancies between the
301 nighttime and daytime *R*_{S/N}, increase of vehicle emissions at night was presumably not the dominant
302 driver for the much stronger diurnal variations of MAE₃₆₅ observed in spring. Actually, MAE₃₆₅ was
303 almost independent of *R*_{S/N} for the spring samples. For example, the MAE₃₆₅ values were found to

304 fall into two well-separated ranges (above 2 and $\sim 0.5\text{--}1.5\text{ m}^2/\text{gC}$, with the former observed only at
305 night) for the samples with relatively low $R_{S/N}$ levels (below 0.4), indicating that reduced $R_{S/N}$ was
306 ineffective to explain the high MAE_{365} events encountered in spring (Figure 5f). In addition to
307 increased vehicle emissions at night, therefore, there must exist other factors which were more
308 responsible for the significant diurnal variations of springtime MAE_{365} .

309 We first evaluated the influence of secondary aerosol formation. The spring campaign
310 experienced lower RH and substantially higher temperatures compared to winter, by $\sim 25\%$ and
311 $30\text{ }^\circ\text{C}$, respectively. The springtime SOR ~~were~~ appeared to be slightly lower than the wintertime
312 results (0.12 ± 0.06 vs. 0.15 ± 0.07), whereas an opposite pattern was observed for NOR ($0.16 \pm$
313 0.08 vs. 0.12 ± 0.06). The seasonal variations of SOR and NOR provided additional evidence for
314 the inferences that the sulfate and nitrate formation was more strongly contributed by heterogeneous
315 and photochemical reactions, respectively. For the spring campaign, the daytime and nighttime SOR
316 were in general comparable (Figure S1a) and no clear evidence was observed for the prevalence of
317 heterogeneous chemistry, presumably due to the rare occurrence of high RH conditions either during
318 the day or at night. Unlike SOR, the daytime NOR ~~were considerably~~ tended to be slightly higher
319 than the nighttime results (0.18 ± 0.09 vs. 0.14 ± 0.08 ; Figure S1b), pointing to enhanced
320 photochemistry during the day. This pattern could be partially responsible for the relatively low
321 daytime MAE_{365} , since secondary brown carbon was typically less light-absorbing than primary
322 BrC (Kumar et al., 2018; Cappa et al., 2020; Ni et al., 2021). However, MAE_{365} did not exhibit clear
323 dependence on NOR or the nitrate to OC ratio (NO_3^-/OC), e.g., the high MAE_{365} events were found
324 to be associated with moderate NOR and NO_3^-/OC levels (Figure S2). Thus for the spring campaign,
325 photochemistry should not be the major influencing factor for MAE_{365} , either.

326 We then investigated the role of biomass burning. Unlike the wintertime results, MAE₃₆₅
327 showed a strong positive correlation with LG/OC ($r = 0.84$) in spring (Figure 5e), suggesting
328 biomass burning emissions as the dominant driver for the variations of MAE₃₆₅. It is noteworthy
329 that the LG to OC ratios were substantially higher in spring than in winter (2-tailed $p = 0.000$), with
330 averages of $3.11 \pm 1.70\%$ and $0.99 \pm 0.26\%$, respectively. This pattern could not be explained by
331 seasonal variations in residential consumption of biofuels, since April experienced much higher
332 temperatures than January (averaging 11 and -19 °C, respectively). Instead, the elevated springtime
333 LG/OC should be attributed primarily to open burning, as supported by the intensive fire hotspots
334 detected around Harbin in April (Figure 2b). The seasonal variations of LG to K⁺ ratio (LG/K⁺) also
335 suggested that the dominant burning ways were different between winter and spring. Compared to
336 the relatively small and constant LG/K⁺ observed in January (0.46 ± 0.11), the ratios were nearly
337 tripled in April (1.28 ± 0.61) with more significant sample-by-sample differences (between ~ 0.5 –
338 3.5) (Figure 3b). Recalling that the transition from flaming to smoldering combustion favored the
339 increase of LG/K⁺ (Gao et al., 2003), the springtime burning should have relatively low and variable
340 combustion efficiencies. This inference was in line with the fact that the agricultural fires were
341 usually uncontrolled, e.g., with respect to water content of crop residues and abundance of oxygen.
342 In all, for the spring campaign, the dominant driver for the variations of LG/OC and MAE₃₆₅ could
343 be further identified as open burning. Subsequently, the higher LG/OC and MAE₃₆₅ at night (Figures
344 5b–5c) could be attributed primarily to increased agricultural fires. The preference on nighttime
345 burning was not surprising, since the agricultural fires were illegal, i.e., nominally prohibited by the
346 Government of Heilongjiang Province.

347 It should be noted that the agricultural fire emissions increased LG/OC but had minimal

348 influence on $R_{S/N}$ (Figure S3). For example, the nighttime samples collected in spring differed
349 substantially with respect to the impact of agricultural fires, as indicated by their variable LG/OC
350 which spanned nearly one order of magnitude. However, no clear pattern was observed for $R_{S/N}$ with
351 increasing LG/OC, e.g., linear regression of $R_{S/N}$ on LG/OC showed an extremely low r value of
352 0.07.

353 The frequent occurrences of agricultural fires during April, 2021 to some extent masked the
354 “background” MAE_{365} , i.e., the value representative for the spring conditions without significant
355 influence of open burning. In spring, all the samples with LG/ K^+ ratios of above one, i.e., a chemical
356 signature for apparent impacts of agricultural fires, were found to have LG/OC ratios larger than
357 2%. In addition, LG/OC ratio could also work as an estimate of the strength of biomass burning
358 impact. Thus in the following discussions, LG/OC of $> 2\%$ was used as an indicator for open burning
359 episodes and correspondingly, spring samples with LG/OC of below 2% were referred to as typical
360 ones. MAE_{365} averaged 0.80 ± 0.22 m²/gC for the typical samples of spring, lower than results from
361 the winter campaign (1.55 ± 0.18 m²/gC; Figure S4a). This seasonal pattern coincided with the
362 overall lower $R_{S/N}$ in spring (Figure S4b). It was unlikely that the number of in-use vehicles or the
363 fleet composition in Harbin could vary significantly between January and April of the same year.
364 Thus the reduced springtime $R_{S/N}$, i.e., the relatively low MAE_{365} with the absence of agricultural
365 fires, should be caused mainly by the decrease of coal combustion emissions, e.g., due to the less
366 demand for heating.

367 3.3 Unique wavelength dependence of BrC absorption during agricultural fire episodes

368 The agricultural fires not only elevated MAE_{365} but also changed the wavelength dependence
369 of brown carbon. For the wavelength range used for AAE calculation (310–460 nm), the detection

370 limit of optical attenuation (ATN_{LOD}) was ~ 0.02 , which was determined as three times the maximum
371 standard deviation of parallel ATN_{λ} results from blank filters. Before further discussions, we
372 introduced a new term “relative $\ln(ATN_{\lambda})$ ”, i.e., $\ln(ATN_{\lambda})^*$ calculated as $\ln(ATN_{\lambda}) - \ln(ATN_{LOD})$. A
373 benefit of using the new term was that a $\ln(ATN_{\lambda})^*$ value of zero corresponded to $ATN_{\lambda} = ATN_{LOD}$
374 and thus $\ln(ATN_{\lambda})^*$ could be considered “real” absorption by chromophores in solutions.
375 ~~corresponded to ATN_{LOD} and thus could be interpreted independently, e.g., ATN_{LOD} was~~
376 ~~independent of the sampling or analytical procedures such as the volume of methanol used for~~
377 ~~extraction.~~ It should be noted that the use of $\ln(ATN_{\lambda})^*$ would not influence the determination of
378 AAE, since the same slope would be derived from the regressions of $\ln(ATN_{\lambda})^*$ and $\ln(ATN_{\lambda})$ on
379 $\ln(\lambda)$. For the typical samples of spring, the dependence of $\ln(ATN_{\lambda})^*$ on $\ln(\lambda)$ could be properly
380 approximated by a linear function, usually with r values of above 0.995. In this case, AAE could be
381 reliably determined, and an average value of 6.92 ± 0.28 was obtained.

382 The relationship between $\ln(ATN_{\lambda})^*$ and $\ln(\lambda)$ became non-linear for the open burning episodes.
383 To more quantitatively describe the non-linearity, we added an “auxiliary line” to each measured
384 spectrum (Figure 6a), by drawing a line between the two points with x values of $\ln(310)$ and $\ln(460)$.
385 The “auxiliary line” could be considered an assumed spectrum with linear dependence of $\ln(ATN_{\lambda})^*$
386 on $\ln(\lambda)$. The measured spectrum was always above the assumed one and their largest difference
387 was typically observed at ~ 365 nm, pointing to the presence of distinct BrC chromophores with
388 absorption peak around this wavelength.

389 The influence of such chromophores on BrC absorption could be estimated by the following
390 three indicators. The first one (F) was related to the difference between the measured and assumed
391 $\ln(ATN_{\lambda})^*$ at 365 nm:

392 $F = \left[\ln(\text{ATN}_{365})_{\text{m}}^* - \ln(\text{ATN}_{365})_{\text{a}}^* \right] / \ln(\text{ATN}_{365})_{\text{a}}^*$, where the subscripts “m” and “a” indicate
 393 results from the measured and assumed spectra, respectively (Figure 6a). The second indicator (K)
 394 was related to the area enclosed between the two spectra (S_2): $K = S_2/S_1$, where S_1 indicates the area
 395 enclosed by the assumed spectrum and x -axis (Figure 6b). The last indicator was $\Delta(b_{\text{abs}})_{365}$
 396 calculated as $(b_{\text{abs}})_{365}^{\text{m}} - (b_{\text{abs}})_{365}^{\text{a}}$, where the superscripts “m” and “a” indicate absorption
 397 coefficients calculated based on the measured and assumed spectra, respectively. F and K exhibited
 398 a strong linear correlation for the open burning episodes ($r = 0.99$; Figure 6c), indicating that the
 399 differences between the measured and assumed spectra were likely caused by the same class of BrC
 400 compounds. In addition, these compounds could be primarily traced back to biomass burning, since
 401 $\Delta(b_{\text{abs}})_{365}$ showed a positive dependence on LG/OC (Figure 6d). ~~A candidate for such compounds~~
 402 ~~was $\text{C}_7\text{H}_7\text{NO}_4$ (a methyl-substituted nitrocatechol)~~; Candidates for such compounds were aromatic
 403 species with nitro-functional groups, based on a synthesis of absorption spectra measured for
 404 various BrC chromophores (Huang et al., 2020) and molecular characterization results for biomass
 405 burning emissions (Lin et al., 2016, 2017; Xie et al., 2019, 2020). Chamber experiments by Iinuma
 406 et al. (2010) suggested that ~~$\text{C}_7\text{H}_7\text{NO}_4$~~ aromatic compounds with nitro-functional groups could also
 407 be formed through photooxidation of gaseous precursors emitted by biomass burning (*m*-cresol). In
 408 this study, however, all the samples with relatively high $\Delta(b_{\text{abs}})_{365}$ levels (e.g., above 20 Mm^{-1}) were
 409 collected at night, indicating that the distinct BrC chromophores with absorption peak at $\sim 365 \text{ nm}$
 410 ~~(like $\text{C}_7\text{H}_7\text{NO}_4$)~~ were more strongly associated with primary emissions from agricultural fires. In
 411 addition, the chromophores seemed to be subject to photo-bleaching, as both F and K decreased
 412 substantially (by $\sim 65\%$) during the day compared to the nighttime results (Figure 7).

413 For the open burning episodes, the distinct absorption peak at $\sim 365 \text{ nm}$ prohibited a proper

414 determination of AAE. If enforcing a linear function for the dependence of $\ln(\text{ATN}_\lambda)^*$ on $\ln(\lambda)$, lower
415 r values would be derived (down to ~ 0.97 , with an average of 0.992 ± 0.007) compared to the typical
416 samples (averaging 0.998 ± 0.002). In addition, r showed a decreasing trends with the increases of
417 LG/OC (Figure 6e) and F (Figure S5), suggesting that the relationship between $\ln(\text{ATN}_\lambda)^*$ and $\ln(\lambda)$
418 deviated more significantly from linearity as the ~ 365 nm absorption peak, i.e., the influence of
419 agricultural fires, became more significant. We suggest that for the open burning episodes, the AAE
420 results should be interpreted with caution, although they could be calculated mathematically with
421 reasonable r values (e.g., even the minimum r appeared acceptable).

422 **3.4 Diurnal variations of wintertime AAE**

423 Similar to the typical samples of spring, $\ln(\text{ATN}_\lambda)^*$ exhibited linear dependences on $\ln(\lambda)$ for
424 all the winter samples. The wintertime AAE were higher at night compared to those observed during
425 the day (with averages of 7.33 ± 0.14 and 6.76 ± 0.11 , respectively; 2-tailed $p = 0.000$), consistent
426 with the pattern observed during winter in Beijing (Li et al., 2020). The relative abundance of
427 secondary OC (SOC) has been considered an important influencing factor for AAE, e.g., an
428 increasing trend was observed for AAE during long-range transport of BrC over the Indo-Gangetic
429 Plain (Dasari et al., 2019). Although SOC or its organic tracer was not determined in this study,
430 previous source apportionment results from Harbin (based on PMF) showed a strong correlation
431 between SOC and sulfate, with largely consistent relationships among different campaigns (Cheng
432 et al., 2022b). Thus we used sulfate as an indicator for SOC. During the winter campaign, the sulfate
433 to OC ratios were lower at night (averaging 0.38, compared to 0.44 during the day; 2-tailed $p =$
434 0.011), pointing to decreased fractions of SOC in OC. This inference was consistent with the higher
435 LG/OC and $R_{S/N}$ levels observed at night, which had been attributed to increased emissions from

436 residential biomass burning and vehicular exhausts, respectively. Thus regarding the association
437 between AAE and SOC formation, results from the winter campaign were inconsistent with Dasari
438 et al. (2019), but the reason remained unclear. Molecular characterization of organic aerosols should
439 be necessary to unfold the response of AAE to changes in BrC sources.

440 **4. Conclusions**

441 Diurnal variations of BrC were investigated during two distinct seasons in the northernmost
442 megacity in China. The winter campaign was characterized by low temperatures rarely seen in other
443 hotspots of air pollution studies such as the North China Plain. The wintertime BrC aerosols were
444 slightly more absorbing at night, with an average MAE_{365} of $1.61 \pm 0.15 \text{ m}^2/\text{gC}$ compared to $1.48 \pm$
445 $0.18 \text{ m}^2/\text{gC}$ during the day. Various indicators were used to explain the observed diurnal variations
446 of MAE_{365} , including those associated with biomass burning emissions (LG/K^+ and LG/OC),
447 relative importance of coal combustion and vehicle emissions ($R_{S/N}$) and secondary aerosol
448 formation (SOR and NOR). For the winter campaign, the nighttime samples were characterized by
449 increased BB emissions from residential sources, enhanced heterogeneous chemistry and weakened
450 photochemical reactions. But none of these factors was identified as the dominant driver for the
451 higher MAE_{365} at night. Instead, MAE_{365} exhibited a negative dependence on $R_{S/N}$, and the lower
452 $R_{S/N}$ and thus higher MAE_{365} at night were primarily attributed to increased emissions from heavy-
453 duty diesel trucks, which were not allowed in the main urban area during the day. In addition, the
454 wintertime AAE were higher at night but it remained difficult to unfold the underlying connection
455 between this diurnal pattern and the changes in BrC sources.

456 The spring campaign was characterized by frequent occurrences of agricultural fires, with more
457 pronounced diurnal variations of MAE_{365} (averaging 0.98 ± 0.31 and $1.69 \pm 0.65 \text{ m}^2/\text{gC}$ for the

458 daytime and nighttime samples, respectively). Unlike winter, the springtime MAE₃₆₅ were mainly
459 influenced by open burning emissions, as suggested by the positive dependence of MAE₃₆₅ on
460 LG/OC and the lack of correlation between MAE₃₆₅ and $R_{S/N}$. The higher nighttime LG/OC
461 indicated that the farmers preferred burning the crop residues at night, presumably because
462 agricultural fires were nominally prohibited by the local government. In addition, BrC exhibited
463 distinct light absorption spectra during agricultural fire episodes, as indicated by the non-linear
464 relationship between $\ln(ATN_\lambda)^*$ on $\ln(\lambda)$. The non-linearity was mainly caused by chromophores
465 with absorption peak at ~365 nm, which became more significant with increasing BB influence. A
466 ~~candidate for the compounds at play was C₇H₇NO₄, based on a synthesis of absorption spectra~~
467 ~~measured for various BrC chromophores and molecular measurement results for BB emissions.~~
468 Aromatic species with nitro-functional groups were a possible class of compounds that were at play.
469 The presence of such chromophores, i.e., the distinct absorption peak at ~365 nm, prohibited a
470 proper determination of AAE for the spring samples impacted by agricultural fires.

471 **5. Implications**

472 MAE₃₆₅ and AAE are key parameters for simulating climate effects of brown carbon. In winter,
473 although Harbin experiences low temperatures rarely seen in other Chinese megacities, the observed
474 MAE₃₆₅ and AAE were largely comparable with the typical results from other regions in Northern
475 China (e.g., Beijing; Cheng et al., 2016). In addition, BrC's optical properties were indeed different
476 between daytime and nighttime samples, which were likely associated with increased HDDT
477 emissions at night. However, the diurnal variations (~10% higher at night for both MAE₃₆₅ and AAE)
478 appeared negligible compared to uncertainties in simulating the mass concentration of BrC, i.e.,
479 organic aerosol. Thus for typical winter conditions in Northern China (without open burning), it

480 may be practical to use fixed MAE₃₆₅ and AAE values for estimating the wavelength-resolved
481 absorption by organic aerosol in climate models.

482 The spring campaign suggested another scenario, that the agricultural fires exhibited strong
483 influences on optical properties of brown carbon, as highlighted by the ~365 nm peak in BrC's
484 absorption spectra. The distinct peak on one hand effectively elevated MAE₃₆₅, and on the other
485 hand complicated the determination of AAE. In addition, the peak became less significant during
486 the day, indicating that the organic compounds at play were likely subject to photo-bleaching. BrC
487 emitted by the fires remained difficult to constrain, partially due to the variable combustion
488 efficiencies. This in turn resulted in challenges for simulating climate effects of the open burning
489 aerosols. Given the massive agricultural sector in Northeast China, more studies are necessary to
490 understand the emissions, transformation and impacts of the fire-induced pollutants.

491 **Data availability.** Data described in this manuscript can be accessed at
492 <https://doi.org/10.5281/zenodo.7874760> (Cheng, 2023).

493 **Author contributions.** YC and JL designed the study and prepared the paper with inputs from all
494 the co-authors. XC, YZ and QY carried out the experiments. QZ and KH validated the results and
495 supervised the study.

757

758 **Figure 1.** (a) Dependence of $(b_{\text{abs}})_{365}$ on MSOC, (b–d) diurnal variations of MAE_{365} , LG/OC (on a
759 basis of carbon mass) and $R_{S/N}$, and (e–f) dependences of MAE_{365} on LG/OC or $R_{S/N}$ during winter.
760 In (a), the dashed line indicates linear regression result based on all the winter samples, with K_{all} as
761 slope (intercept was set as zero). In (b–d), lower and upper box bounds indicate the 25th and 75th
762 percentiles, the whiskers below and above the box indicate the 5th and 95th percentiles, the solid
763 circles below and above the box indicate the minimum and maximum, and the open circle within
764 the box marks the median (the same hereinafter). Comparison of (e) and (f) suggests that the
765 wintertime MAE_{365} was more strongly influenced by $R_{S/N}$ compared to LG/OC . The dependence
766 shown in (f) could be approximated by the following function for all the winter samples ($r = 0.61$):
767 $\text{MAE}_{365} = (-0.51 \pm 0.09) \times R_{S/N} + (1.84 \pm 0.05)$.

768

769 **Figure 2.** Cumulative fire hotspots ~~Active fires (red circles)~~ detected ~~during~~ throughout the (a)
 770 winter and (b) spring measurement periods around Harbin, with their locations shown by the red
 771 circles. ~~The location of another central city of the HC metropolitan area, Changchun, is also shown.~~
 772 The HC metropolitan area has two central cities as marked by the blue circles. The fire data were
 773 based on the joint NASA/NOAA Suomi National Polar-orbiting Partnership (S-NPP) satellite, and
 774 were downloaded from the Fire Information for Resource Management System (FIRMS;
 775 <https://firms.modaps.eosdis.nasa.gov/>, last access: 1 January, 2023).

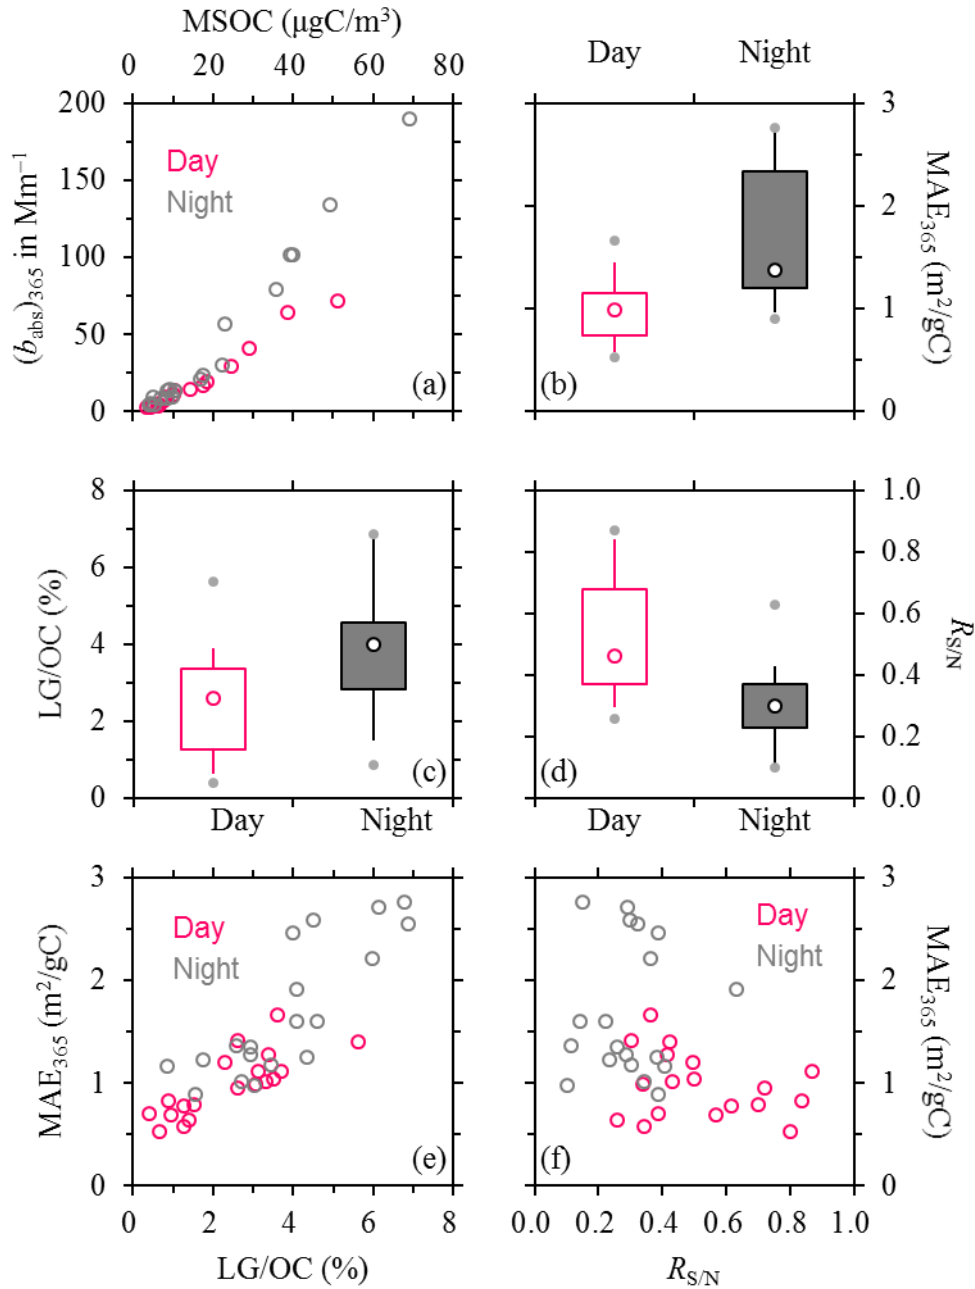

776

777 **Figure 3.** Dependences of levoglucosan on K^+ during (a) winter and (b) spring. In (a), the dashed
 778 line indicates linear regression result based on all the winter samples, with K_{all} as slope. The
 779 regression line of winter campaign is also shown in (b) for comparison to highlight the increased
 780 and variable LG/K^+ ratios in spring. The relatively low and constant LG/K^+ in winter were attributed
 781 to residential burning of crop residues, a routine activity occurring every day in rural areas for
 782 cooking and heating. The higher LG/K^+ in spring were associated with agricultural fires, as
 783 supported by the intensive fire hotspots detected.

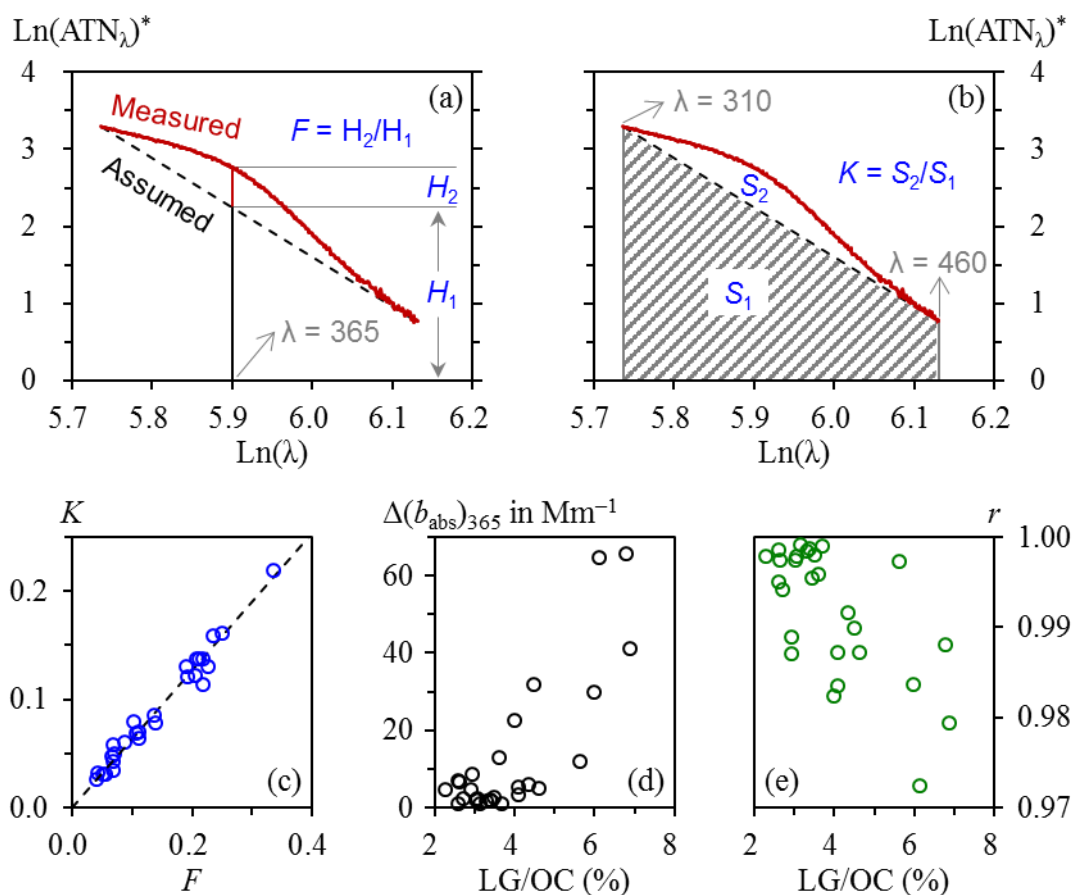

784

785 **Figure 4.** Diurnal variations of (a) SOR and (b) NOR in winter, with results from different RH
 786 ranges shown separately. Daytime and nighttime samples had ~~the same~~ a common RH range of 70–
 787 80%, whereas low RH levels of 60–70% and high RH levels of 80–90% occurred only during the
 788 day and at night, respectively.

789

790 **Figure 5.** The same as Figure 1 but for spring. MAE₃₆₅ showed more pronounced diurnal variations
 791 in spring than winter, although the daytime vs. nighttime discrepancies in $R_{S/N}$ were comparable
 792 between the two seasons. Comparison of (e) and (f) suggests that unlike winter, the springtime
 793 MAE₃₆₅ was more strongly influenced by LG/OC than by $R_{S/N}$. The dependence shown in (e) could
 794 be approximated by the following function for all the spring samples ($r = 0.84$): $\text{MAE}_{365} = (30.48 \pm$
 795 $3.28) \times \text{LG/OC} + (0.39 \pm 0.12)$, where LG/OC is on a basis of carbon mass and in %.

796

797 **Figure 6.** Nonlinearity of $\ln(ATN_\lambda)^*$ on $\ln(\lambda)$ during agricultural fire episodes in spring: (a–b)
 798 illustrations of the determination of F and K , (c) comparison of K and F , and (d–e) dependences of
 799 $\Delta(b_{\text{abs}})_{365}$ and r on LG/OC. In (a) and (b), the measured spectrum correspond to the nighttime sample
 800 collected on April 21, 2021, which had an LG/OC of 6.87%; the assumed spectrum was generated
 801 by drawing a line between the two points with x values of $\ln(310)$ and $\ln(460)$; H_1 indicates
 802 $\ln(ATN_{365})^*$ of the assumed spectrum, while H_2 indicates the difference in $\ln(ATN_{365})^*$
 803 between the two spectra; S_1 indicates the area enclosed by the assumed spectrum and the x -axis, while S_2
 804 indicates the area enclosed between the two spectra. In (c), the dashed line indicates linear regression
 805 result (intercept was set as zero) and the corresponding r value was 0.99. In (e), r was derived from
 806 linear regression of $\ln(ATN_\lambda)^*$ on $\ln(\lambda)$. Although the r values seemed reasonable, the AAE results
 807 should be interpreted with caution given the apparent absorption peak at ~ 365 nm.

808

809 **Figure 7.** Dependence of F , a measure of the significance of the ~ 365 nm absorption peak, on
 810 LG/OC during agricultural fire episodes in spring. For a given LG/OC range, F decreased
 811 substantially during the day, likely due to photo-bleaching of chromophores associated with the
 812 ~ 365 nm peak. The same conclusion could be reached based on K , another indicator for the
 813 significance of the ~ 365 nm peak.
